The effect of nutritional deprivation is chiefly on lean muscle mass. More and more muscle is used for neoglucogenesis. Ultimately, even the intercostals, the diaphragm and the upper abdominals are compromised, and there is insufficient muscle mass to perform the work of breathing. This is one reason why it is difficult to wean patients after a very prolonged period of ventilator support. In some instances, the muscles are so atrophic that even with hyperalimentation, muscle mass does not increase sufficiently for the patient to breathe on his own.

Berk is of the opinion that starvation in the presence of sepsis can contribute to multiple organ dysfunction and failure, particularly of the liver and kidneys.[1] It was pointed out earlier that rapidly turning over proteins (such as enzymatic proteins produced by liver cells and kidney tubules), are used for gluconeogenesis to provide energy in patients with poor nutrition. It has been postulated that a significant contribution to hepatic and renal dysfunction may be due to cannibalization of important functional elements for gluconeogenesis.[1]

METABOLIC EFFECTS OF NUTRITIONAL DEPRIVATION IN "INJURY" (SEPSIS, TRAUMA, CATABOLIC CRITICAL ILLNESSES)

The energy consumption pattern following "injury" is altered, an increased proportion of energy (caloric) needs being derived from protein breakdown, rather than from the utilization of carbohydrates and fats. The requirement for an increased protein intake in these circumstances is obvious. The reason for altered utilization of energy substrates is due to glucose intolerance that develops as a response to hypercatabolic critical illnesses. Thus, during stress, the maximal oxidation rate of glucose is only marginally increased to 3–5 mg/kg per minute. The reasons for glucose intolerance include elevated levels of catecholamines and other catabolic hormones, increased glucagon levels with a high glucagon-insulin ratio, and a poor uptake and utilization of glucose by tissues, in particular by the liver. In fact, there exists a state of "insulin resistance" during the "stress" produced by a critical illness. The inability to take up and utilize glucose has been thought to be related to both receptor and postreceptor defects in tissue cells. Postreceptor alterations in glucose metabolism may involve steps responsible for glucose uptake (transport and phosphorylation), glycogenolysis, glycolysis or oxidation. If exogenous glucose is not supplied (as in starvation), muscle, brain and other tissues will use for energy purposes glucose derived from muscle protein breakdown (gluconeogenesis), or ketone bodies derived from free fatty acids liberated by lipolysis. In addition, muscle is capable of using the branched-chain amino acids (leucine, valine and isoleucine) for energy directly, without the intervention of glucose.

In the metabolic pattern produced by "injury" (e.g. sepsis, severe trauma), in addition to glucose intolerance, there is an inability of the liver to manufacture ketone bodies, and an impairment in the utilization of fatty acids for energy. There is thus a marked increase in the breakdown of lean body mass to meet increased energy needs, and to provide the necessary calories for function of vital organ systems.

The association of fever, tissue damage, blood, plasma and protein loss, compound the metabolic problems in critically ill patients. Additional metabolic requirements secondary to the increased work of breathing may deprive important organ systems of necessary energy substrates, the latter being partially diverted to muscles of respiration. Fever significantly adds to caloric needs. Each degree of fever causes a 10–13% increase in oxygen consumption,[1] necessitating an increase in calorie requirement.

NUTRITIONAL ASSESSMENT

How does one assess nutrition or rather the degree of malnutrition in a critically ill individual?

- The general appearance of the patient with emphasis on the presence of wasting of the upper body and of the muscles mass, particularly of the upper limbs is a quick clinical method of assessing the nutritional state.
- A weight loss of 10th or 10% of usual weight is clinically important, weight loss of 20–30% suggest moderate protein calorie malnutrition; a weight loss of 30% or more is to be considered as severe protein calorie malnutrition and is often associated with death. Unfortunately, consideration of the body weight in many critically ill individuals is vitiated because of the frequent occurrence of salt and water retention and fluctuations in fluid electrolytes balance.
- Anthropometrics (measurement of triceps skin fold thickness and mid-arm circumference) are reasonably accurate reflections of the lean muscle loss as even if edema is present, it is not generally present in the upper limbs.
- A patient weight less than 80% of the ideal body weight (IBW) or body mass index (BMI) less than 18.5 indicates moderate malnutrition. A body weight less than 75% of IBW or a BMI less than 16 kg/m^2 signifies severe malnutrition. The urgency and degree of nutritional support is obviously much greater in those with significantly lowered body weight and BMI.
- Malnutrition in critically ill individuals is closely mirrored in the total lymphocyte count and the skin test reactivity. A total lymphocyte count <1,000/mm^3 and a loss of delayed skin sensitivity to common antigens (a measure of impaired cellular immunity) is frequently associated with malnutrition.[5]
- Subjective global assessment (SGA) evaluates nutritional states by using clinical parameters—history, physical findings and symptoms. The SGA determines if: (1) the poor nutritional state is related to poor ingestion, poor digestion or malabsorption; (2) if the degree of malnutrition has affected organ function and body composition; (3) whether the patient's illness or disease has influenced nutrient requirements.
- History and physical examination. Important features in history include the medical and surgical background of current and past illness with specific reference to conditions that could impair ingestion, digestion or absorption of nutrients.

Physical examination should carefully seek evidence of protein calorie malnutrition, deficiency of essential fatty acids, anemia, vitamin deficiencies and deficiency of trace elements.

- Biochemical parameters—
  - Serum proteins and serum albumin levels. The serum albumin level in particular is a good marker or predictor of malnutrition, as it provides an index of the visceral and somatic protein stores in a critical illness. There are however a few important points to be remembered in interpreting low serum albumin levels. A fall in the serum albumin may be brought about by rapid intravenous hydration or an overhydrated state, rather than by a change in the nutritional status. Again, low albumin levels may occur with increased catabolism, decreased synthesis (as in liver disease),

or in increased loss (as in burns, large wounds, in feces or in urine), even when the patient has been adequately nourished. Finally, even if a low serum albumin level in a critical illness serves as a marker for the initial nutritional state, it does not serve as a marker if the nutritional state has improved following nutritional support. This is because serum albumin has a half-life of 20 days and the plasma level does not rise significantly for 4–5 weeks following nutritional repletion.

- Estimation of levels of serum transferrin, thyroxin-binding prealbumin, retinol-binding protein and fibronectin. Lowered levels of transferrin (half-life 8 days), thyroxin-binding prealbumin (half-life 2 days), retinol-binding protein (half-life 12 hours), and fibronectin (half-life 12 hours), have all been used in well-equipped laboratories as indices of malnutrition. A significant rise in these proteins following repletion is observed fairly early and points to an improved nutritional state. Prealbumin is measured by many laboratories. It is a transport protein synthesized by the liver and transported in the serum as a complex of retinal binding protein. It is a sensitive indicator of protein deficiency and of improvement in protein status following good nutrition. We have never used these esoteric markers for reasons of cost. Though the above biomarkers may be of use, they cannot replace a holistic evaluation of the patient based on history, clinical examination, and on simple laboratory data.
- Estimation of 24 hours urinary urea nitrogen excretion and determination of nitrogen balance. This test evaluates somatic protein status. It provides a good index of protein breakdown, and if the protein intake is known, the nitrogen balance can easily be calculated.

$$\text{Nitrogen Balance} = \text{Nitrogen Intake} - \text{Nitrogen Excretion}$$

$$= \frac{\text{Protein intake}}{6.25} - (\text{24 hours urinary urea nitrogen excretion} + 4)$$

The 4 g are added to the urinary nitrogen loss to account for fecal and other losses in patients fed via the gut. Fecal loss of nitrogen is often much less. It is near zero to 1 g when patients receive total parenteral nutrition (TPN) even when there is diarrhea.[6]

A urinary loss of less than 6 g is normal; loss of 6–12 g/day is mild; loss of 12–18 g is moderate and more than 18 g/day indicates severe catabolism. Since 1 g of urea nitrogen is equivalent to 6.25 g of nonhydrated protein, a total loss of 16 g nitrogen would mean that about 100 g protein needs to be given to maintain nitrogen balance.

The above concept holds as long as the urine is a major source of nitrogen loss. It does not hold in patients who lose large quantities of nitrogen through the gut as in diarrhea, or through the surface of extensive weeping wounds. Nitrogen balance cannot be correctly evaluated by this equation in patients with nitrogen retention due to renal insufficiency.

- Estimation of fecal fat over 24 hours. An excretion of more than 5–7 g of fat in the stools following a diet containing 75 g of fat is an important marker for malabsorption.

In conclusion, the statement issued by the National Institute of Health, American Society for Parenteral and Enteral Nutrition and the American Society for Clinical Nutrition is worth quoting—

"There is no gold standard for determining nutritional status because: (1) there is no universally accepted clinical definition of malnutrition; (2) all current assessment parameters are affected by illness and injury; (3) it is difficult to isolate the defect of malnutrition from the influence of the disease in clinical outcome, and (4) it is not clear which of the commonly used nutrition assessment techniques is the most reliable because of the paucity of comparative data."

Perhaps, the most commonly used markers are weight loss, serum albumin, Subjective Global Assessment (SGA) and stress levels [as judged by the Acute Physiology and Chronic Health Evaluation (APACHE) II score] as they are both simple to measure and generally accepted.

TIMING FOR NUTRITIONAL SUPPORT

Theoretically speaking, any critically ill patient who is unable to take adequate nutrition should promptly receive nutritional support. There are however important points to consider before initiating nutritional support, and in particular parenteral nutritional support.

- Nutritional deprivation, in an illness lasting for a few days, is not likely to produce problems or complications. The number of days that a patient can withstand inadequate nutrition depends on age, previous nutritional status, previous state of health, and the presence of sepsis or trauma. An adult under 60 years of age, and in a previously good nutritional state, will withstand 14 days of poor nutrition in a moderately catabolic illness, without demonstrating a measurable defect. For patients between 60–70 years, this tolerance drops to 10 days, and for those more than 70 years, to less than 7 days.[1] *Nevertheless, one does not await the effects of starvation before starting nutritional support.*
- The excessive cost of parenteral nutrition precludes its unnecessary use during short periods of inadequate nutrition in a critical illness.
- Nutritional support, and in particular parenteral nutritional support, has inherent risks and can cause dangerous iatrogenic complications. These risks may well outbalance the risk of poor nutrition that is anticipated to last just under a week.
- For improved outcomes, *current recommendations advocate early nutritional support in patients critically ill in the ICU.*[3] Our policy is to initiate support promptly if enteral feeds are feasible. If enteral feeds are not feasible, or provide only a portion of the patient's nutritional requirements, we initiate parenteral nutrition within

3–5 days depending on the severity of the catabolic nature of the illness.

- *In an acute, hypercatabolic critical illness, stabilization of hemodynamics, and correction of fluid, electrolyte and acid-base balance take precedence over nutrition.[7] The latter can be started once the patient is reasonably stable in relation to the above mentioned vital parameters.*

INDICATIONS FOR PARENTERAL NUTRITION

Parenteral nutrition is indicated in patients in whom the gut does not function, or in those who undergo any form of treatment which precludes the use of the gut for the foreseeable future. Parenteral nutrition improves the outcome in the short bowel syndrome, enterocutaneous fistulae with a large leak greater than 500 mL from the fistulae, major burns, and acute tubular necrosis. Nutritional support is also of value in necrotizing or suppurative pancreatitis (till such time as the gut can be used), sepsis, prolonged ileus from any cause, stomal dysfunction after surgery, and in large wounds causing loss of proteins from the wound surface. Nutritional support is often offered to selected patients with cancer and to malnourished patients as a preparation for major surgery. Parenteral nutrition may be a supplement to enteral nutrition in many of these problems, so that caloric requirements and adequate protein intake are ensured. In many instances where the gut does not work or cannot be used, TPN is employed.

INDICATIONS FOR ENTERAL FEEDING

Patients with a functioning small bowel, who for any reason cannot take food orally, or who cannot meet their nutritional requirements, are given special supplements and/or tube feedings. The important indications, contraindications and further details of enteral nutrition are discussed later in this chapter.

Summary of evidence-based guidelines for nutrition support is listed in Box 1.

Box 1: Summary of evidence based guidelines for nutrition support

- Enteral nutrition is preferred over parenteral nutrition for critically ill patients who require nutrition support
- Bowel sounds are not required for the initiation of enteral feeding
- Immune modulating enteral formulations should be used for critically ill patients on mechanical ventilation but with caution in patients with severe sepsis
- Patients with ARDS and severe acute lung injury require enteral feeding containing anti-inflammatory lipids (i.e. omega-3 fish oil) and antioxidants
- Antioxidant vitamins and trace minerals, specifically containing selenium, should be given to all critically ill patients receiving nutritional therapy
- Enteral nutrition regimens not containing glutamine should be supplemented with glutamine in burns, trauma and critical illness
- Protocols to promote moderately strict control of serum glucose levels (110–150 mg/dL) when providing nutrition support are recommended

Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.). J Parenter Enteral Nutr. 2009;33(3):277-316.

NUTRITIONAL REQUIREMENTS

Caloric Requirements

On an average, most critically ill individuals expend and therefore need 25–35 kcal/kg IBW per day. The resting metabolic expenditure can also be estimated by using the Harris-Benedict (HB) equation.[8] This formula or equation is as follows—

In Males: HB = 66.5 + 13.7 W + 5 H – 6.8 A
In Females: HB = 66.5 + 9.6 W + 1.7 H – 4.7 A
where W = Weight (kg); H = Height (cm); A = Age

The caloric requirement increases with the stress and catabolism of illness. Calvin Long's stress factors[9] take the catabolism of illness into consideration. Thus, the caloric requirement is as follows—

1.3 × HB for sepsis or uncomplicated major surgery

1.5 × HB for complicated sepsis (with organ failure) and burns <20%

2 × HB for burns >20%

We are of the opinion that it is quite unnecessary to use either the Harris-Benedict equation or the Calvin Long's "stress factors". Predictive equations can be notoriously unreliable in critically ill individuals[10] and the use of "corrective stress factors" invariably overestimates the caloric requirements of critically ill patients.

It is best to initially administer 25 kcal/kg per day in which total kilocalories in the day are split into 20% protein, 30% fats and 50% carbohydrates. Current recommendations in ICU patients are to apportion 60–70% of nonprotein calories as carbohydrates and 30–40% as fat. Proteins and carbohydrates provide 4 kcal/g, and fats provide 9 kcal/g (Table 1).

Carbohydrates

These are important and provide ready fuel for energy. Excessive glucose administration however has the following disadvantages—

- It increases norepinephrine secretion; this in turn increases energy expenditure, glucagon secretion and insulin resistance.
- Glucose is poorly utilized in sepsis and other catabolic states. Excessive glucose and carbohydrate administration will thus lead to severe hyperglycemia, particularly in diabetics.[11]

Table 1: Caloric requirement in a critically ill adult

Nutrient	*Quantity*	*Percentage of total calories*	*Initial requirement for 60 kg adult*
Total calories	25 kcal/kg/day	100	1500 kcal/day
Protein, peptides	1–1.75 g/kg/day	15–25	60–70 g/day 240–280 kcal/day
Carbohydrates	3–3.5 g/kg/day	40–60	190 g/day 760 kcal/day
Fats	0.75–1 g/kg/day	20–30	50 g/day 450 kcal/day

Micronutrients in the form of vitamins, minerals and trace elements should also be adequately provided to meet the needs of the patient.

- Excessive glucose is converted to fat in the liver, and produces steatosis.
- In critically ill patients, excessive use of glucose for non-protein calories nearly doubles the production of carbon dioxide. This increases pulmonary workload. Weaning therefore becomes difficult in patients on ventilator support.

Lipids

Lipids provide 30–50% of ingested calories, and are as good as hypertonic glucose in improving protein synthesis in catabolic patients. Linoleic acid is the only essential fatty acid that must be provided for. It should constitute 4% of the total caloric intake, else a fatty acid deficiency results.[12] The latter is typically seen after a few weeks of fat-free intravenous alimentation. The clinical manifestations include an eczema-like rash with neutropenia and thrombocytopenia. The syndrome can be countered by the use of intravenous lipid emulsions or the oral intake of 10–15 mL/day of safflower oil.

Protein Requirements

The minimum protein intake is 0.5 g/kg per day. In most patients in the ICU, an intake of 0.75–1 g/kg per day suffices. In highly catabolic states (severe burns, tetanus), the intake is between 1.5 g/kg per day and 2 g/kg per day.

Protein catabolism can be measured as stated earlier, by estimating the 24-hour loss of urea nitrogen in the urine. Nitrogen balance studies may help adjust protein intake. Nevertheless, it is generally impossible to prevent loss of lean muscle weight in critically ill catabolic patients. *It is therefore unwise to use large quantities of proteins.* This merely adds to the metabolic problems encountered during nutritional support. Attempts to provide adequate protein to patients in hepatic or renal failure may fail because of increasing azotemia or worsening encephalopathy. Indications for a decrease in protein administration include rising blood urea nitrogen (BUN) that exceeds 100 mg/dL or an elevated serum ammonia level that is associated with encephalopathy.

Water and Electrolytes

Carbohydrates given to a malnourished patient reduce salt and water excretion. If sodium is also provided simultaneously, there is a significant expansion of the extracellular volume, resulting in weight gain. Many catabolic states may also be associated with diminished salt and water excretion. The possibility of a fluid overload must therefore always be kept in mind following the initiation of TPN.

Vitamins

Twelve essential vitamins need to be supplied. The daily requirements may be much higher in seriously ill or catabolic patients. Low serum values of vitamins were observed in 25% of adult males in a surgical ICU.[13] Intravenous replacement therapy even in large doses failed to correct these low values in as many as 40% of these patients.[13]

Thiamine deficiency, folate deficiency and deficiency of Vitamins A, C and E are fairly often observed.[13,14]

Trace Elements

The nine necessary trace elements that need to be included in nutritional support are iron, zinc, manganese, molybdenum, copper, chromium, selenium, iodine and cobalt. They are present in many enteral feed formulations, but some of these trace elements may need to be added to TPN solutions. Requirements of trace elements may increase in patients with diarrhea or malabsorption. Supplements of manganese and copper are avoided or reduced in patients with liver cell dysfunction.

Total caloric requirement for either parenteral or enteral feeds and in particular the protein content supplied will depend both on the nature of the illness and the background nutritional state of the patient. The recommendations for nutritional requirement in different critical problems are discussed later in this chapter.

METHODS OF NUTRITIONAL SUPPORT

There are two methods of nutritional support: enteral and parenteral. Nutrition provided totally by the parenteral (i.e. intravenous) route is termed TPN. Parenteral nutrition is generally provided through a central vein; it could also be given via a peripheral vein. Both parenteral and enteral routes are often used in the same patient. Though both methods can provide equal nutritional support, the enteral mode or method is always to be preferred whenever this is possible.

The following points need to be kept in mind—

- Parenteral nutrition alters the normal physiology of nutrition. Physiological changes during parenteral nutrition include an alteration in body composition, and an increased blood flow to the gut.[15]
- Hepatic dysfunction, in particular steatosis, is frequent with parenteral nutrition. There are also changes in the blood levels of pancreatic and GI hormones.
- The absence of direct enteral stimulation by nutrients during parenteral nutrition can disturb the structural and functional integrity of the gut.[16-20]
- The absence of enteral nutrition reduces the immune function of the gut. The gut can be an important portal of entry for pathogens in critically ill patients. Translocation of bacteria from within the lumen to the mesenteric glands and then to the bloodstream is ordinarily prevented by gastric acid, intact peristalsis and normal bacterial gut flora. These factors are altered in an intensive care setting by antacids, H_2-antagonists, antibiotics, as also by disuse atrophy of the gut in patients on parenteral feeds. IgA normally present in the intestinal mucosa is also decreased in parenterally fed patients. This robs the gut of an important immune defense mechanism. It is likely that enteral feeds besides maintaining the absorptive function of the mucosa, also maintain the functional integrity of the mucosal barrier, and prevent translocation of bacteria outside the lumen of the gut. The latter aspect may be of great importance in critically ill patients in an ICU setting.
- Parenteral nutrition is far more expensive than enteral nutrition.
- Both methods can be associated with complications—technical, infectious and metabolic. Parenteral nutrition has however greater hazards when compared to enteral feeding.[21]
- Parenteral nutrition should be terminated once enteral feeds are tolerated.

ENTERAL NUTRITION

Indications

Full enteral support is indicated in the following conditions[22]—

- Malnourished patients whose oral intake is poor for 3–5 days.
- Well-nourished patients with poor oral intake for 7–10 days.
- Inability for whatever reason to eat adequately: oropharyngeal lesions, esophageal lesions, neurological disorders involving the upper GI tract.
- Following massive small bowel resection (90%)—enteral nutrition helps in the regeneration of small bowel mucosa.
- Enterocutaneous fistulae with an output of less than 500 mL/day. Enteral feeds allow absorption, and probably do not interfere with spontaneous closure of the fistulae.
- Severe full thickness burns. There is some evidence that early enteral feeds limit sepsis and reduce protein loss from the bowel in these patients.
- Following major upper GI surgery (total esophagectomy or total gastrectomy), feeds administered through a tube catheter jejunostomy are necessary.
- Following surgery for necrotizing, suppurative pancreatitis. Initial TPN in these patients is followed by jejunostomy feeds or feeds through a nasojejunal tube following recovery of small bowel function.

Although enteral feeds are generally well tolerated in critically ill individuals, there are case reports of bowel infarction during jejunal feeds in pressor-dependent patients.[23] It was postulated that jejunal feeds increased oxygen demand in a segment of the bowel that was poorly perfused. It is therefore best to commence enteral feeds only after the patient is hemodynamically stable. Initial feeds should be small; they should be gradually increased if the patient tolerates them.

Contraindications

Enteral feeds are contraindicated in—

- Generalized suppurative peritonitis.
- Complete intestinal obstruction.
- Ileus from any cause.
- Ischemia to the bowel.
- Patients with severe shock.
- Enterocutaneous fistulae with a large output.
- Acute fulminant necrotizing pancreatitis (in the early phase).

In severe uncontrolled diarrhea, we give arrowroot, electral water (water + electrolytes), weak tea without milk orally, and give the main nutritional support through intravenous alimentation.

Access

Enteral feeds can be infused into the stomach, duodenum or jejunum. This can be achieved by a nasogastric tube, nasoduodenal or nasojejunal tube, a percutaneous feeding gastrostomy, or a jejunostomy. A feeding jejunostomy is fashioned through a tube or catheter (tube jejunostomy) at surgery.

Gastric Feeding

Enteral feeds infused into the stomach can have both advantages and disadvantages. The advantage is that the stomach initiates digestion though no nutrients are absorbed. Gastric acid secretion helps to sterilize gastric contents and the risk of bacterial contamination of the gut is reduced. The stomach can also protect the gut from an osmotic load. In the presence of hyperosmotic fluid, the motility of the stomach is reduced. Gastric secretions dilute the hyperosmolar load till it is isoosmolar; the contents then pass through the pylorus into the duodenum and small gut.

The major disadvantage of enteral feeds infused into the stomach, is the development of gastric atony. Gastric atony is more frequent than atony of the small gut in critically ill patients.

Feeds cannot be continued in the presence of severe atony, else there is the danger of aspiration pneumonia. When enteral feeds are infused into the stomach, gastric residual volume should be monitored frequently—every 2–4 hours. In spite of monitoring, acute gastric atony with dilatation can occur suddenly, and in critically ill patients can cause massive aspiration of gastric contents into the lungs. It is then mandatory to discontinue gastric feeds.

Gastric feeds can be given through a nasogastric tube in critically ill patients. If for some reasons gastric feeds need to be given for several weeks or months, it is best if they are given through a percutaneous endoscopic gastrostomy (PEG).

Duodenal Feeding

Duodenal feeding is often preferred for the above reasons to gastric feeding. The feeding tube is inserted through the nostril or through a gastrostomy. At times in presence of gastric atony, it is necessary to insert a separate nasogastric tube in order to aspirate gastric contents, or to administer sucralfate for treatment or prevention of bleeds caused by stress ulcers.

The earlier feeding tubes were large bore (14–16 Fr), rigid tubes placed in the stomach. For reasons of economy, we still have to make do with these tubes. The newer feeding tubes are narrow (8 Fr), flexible and are available in longer lengths for intubation of the small bowel.[24] These tubes add to patient comfort and reduce the risk of reflux and aspiration pneumonia. Because of lack of easy availability and increased expense, we use the new narrow tubes only in rare instances. The finer tubes however have one disadvantage, and that is the risk of misplacement of the tube in the tracheobronchial tree, with disastrous consequences. The fine bore tubes require a stylet for insertion, and in ill patients with a blunted cough reflex, can quite easily go through the larynx and into the trachea. They can also pass by the side of the inflated cuff of an endotracheal or tracheostomy tube. If this goes unrecognized, a small bore feeding tube may find its way right into the pleural space. The tube position should therefore always be checked. The tip of the tube is radiopaque, and a chest X-ray should show the tube below the diaphragm. A lateral view of the chest should also be done if there is doubt about the tube placement. Aspiration of contents through the tube helps; if the aspirate has an acid content pH (<3), the tube lies within the stomach.[25]

Jejunal Feeding

Jejunal feeding is now being used frequently all over the world. It is used particularly in patients following major abdominal surgery, and severe trauma. The technique is either a needle jejunostomy or a tube (catheter) jejunostomy. A feeding jejunostomy allows full use of the gut despite ileus involving the stomach and the large bowel. When for any reason enteral feeds in the stomach are contraindicated, we prefer to infuse feeds through a jejunostomy. Technically, small bore tubes advanced through the pylorus into the small bowel, avoid quite a few problems associated with a direct feeding jejunostomy. It is often difficult to maneuver these newer fine bore tubes through the pylorus into the small bowel. The procedure is preferably done under fluoroscopic guidance.

Starting Tube Feeds

A test infusion is indicated to determine the safety of gastric feeds. A volume of N saline equivalent to the desired hourly feeding volume, is infused into the stomach (in patients with nasogastric tubes) over 1 hour. The feeding tube is clamped for 30 minutes, and the residual volume aspirated. If the volume is less than 50% of the infused quantity, gastric feeding can be started. If during feeds the aspirated residual volume increases, the feeds need to be given at a slower rate, or temporarily stopped. It is best to give the test volume as an infusion and not as a bolus. The latter causes gastric distension and can delay gastric emptying. The residual volume can then be greater than that observed if the volume load had been given by an infusion.

Feeding Patterns

Intermittent infusions are now frowned upon, though we admit to its use over the years. The popular method of delivery is by a continuous infusion over 16 hours. This is believed to reduce the risk of aspiration and diarrhea; it also produces more weight gain and a positive nitrogen balance.[26]

Tube feedings are initiated by starter regimes that use less calories and a slower infusion rate. Both caloric intake and volume are then increased to desired levels over a few days. The rationale is to initially avoid the occurrence of diarrhea by not overloading a gut, which has had no nutrients to deal with for the preceding 4–7 days. Many units however forego starter regimes, and commence full enteral feeds from the outset, except in patients who have had no enteral feeds for several days. Starter regimes should always be used when enteral feeds are administered through a jejunostomy or through a nasojejunal tube. This is because the small bowel does not have the reservoir capacity of the stomach, and diarrhea invariably results, if feeds are not initiated through starter regimes. An isotonic feeding formula is diluted to a quarter of its strength, and started at 25 mL/hour.[27] The infusion rate is increased by 25 mL every hour, till the target rate is achieved.[28] The concentration of the feeding solution is now increased over the next few days, full nutrition being achieved within 4 days.[27] Jejunal feeds are preferably given as an infusion over a 6-hour period.

Types of Enteral Feeds (Formulations)[29]

Unfortunately, very few satisfactory special formulations for enteral feeds are available in our country. A frequently used formulation is *Ensure*, which is both lactose and gluten free. 1 mL of this formulation provides one calorie. The calories contained in one serving amount to 250 calories in 250 mL. Each serving of 250 calories contains 9 g of protein (14.2% calories), 9 g of fat (31.8% calories) and 34 g carbohydrates (54% calories) + 200 g water + 24 key vitamins and minerals.

1,500 mL of the formulation (i.e six servings) would thus give a caloric intake of 1,500 calories with the distribution of protein, carbohydrate and fat as indicated above (i.e. 54 g protein, 54 g fat and 204 g carbohydrates). The formulation has an osmolarity of 379 mOsm/L H_2O.

The formulation *Ensure Plus HN* (available in Western countries) provides a higher caloric and higher protein content. Each serving contains 355 calories in 237 mL, with 14.8 g protein, 11.8 g fat and 47.3 g carbohydrates together with vitamins and minerals. This formulation is hyperosmolar (1.5 kcal/mL), the osmolarity being 500 mOsm/L H_2O.

When special formulations are available (as in Western countries), the following characteristics help in selecting the appropriate formula for the patient—

- *Caloric Density and Osmolality*—
  - The formulations that provide 1 kcal/mL are isotonic to plasma, and are preferred for small bowel feeds. They include preparations such as Osmolite or Isocal.
  - The formulations, which provide 1.5–2 kcal/mL are hypertonic or high density formulas, and are preferred when fluid intake needs to be restricted. These feeds should be administered preferably into the stomach. Gastric secretions dilute the feeds and render them isotonic before they reach the small bowel. High caloric density formulations include Osmolite HN (2 kcal/mL) and Isocal HN (2 kcal/mL).
- *Protein content* Most enteral formulas provide up to 14–20% of total calories as proteins. There is no evidence to suggest that higher protein content improves morbidity or mortality. Intact protein is more difficult to absorb than hydrolysated protein. The latter is preferred in malabsorption and in the short bowel syndrome. Peptide-based formulas can reduce diarrhea from tube feedings.[30] Formulas containing peptides and amino acids are derived from hydrolysis of casein, whey, lactalbumin and sugar.
- *Fat complexity* Median chain triglycerides are easier to absorb than long chain triglycerides, and are favored in patients with malabsorption. Most enteral formulas have long chain triglycerides, but some have a combination of both (e.g. Isocal). Linoleic acid and linoleinic acid are necessary to prevent fatty acid deficiency. Omega-3 fatty acid has been included in disease specific formulas.

Classification of Enteral Feeds[29]

Enteral feeding formulas are classified according to the nature of nutrients, or the ease of absorption.[31] The important enteral feeds and formulations available in the West are listed below.

- *Liquidized or blenderized food* They are liquid forms of table food. We can use these enteral feeds for most patients (see below).
- *Lactose-free formulas* There are several standard feeding formulas available in the West. These standard formulations are indicated in patients with a normal GI tract who do not tolerate lactose. Examples: Isocal 1 kcal/mL; Sustacal HC 1.5 kcal/mL; Isocal HCN 2 kcal/mL.
- *Chemically defined formulas* These contain hydrolysated protein instead of intact protein, to facilitate absorption, and are indicated in patients with impaired ability to absorb nutrients. Examples: Criticare HN; Vital HN.
- *Elemental formulas* The elemental formulas contain amino acids. Most of the nutrients are well absorbed in the jejunum. These are indicated in patients with limited absorptive capacity and are often used for jejunal feeds. Example: Vivonex 1 kcal/mL.

Liquefied or Blenderized Feeds

We have devised for our unit enteral feeds that contain naturally available nutrients. These nutrients include milk, whey, curds, fruit juice, protein powders, glucose, and liquidized potatoes, rice and vegetables. The protein content can be further increased in those intolerant to milk or milk products by liquidizing chicken or meat. Alternatively, high protein-containing powders can be added. The commonly used protein preparations are listed in Table 2. Fat content is provided by measured quantity of butter. This cocktail is made up to a desired volume by the addition of water and fed to the patient at the rate of 200 mL 2 hourly. It is easier to feed liquidized food in the above fashion through the old-fashioned nasogastric tube. The buttermilk diet (BMD) can be used for patients with increased caloric requirements (e.g. those with severe burns) (Box 2); 1 L of BMD provides 1,000 kcal, 60 g of proteins and 340 g of carbohydrates. Jejunostomy feeds require more meticulous preparation before they can be given through the jejunostomy catheters. Nevertheless, it is important to be aware of what is available in the outside world, even if these preparations remain at present of theoretical interest. It must be said that in our unit, the morbidity and mortality of critically ill patients given enteral nutritional support in the manner outlined above, is no higher than that observed in units in the West that use special feeding formulas. We do encounter diarrhea with the liquidized food prepared as described above, but it is generally controllable.

A sample of nasogastric tube vegetarian/nonvegetarian, blenderized feed administered in the ICU at the Breach Candy Hospital, Mumbai, is detailed in Table 3.

Complications of Enteral Feeding

- *Gastric retention, vomiting and aspiration pneumonia* These are most often observed when feeds are infused into the stomach. The reported incidence of aspiration varies from 1% to 44%.[30] Aspiration is less likely when feeds are infused into the duodenum or jejunum. A trace of bright color may be added to feeds when aspiration is suspected. If respiratory secretions aspirated through a tracheostomy or endotracheal tube are similarly colored, it is a pointer to definite aspiration.
- *Diarrhea* This is the most frequent and most troublesome complication of enteral feeding.

  The following steps should be taken to control the diarrhea—

Table 2: Commonly used protein preparations

Name of product	*Amount*	*Energy*	*Carbohydrates*	*Proteins*	*Fats*
Resource	25 g	112	15.0	4.0	4.0
Nourish standard	25 g	111	14.0	4.0	4.0

12

Box 2: Composition of the buttermilk diet

- Curd: 1 liter
- Eggs: 4
- Bananas: 4
- Sugar: 10 tablespoons
- Total volume: 1760 mL
- Calories provided: 1760 kcals
- Proteins: 60 g
- Carbohydrates: 340 g

- Reduce the feeds by half. Avoid lactose in the feeds, and avoid bolus feeding. Use Pectokab (pectin and kaolin combination), and aluminum hydroxide; stop magnesium antacids if they are being administered. Examine stools for ova, parasites and Cl. difficile toxin.
- Use isotonic and not hyperosmotic solutions.
- Check if antibiotics could possibly be causing diarrhea.
- When available, special feeding formulas containing amino acids alone, or in combination with small amounts of peptide, may be used. These may help in patients with poor digestion and absorption. In patients with pancreatitis, pancreatic enzymes need to be given with enteral feeds.
- If diarrhea still persists, tincture opium 2–3 minims thrice daily, or 10 mL paregoric twice daily may be used for 2–3 days.

Table 3: A sample nasogastric tube vegetarian/nonvegetarian blenderized feed plan

Time	*Feed*	*Quantity (mL)*
6 am	Milk (toned) + 5 tsp protein supplement	150
8 am	Oats porridge puree + 2 tsp honey	150
10 am	Veg soup + 2 tsp olive oil + potato puree	150
12 noon	Rice + dal puree + 2 tsp olive oil	150
2 pm	Sweet lime juice + 2 tsp glucose powder	150
4 pm	Soya milk + nut puree + 2 tsp honey	150
6 pm	Stewed apple puree + 2 tsp honey	150
8 pm	Chapati + chicken (or paneer) + 2 tsp olive oil	150
10 pm	Milk + 5 tsp protein supplement	150
	Water to flush the tube	150

Total quantity: 1,500 mL
Total calories supplied: 1,500 kcal
Proteins: 60 g; visible fat (olive oil): 30 mL
Protein supplement used: Pentasure powder

- If diarrhea relents slowly, build feeds to the desired levels.
- If it continues for a week, it is best to shift to partial parenteral nutrition. As far as possible, it is wise to continue with small enteral feeds (arrowroot, whey, electral water). Total stoppage of enteral feeds often

aggravates diarrhea when enteral feeding is reattempted at a future date.

- *Mechanical problems* Small bore feeding tubes become obstructed by plugs of nutrient material in 10% of patients.[32] The tube should therefore be flushed with water before and after infusion of nutrients.[33] When the tubes are not being used for infusion, they are filled with water and plugged. If the tube is blocked and the block cannot be flushed out with warm water, a warm solution of 7.5% sodium bicarbonate is used to flush the tube. If unsuccessful, the feeding tube needs to be replaced.

PARENTERAL NUTRITION[34-36]

The total caloric requirements, the protein content and the ratio of carbohydrates to fat in patients requiring TPN, have already been discussed. The indications for TPN have also been detailed earlier. The present section will briefly deal with access, type of solutions in use, methods of administration and complications.

Access

In an ICU, TPN is generally given through a central vein. Many intensivists prefer to secure the subclavian vein through the usual percutaneous technique. It is convenient for the patient who can move his head and neck freely, and allows better sterile dressings when compared to a catheter in the internal jugular vein. This central line once secured is reserved solely for infusing nutrients required for TPN. It is best not to infuse drugs, antibiotics, crystalloids or colloid infusions through this line. All other infusions are given through a separate lumen if a triple lumen catheter is in place, or through a separate peripheral vein.

Parenteral nutrition may also be infused through peripheral veins. This is appropriate for short-term nutritional support or in patients in whom central veins are inaccessible. Thrombophlebitis is frequent when peripheral veins are used because of the high osmolality of the nutrient solutions. Nutrient solutions with an osmolality greater than 900 mOsm/L invariably produce peripheral venous thrombophlebitis. Osmolality of nutrient solutions can be reduced by decreasing the glucose concentration and substituting lipid solutions to provide the necessary calories.

Types of Solutions for Use

Dextrose

Dextrose solutions (10%, 20%, 50%) supply 4 kcal/g and constitute the carbohydrate content of parenteral therapy. Solutions with an osmolarity greater than 300 mOsm/L are hyperosmolar. 500 mL of 20% dextrose solution would provide 100 g of carbohydrate with a caloric value of 400 calories.

Lipid Solutions

Fat has a caloric equivalent of 9 kcal/g. Fat emulsions in use are rendered isotonic by addition of glycerol. The chief source of fatty acids in intravenous fatty emulsions is soya bean, with or without safflower. Linoleic acid constitutes 50–65% and linolenic acid 4–9% of the fatty acid content. Fatty emulsions marketed as intralipid are available in India as either 10% or 20% fat emulsions.

Crystalline Amino Acids

The formulations available contain 40–50% of essential amino acids, and 50–60% of nonessential amino acids. Available concentrations of amino acids vary from 3.5–10%, with varying total nitrogenous content (5.4–16 g) of the solutions. The protein content is computed by multiplying the nitrogen content in grams by 6.2, so that a nitrogen content of say 10 g would be equal to a protein content of about 60 g. The exact amino acid and electrolyte profile may also vary in different formulations. From the clinical point of view all products are by and large similar. There are also solutions designed specifically for certain disorders. Solutions preferred for renal failure supply concentrated essential amino acids and L-histidine. Those preferred for hepatic encephalopathy contain a high concentration of branched-chain amino acids (valine, leucine and isoleucine). Vitamins, electrolytes, and trace elements should be provided as additives. Vitamins B and C are extremely important, as are B_{12}, folate, vitamin A and vitamin D. Most vitamins are present in formulations of amino acid mixtures. In large wounds and after major surgeries, extra vitamin C to the extent of 1–2 g/day should be given. Large doses of vitamin A and vitamin D can cause toxicity. 5,000 units of vitamin A and 500 units of vitamin D on a weekly basis are generally adequate. Trace elements, in particular zinc, need to be given separately as deficiency in these elements may result. It is important that other than sodium, potassium and chloride, calcium, magnesium and phosphates need also to be replaced, and at times replenished in depleted body stores.

Administration

Dextrose, intralipid (lipid solution), amino acid solutions can be given as separate solutions through a triple lumen catheter inserted into a central vesdin. The advantage of this method is that one can tailor the exact quantity of carbohydrate, fats, proteins and the total calories that need to be given to a critically ill patient. Currently, many manufacturers supply either all-in-one solutions or two-in-one solutions. All-in-one solutions contain dextrose, amino acid solution and lipid all-in-one pack so that all three are infused from one bag through a single lumen of a central vein catheter. An example of an all-in-one solution is Vitrimix. 1,000 mL of Vitrimix provides for 1,000 kcal; dextrose (75 g) and lipids (20% in 250 mL) supply nonprotein energy, equivalent to about 800 kcal and the nitrogen content of the solution is 7 g (roughly equivalent to $7 \times 6.2 = 43$ g protein). The osmolarity of this all-in-one solution is 960 mOsm/L.

A two-in-one solution has dextrose and an amino acid solution in one pack; the fats would need to be infused (an

Table 4: Frequently used parenteral nutrition solutions

Products	*Total energy (kcal)*	*Nonprotein energy (kcal)*	*Dextrose*	*Nitrogen*	*Lipids*	*Osmolality (mOsm/L)*

**PNA 7, PNA 8, PNA 12 and PNA 16 are also available.
***Intralipid 20% and intralipid 30% are also available. Also available as 500 mL.
****Celepid 20% is also available. Also available as 500 mL.
*****Celemin 5% is also available.

intralipid infusion) separately through a separate lumen of multilumen catheter.

Parenteral nutrition may also be infused through a peripheral vein.

Table 4 lists the frequently used "all-in-one" and "two-in-one" parenteral solutions, the kcal each supplies and the contents in relation to carbohydrate (dextrose), nitrogen and fat. It also lists intralipid solutions and amino acid solutions available as separate infusions.

Monitoring the Patient

The frequency of monitoring depends on the stability of the patient's condition. Vital signs need the usual frequent monitoring. At the start of TPN a full biochemical profile, as also a full blood count, and platelet count should be done. A biochemical profile should include blood glucose, serum electrolytes, bicarbonate, blood nonprotein nitrogen (NPN), creatinine, full liver function tests, and serum proteins, with special reference to serum albumin levels. Serum calcium, phosphorus, alkaline phosphatase, pH of arterial blood and arterial blood gases should also be done. When possible, a nutrition screen should include serum levels of transferrin, prealbumin, and retinol-binding protein. These tests may be repeated once or twice weekly. Serum electrolytes and tests for liver and renal function may need to be repeated more often, depending on the patient's clinical state. The adequacy of the nutritional regime should be assessed at weekly intervals. Nitrogen balance studies may be necessary in highly catabolic complicated cases.

Complications of Parenteral Nutrition (Box 3)

Complications fall into three groups-metabolic complications, catheter-related infections, and complications related to technical problems.

Metabolic Complications

These include disorders in glucose metabolism, chiefly hyperglycemia, deficiency states and hepatic dysfunction. Deficiency states include in particular deficits of magnesium and phosphorus. Fluid and electrolyte disturbances are also observed, and are partly related to the background disease in the patient.

Hyperglycemia[37] Hyperglycemia constitutes the most frequent metabolic complication. It is often produced when 50% dextrose infusions are used instead of 20% dextrose infusions, so as to provide calories and reduce total fluid intake. Diabetics critically ill with catabolic problems show hyperglycemia in spite of large doses of insulin. Corticosteroids also enhance the hyperglycemic state. Careful monitoring of blood glucose is mandatory and an insulin infusion is best started separately through a peripheral line, the dose being adjusted to keep

Box 3: Complications of parenteral nutrition

  - Related to placement of the central venous catheter (see Section Procedures and Monitoring in the Intensive Care Unit)

the blood glucose levels around 150 mg/dL. Insulin, besides controlling the blood sugar, also has a beneficial effect on nitrogen balance. Large doses of insulin however may cause severe hypokalemia. Potassium replacement is therefore important.

The appearance of hyperglycemia in a previously stable patient often heralds the onset of sepsis. The latter may be clinically evident within 12–24 hours. The source of sepsis should be promptly identified and treated; the hyperglycemic state is then easily controlled.

Uncontrolled increasing hyperglycemia from one or more causes listed above, can lead to hyperosmolar nonketotic coma.[37] Fever, obtundation, focal neurological signs, seizures and death characterize the untreated syndrome. Mental obtundation without acidosis should always suggest the possibility of a hyperosmolar nonketotic state. The blood sugar levels may vary from 450 mg/dL to 1,000 mg/dL.

Therapy consists of stopping dextrose infusions, administering large quantities of insulin intravenously in an infusion, and using half-strength saline infusions intravenously.

Hypoglycemia Invariably occurs if high concentrations of dextrose infusions are suddenly stopped. Parenteral infusions of dextrose should always be slowly tapered, and never suddenly stopped. Five per cent dextrose can be infused through a peripheral vein if necessary.

Hypomagnesemia May clinically manifest with tingling in the limbs and around the mouth. Serum magnesium levels are often reduced to less than 0.6 mg/dL. The average requirement of magnesium is 8–16 mEq/day. In patients whose magnesium stores need to be repleted, or in those with diarrhea or hepatic dysfunction, the requirement of magnesium may be significantly increased.

Hypophosphatemia Inadequate intravenous administration of phosphate may progress over a period of time to increasing phosphate deficiency. Severe deficiency leads to mental obtundation and coma. Lethargy and a slurred thick speech are early features. If unrecognized, the patient becomes increasingly obtunded and fully comatose. Hemolysis, rhabdomyolysis and heart failure may occur. The normal phosphate requirement is estimated to be 90 mEq/day. This level may be increased in hypercatabolic states, or when there is excessive loss of phosphates from body stores.

Hepatic dysfunction A rise in the serum transaminases and the alkaline phosphatase is often observed in patients on TPN. It is usually a self-limited, nonprogressive complication. A progressive rise in the serum bilirubin is almost always not due to TPN. An ultrasound examination is necessary in such patients to exclude abdominal sepsis, biliary obstruction, acalculous cholecystitis or liver steatosis. The current use of glucose plus lipid solutions to share in the caloric requirement has reduced the incidence of liver steatosis. Causes that could probably contribute to hepatic dysfunction during TPN include the effects produced by breakdown products of amino acids and bacterial endotoxins, excessive carbohydrate administration, essential fatty acid deficiency, lack of enteral stimulation of the gut with altered levels of gut hormones,[1] and the presence of complicating sepsis.

Catheter-Related Infections

Catheter-Related Sepsis This is a dreaded complication of TPN. Infection can be bacterial, fungal or both. Aseptic care of the catheter, and restriction of use of the catheter solely for the purpose of TPN, has reduced the incidence of catheter-related sepsis from 6% to 27%, to the current acceptable rate of 1–3%.[1] The subject is discussed at length in the Section Fever and Acute Infections in a Critical Care Setting.

Thrombosis of the Subclavian Vein The incidence of clinically apparent thrombosis is 2–5%. Venographic studies have however shown an incidence as high as 20–50%, the majority being asymptomatic.[38] Catheter insertion may injure the intima of the vein and initiate thrombosis. A fibrin sleeve often forms around the tip of the catheter, extending for a centimeter or two proximally. This may constitute a nidus for a sleeve thrombus. Hypertonic infusions (particularly the use of 50% dextrose) are irritant and may also contribute to thrombus formation. The composition of the catheter has been incriminated in thrombosis of the subclavian vein. Polyvinyl catheters act as a strong irritant; silastic catheters have the least irritant effect. Finally, background diseases like sepsis or malignancy can lead to hypercoagulable states that promote thrombus formation.

Pain and swelling of the arm are clinical manifestations of subclavian vein thrombosis. The latter, as stated above, may however be asymptomatic. A subclavian vein thrombus may become infected, and cause a septic thrombophlebitis of the vein. Pulmonary embolization can also result.

Treatment involves prompt removal of the catheter, and anticoagulation with heparin. Treatment of septic thrombophlebitis involves in addition, the use of antibiotics.

Technical Complications

These have been discussed in the Section Procedures and Monitoring in the Intensive Care Unit. They are related to the

Table 5: Recommendations for specific clinical conditions

Clinical condition	*Initial caloric requirement (kcal/day)*	*Proteins (g/kg/day)*	*Comments*
Polytrauma	25–30	1.5	Immune-modulating formula may be of benefit
Major cardiothoracic surgery	25	1.2–1.5	Immune-modulating formula may be of benefit
Severe burns	30–35	1.5–2.5	Higher protein intake improves outcome
Fulminant tetanus	30–35	1.5–2	Higher calories and high protein intake helps blunt or reduce catabolism
Acute renal failure (not on dialysis)	25	0.5	Restrict water, sodium and potassium
Acute renal failure (on dialysis)	25	1.5	Protein needs higher because of catabolic state and loss of protein in dialysis
Liver failure	25	0.5–1	Use 0.5 g/kg/day in hepatic encephalopathy; branch chain amino acids may improve central nervous system function
Acute hypercapnic respiratory failure	25	1.2	Reduce carbohydrates to reduce VCO_2 in severe obstructive lung disease; reduce fats in TPN in ARDS
Pancreatitis	25	1–1.5	Small bowel feeds (preferably with a peptide-based formula) are well tolerated
Inflammatory bowel disease	25	1–1.5	Small bowel feeds (preferably with a peptide-based formula) are well tolerated

placement of the central venous catheter in the subclavian or jugular vein, by the percutaneous technique.

12

NUTRITIONAL SUPPORT IN SPECIAL CONDITIONS (TABLE 5)

Renal Failure

Nutritional support in renal failure increases the risk of fluid overload, and uremic symptoms. The following special points merit consideration—

- Nutritional support is absolutely necessary in hypercatabolic patients with renal failure. It should be begun early and should be combined with hemodialysis or hemofiltration. If the patient is hemodynamically unstable, continuous hemofiltration is used to control fluid overload and uremia.
- In patients who are not dialyzed and are in renal failure. The protein intake is restricted to 0.5 g/kg per day, and standard formulations are used. The fluid is restricted to 0.8–1 L/day if the urine output is low. In the absence of clinical improvement, hemodialysis or hemofiltration should be commenced. Once dialysis is begun, the protein intake is suitably increased to 1 g/kg per day, or even more in catabolic states.
- If enteral feeding is used, the fluid intake and protein intake should be carefully calculated. A carbohydrate:fat ratio of 60:40 should be used to meet caloric needs. Insulin may be required to manage glucose intolerance in these patients.
- During hemodialysis, there is a loss of 6–12 g of amino acids per treatment, and a loss of 25–30 g of glucose during a 6 hour dialysis session. Hemofiltration results in the loss of 4 g amino acids per day. When calculating nutritional requirements, these losses should be considered and made good. When dialysis is in the form of peritoneal dialysis, there is a net gain in glucose of 120–150 g/day from the dialysate fluid. This amount thus needs to be subtracted from the nutritional supplementation.
- The use of essential amino acid formulas is controversial. The rationale for the use of essential amino acids is that endogenous nitrogen can be used to synthesize nonessential amino acids, thereby reducing the degree of rise in the BUN. Essential amino acid formulations are probably only indicated when a patient in renal failure is a poor risk for dialysis, and when standard formulations produce a rapid rise in the BUN. Fluid overload remains a problem even with special amino acid formulations. In less catabolic patients, the protein intake should be kept at 0.3 g/kg per day.

Hepatic Failure

If there is no encephalopathy, the protein intake is kept at 1 g/kg per day. In the presence of encephalopathy, the protein is restricted to 0.3 g/kg per day or even less, of the standard formulations and solutions. It has been shown that the infusion of branched-chain enriched amino acids improves encephalopathy in many patients. A meta-analysis of six large studies in patients with liver disease showed that the mortality in those receiving branched-chain enriched amino acids was 24% in contrast to 43% in the control group.[39] The intake of branched-chain amino acids should start with 0.25–0.5 g/kg per day. In hypercatabolic states, this is gradually increased to 1 g/kg per day. The caloric requirement should be given by glucose and fat in the ratio of 60:40.

Respiratory Failure

Nutritional support is of importance in critically ill patients with respiratory failure. The aim is to improve respiratory muscle strength to help counter the impedance to ventilation

produced by either severe restrictive disease as in acute respiratory distress syndrome (ARDS), or by severe airways obstruction as in chronic bronchitis, emphysema. A poor nutritional state is an important cause of unsuccessful weaning from ventilator support.

Patients with chronic airways obstruction who are hypercapnic may experience a further rise in PCO_2 if carbohydrates are given in excess. This is because the metabolism of carbohydrates leads to CO_2 production. A significant increase in the volume of CO_2 produced can only be got rid off by an increase in alveolar ventilation. Patients with severe chronic airways obstruction may be unable to increase their alveolar ventilation to washout the excess CO_2. The $PaCO_2$ therefore rises. Carbohydrates should be restricted in these patients, particularly when they are being weaned from ventilator support. The total caloric requirement and protein remain as described earlier but the carbohydrate:fat ratio should be 40:60.

On the other hand, in patients with ARDS, lipid emulsions may interfere with gas exchange and it is preferable to restrict fats and keep the carbohydrate: fat ratio at 65:35 when the patient is on parenteral nutrition.[40]

Cardiac Failure

The major feature in TPN is to restrict salt and water intake. Sodium, potassium and magnesium should be carefully monitored. TPN is started with half the caloric requirement over 3–4 days in order to avoid pulmonary edema secondary to refeeding and increased metabolic rate. It is then gradually increased to the required level. The caloric and protein intake is as discussed in earlier sections, with a glucose:fat ratio of 60:40. Ischemic myocardium derives its energy from anaerobic metabolism. The use of parenteral nutrition with adequate glucose, potassium and insulin may provide substrate delivery to such ischemic areas.[41]

Pancreatitis

Recent trials suggest that jejunal enteral feeds of a peptide-based diet are well tolerated in patients with severe pancreatitis. Enteral nutrition should be attempted before starting TPN in the majority of patients with acute pancreatitis. In fact, septic complications in necrotizing pancreatitis are reduced in those receiving enteral feeds when compared to those receiving TPN.[42] However, in fulminant pancreatitis with ileus and complicating sepsis, TPN is imperative. Jejunal enteral feeds should be started slowly when gut function returns.

Thermal Injury

Patients critically ill with severe burns need 30–35 kcal/kg daily and 2 g of protein per kg per day. Increased protein intake appears to reduce both morbidity and mortality in these patients. The gut should be used as far as possible; nutrition if needs be can then be supplemented by parenteral therapy.

Metabolic Stress Syndrome and Diabetes

Metabolic stress syndrome is a condition of elevated blood glucose levels in nondiabetics in an ICU setting. It is not due just to caloric intake, but is related to increase in counter-regulatory hormones and insulin resistance. It should be countered by the use of a titrated dose of insulin, so as to keep blood glucose levels not greater than 140 mg/dL. In a prospective randomized study in 765 critically ill mechanically ventilated patients, a tight control over blood glucose with insulin, reduced mortality by 43% and also resulted in a significant reduction in morbidity.[43]

Diabetic patients receiving TPN frequently have serum glucose and electrolyte levels difficult to control. Insulin administration is vital for effective parenteral alimentation. TPN should be initiated in diabetics with just 150 g of glucose in 24 hours. A quarter to half of the patients daily insulin requirement should be added to the TPN solution; further doses of subcutaneous insulin are given according to a sliding scale, the dose of insulin being based on bedside glucose estimations every 3–4 hours. It is always preferable to add insulin to the TPN solution to control elevated blood sugar levels. The use of separate intravenous infusions of insulin and TPN solution can cause severe hypoglycemia in these critically ill patients.

IMMUNONUTRITION OR IMMUNITY-ENHANCING FORMULAS

Combinations of various nutrients, which enhance immune activity and immune response have been in use over the last few years. These immunomodulating nutrients include glutamine, arginine, omega-3 fatty acids, neucleotides and antioxidant vitamins. Glutamine, which accounts for more than 60% of the body's free amino acid pool is markedly decreased in stress and starvation. Supplements of glutamine are believed to be of use in patients with multiple trauma, sepsis, severe burns, AIDS, inflammatory bowel disease. Glutamine supplements can be given by the enteral route or intravenously. Arginine plays a role in lymphocyte proliferation and wound healing. Omega-3 fatty acids may reduce production of inflammatory mediators by neutrophils, macrophages and endothelial cells. Neucleotides are believed to enhance immune function.

The use of immune-enhancing formulas are reported to be associated with lower rates of infection, decreased time on ventilator support and decreased length of stay in the ICU.[44]

Fever and Acute Infections in a Critical Care Setting

- General Considerations and Noninfective Causes of Fever in the ICU
- Nosocomial Infections
- Community-Acquired Fulminant Infections Requiring Critical Care
- Antibiotic Therapy in the Intensive Care Unit
- Invasive Fungal Infections in the ICU

CHAPTER 43

General Considerations and Noninfective Causes of Fever in the ICU

GENERAL CONSIDERATIONS

The incidence of acute infections requiring critical care is probably higher in the poor developing countries of the world than in developed regions. The nature of acute infections is also often different. In India, we see most of the infections that prevail in the West, as also other acute infections that the Western half of the world hardly ever encounters. This is related to differing geographical, environmental and socioeconomic factors.

Patients with infection in intensive care units fall into three groups—

1. *Patients with severe community-acquired infections who need critical care* These include in our part of the world, patients with bacterial sepsis, severe tetanus, severe *Plasmodium falciparum* infections, severe community-acquired pneumonia, disseminated hematogenous tuberculosis, violent Gram-negative infections chiefly originating in the gastrointestinal tract, fulminant amebic infections, fulminant meningitis, hemorrhagic dengue fever, severe leptospiral disease and other miscellaneous acute infections.
2. *Patients with nosocomial (i.e. hospital-acquired) infections* These can occur either in patients admitted to hospital wards, the infection being serious enough to merit critical care, or in patients already admitted to the intensive care unit (ICU). In our ICU, the rate of nosocomial infection in patients requiring life support for more than 2 weeks is five-fold higher than in those admitted to the general wards, who do not require ICU care. However, the proportion of nosocomial infection in the ICU vis-à-vis the general wards differs in different hospitals in Mumbai, and in different centers of this country.
3. *The immunocompromised and, in particular, the neutropenic patients in the ICU* fall in a separate category. Such patients are extremely vulnerable to nosocomial infections in the ICU, because of a hostile environment where the risk of infection is high, and also because they lack appropriate defense mechanisms against infection.

Fever and infections in neutropenic patients are dealt with in the Section The Immunocompromised Patients. Important infections and the background factors underlying these infections in the other two groups of patients are dealt with in subsequent chapters of this section. The present chapter deals with *nosocomial fever (i.e. fever that appears 24–48 hours after admission) in a critical care setting, unrelated to infection.*

FEBRILE RESPONSE

The normal temperature ranges from 36°C (am) to 38°C (pm) with a mean temperature of 37°C (98.6°F). It is measured in the mouth as oral temperature and more reliably in the rectum as the rectal temperature. A febrile response is the hallmark of infection. It is however important to bear the following facts in mind when considering the febrile response—

- Fever and its attendant symptoms of malaise, together with leukocytosis can occur in the absence of infection. A careful consideration of the background clinical features of a patient with pyrexia in the ICU, and a search for nonspecific causes of pyrexia is imperative, if unnecessary use of antibiotics (with all its attendant dangers) is to be avoided.
- The height of the fever and the clinical appearance of the patient need not constitute a reliable guide either to the presence or to the severity of the infection. High fever with

rigors could be due to a pyrogen reaction from an infusion, or due to a drug reaction, while minimal temperature elevations and even normal or subnormal temperatures may be associated with life-threatening sepsis.

- A normal oral and axillary temperature in a setting where fever is expected should always prompt one to measure the rectal temperature. A very high rectal temperature with normal or only modest elevation of axillary temperature is a feature of fulminant tetanus, in many patients with *P. falciparum* infection and in some patients with life-threatening sepsis. Rectal temperatures closely approximate the core temperature and are standard measurements in most ICUs in Europe and the United States. Oral temperature is fairly reliable (1° less than rectal and 1° greater than axillary temperature), but in problem patients, and in those with a marked discrepancy between the oral and the rectal temperatures, the latter should be monitored. Alternative methods for monitoring core temperatures are now available in the form of thermistors placed in bladder catheters, pulmonary artery catheters and ear probes. These however are expensive, and in a poor country like ours, unnecessary for patient care.
- Infants and elderly patients may not respond with the expected temperature pattern even in serious infections.

NONINFECTIVE CAUSES OF FEVER IN THE ICU[1-4] (BOX 1)

In a pyrexial patient under critical care, the clinical background or setting should dictate the initial bedside evaluation of the fever. The following noninfective causes of pyrexia should come to mind and should be carefully evaluated. Unnecessary, expensive investigations are avoided by a careful clinical examination.

TRAUMA

Trauma and, in particular, crush injuries can induce a systemic febrile response even in the absence of infection.

POSTOPERATIVE FEVER

About 10% of patients may develop an elevated temperature in the first 72 hours of surgery even in the absence of wound or other infection. Most such fevers are mild to moderate, occur as a single episode and are short-lasting. Expensive investigations are best deferred if the wound is clean and clinical examination reveals no cause for the fever. A sterile serous collection beneath a portion of the wound may lead to a low-grade fever mainly occurring in the afternoon or evenings for 8–12 days, till such time as the serous collection is absorbed or drained. Fever persisting well beyond 72 hours of surgery needs careful evaluation for possible infection. The sites needing special attention are the wound, the lungs, the urinary tract and, in patients who have had abdominal surgery, the abdomen.

Box 1: Noninfective causes of fever in the ICU

- Trauma (especially crush injuries)
- Postoperative
- Malignant hyperthermia
- Neuroleptic syndrome
- Thromboembolism
- Blood in body cavities and large hematomas
- Postcardiotomy syndrome/Dressler's syndrome
- Myocardial infarction
- Procedures or therapeutic measures, e.g. blood transfusions, infusions
- Drug fever
- Neurological causes—posterior fossa syndrome
- Pancreatitis
- Acalculous cholecystitis
- Bowel infarction
- Other rare causes, e.g. tumors, adrenal insufficiency or exacerbation of hyperthyroidism

MALIGNANT HYPERTHERMIA[5]

This is a very rare disorder caused by an abnormal release of calcium from skeletal muscles following the use of general anesthetics and muscle relaxants.[1] Initially it is characterized by muscle rigidity, tremulousness, tachycardia, labile blood pressure and ventricular arrhythmias. The striking muscle rigidity is due to the abnormal release of calcium from the sarcoplasmic reticulum of skeletal muscles.[5] Cyanosis may be marked and pulmonary embolism may be wrongly diagnosed. Fever with shivering occurs in 30% of patients; hyperpyrexia with temperatures ranging from 104°F to 107°F may occur. Fever and early features of the syndrome more often start in the operation theater during the recovery period or are apparent soon after transfer to the ICU. If untreated, myoglobinuric renal failure may be observed. Immediate treatment with dantrolene reduces morbidity and mortality. An intravenous bolus of 1–2 mg/kg of the drug is given and is repeated every 15 minutes, if necessary, to a maximum of 10 mg/kg. A maintenance dose of 1–2 mg/kg orally four times a day for 3 days is then administered.

MALIGNANT NEUROLEPTIC SYNDROME[5]

The malignant neuroleptic syndrome is a consequence of blockage of dopamine receptors from antipsychotic agents (phenothiazines butyrophenones, thioxanthenes). It is characterized by high fever, muscle rigidity, mental obtundation or delirium and excitability. There is often a marked rise in the creatine phosphokinase. It is often misdiagnosed as a central nervous system infection or a brainstem lesion. The offending drug or drugs should be stopped and dantrolene administered in the dosage stated above.

THROMBOEMBOLISM

A low-grade fever may be due to thromboembolism. This risk is highest in postoperative patients, patients immobilized for long periods of time, following cerebrovascular accidents, myocardial infarction and in patients with neoplastic disease. Careful examination for painful swelling of the calves and thighs and for tenderness over the course of the large veins in the lower limbs is at times rewarding. Even so, pulmonary emboli may be shot out from thrombi in the deep veins of the leg, thigh or from thrombosed veins within the pelvis, without the presence of abnormal physical signs.

BLOOD IN THE BODY CAVITIES AND LARGE HEMATOMAS

Accumulation of blood in the thorax, abdomen and the presence of blood in the subarachnoid space produces fever. A large hematoma in any organ or tissue occurring spontaneously as in certain diseases, or following trauma or rupture of a vessel, also produces pyrexia. A clot within a dissecting aneurysm of the aorta is similarly associated with a low-grade fever. An appropriate clinical background should suggest the correct etiology for fever in these patients.

POSTCARDIOTOMY SYNDROME/ DRESSLER'S SYNDROME

Following cardiac or open heart surgery, the persistence of a pericardial rub after 6–7 days, with fever, leukocytosis and an erythrocyte sedimentation rate more than 50 mm/hour, should suggest the diagnosis of a postcardiotomy syndrome. A pleural rub with a pleural effusion in the left pleural space or rarely bilaterally may be present. The possibility that a pleuropulmonary shadow after cardiac surgery could be due to a postcardiotomy syndrome should be kept in mind, else the diagnosis of a nosocomial pneumonia can be wrongly made.

Dressler's syndrome with fever and precordial pain due to pericarditis can occur any time from 7 days to 6 weeks after a myocardial infarct. Pleurisy and pleuropulmonary shadows may also be observed, exactly as after cardiac surgery. The response to corticosteroids is dramatic both in the postcardiotomy syndrome and in Dressler's syndrome. Response to nonsteroidal anti-inflammatory agents or to aspirin is also satisfactory in many patients.

MYOCARDIAL INFARCTION

A critically ill patient from any cause may develop a myocardial infarction. Pain in such individuals literally goes unnoticed, and a low-grade fever with leukocytosis may be cause for concern.

PROCEDURES OR THERAPEUTIC MEASURES

The following procedures or therapeutic measures are associated with fever in the absence of infection.

- *Blood transfusions or intravenous infusions of fluids* Fever is observed in about 5% of patients receiving blood products. Febrile transfusion reactions are discussed in another chapter.
- *Hemodialysis* Temporary fever during dialysis is of uncertain etiology. It could be due to noninfective causes, or due to endotoxin contamination of the dialysis equipment, or due to bacteremia by Gram-positive and/or Gram-negative organisms.
- *Fever following bronchoscopy* This occurs in 10% of patients but should not last for more than one day.

DRUG FEVER

The diagnosis of drug fever is generally made after exclusion of other causes of fever—both noninfective and infective. The fever is usually low grade, but may be high, and may be associated with chills and rigors. A drug rash and/or peripheral eosinophilia, if present, allow for an easy diagnosis; however, Mackowiak and LeMaistre[6] noted a drug rash in only 18% and peripheral eosinophilia in 22% of patients with drug fever. Tachycardia is frequent and hypotension may also occur. Contrary to conventional teaching, a patient with drug fever can appear as ill as a patient with a serious infection.[6] Any drug can theoretically speaking produce drug fever, but fever and drug reactions are most commonly observed with sulphas, quinine, quinidine, penicillin and its derivatives, antibiotics (including beta-lactams), amphotericin B, furadantin, rifampicin, phenytoin and procainamide. If drug fever is suspected, the offending drug should be omitted; if the diagnosis is correct, the fever disappears in 2–3 days.

NEUROLOGICAL CAUSES[7]

An unrecognized subarachnoid bleed is an important cause of fever. Persistent sudden headache, often accompanied by neck stiffness, is the clue.

The posterior fossa syndrome is an important cause of noninfectious origin of fever. It mimics meningitis, because of increased polymorphs in the cerebrospinal fluid (CSF), a low blood sugar and increased protein content. It is distinguished from meningitis by negative CSF culture and the gradual lessening of neurological signs as the red blood cells in the CSF clear with time.

Other causes of central fever should be kept in mind. These include trauma affecting the hypothalamus or any hypothalamic lesion. The fever is often resistant to antipyretics, exceeds 104°F and is characterized by absence of perspiration.

PANCREATITIS

This can complicate the course of a critical illness in an ICU patient, particularly with multiple organ failure, or as a complication of viral hepatitis, or following the use of corticosteroid therapy, or in the presence of shock and hypoperfusion from any cause, or in burns with sepsis.

The diagnosis may be missed in very ill patients and should be suspected if abnormal abdominal symptoms or signs, fever, or an unexplained worsening in the clinical picture is observed against a background where pancreatitis may be a possible complication. The serum amylase and lipase levels are markedly elevated, and the diagnosis can be further confirmed by an ultrasound or computed tomography of the abdomen that show an enlarged, often necrotic pancreas with pancreatic and peripancreatic inflammation (see Chapter Acute Pancreatitis).

ACALCULOUS CHOLECYSTITIS[8]

Acalculous cholecystitis is an important but often undiagnosed cause of fever. It can occur in patients with shock from any cause and is then related to poor intra-abdominal perfusion. It is also observed in patients with sepsis, in particular, abdominal sepsis. The symptoms in critically ill patients are unremarkable. Abdominal tenderness in the right hypochondrium should draw suspicion. The ultrasonography shows increased thickness of the gallbladder wall, gallbladder distension, intramural lucencies, pericholecystic fluid and intraluminal sludge. High resolution computed tomography (HRCT) of the abdomen is generally diagnostic. The diagnosis is often delayed, the disease progressing to increasing ischemia, gangrene and perforation. Surgery is mandatory.

BOWEL INFARCTION

Ischemia and/or infarction of the bowel due to occluded mesenteric vessels can produce fever and is accompanied by abdominal pain and tenderness, but these symptoms may be masked in patients who are critically ill or in those with an altered mental state. Fresh blood per rectum or melena with normal upper gastrointestinal endoscopy findings should suggest the diagnosis. HRCT of the abdomen and mesenteric angiography should prove the diagnosis.

OTHER RARE NONINFECTIVE CAUSES

Other, less common, noninfective causes of fever encountered in an ICU setting include alcohol withdrawal, severe adrenal insufficiency precipitated by the stress of a critical illness, exacerbation of hyperthyroidism in a critically ill individual, fat embolism after trauma and multiple organ failure due to a noninfective etiology. Tumors and lymphomas can also produce fever, particularly during chemotherapy. Vasculitis of any etiology is another rare cause of fever in critically ill patients.

CHAPTER 44

Nosocomial Infections

GENERAL CONSIDERATIONS AND EPIDEMIOLOGY

Nosocomial infections are those which manifest in patients 48 hours after admission to hospital. They are therefore hospital-acquired infections, in contrast to community-acquired infections. Nosocomial infections are directly related to diagnostic, interventional or therapeutic procedures a patient undergoes in hospital, and are also influenced by the bacteriological flora prevailing within a particular unit or hospital. Infections in patients occurring within 48 hours of discharge from hospital are also invariably nosocomial in origin. Nosocomial infections carry a significant morbidity and mortality, particularly when they affect patients in the intensive care unit (ICU).

Critical care units increasingly use high technology medicine for patient care—hemodynamic monitoring, ventilator support, hemodialysis, parenteral nutrition, and a large battery of powerful drugs, particularly antibiotics to counter infection. It is indeed a paradox that the use of high technology medicine has brought in its wake the dangerous and all too frequent complication of nosocomial infections.

By a strange quirk of circumstance, the better equipped an ICU for invasive procedures, the more frequently are these procedures performed for patient care, and the greater is the risk of nosocomial infections. Prospective studies[1] have shown that various invasive devices play a far more important role in determining susceptibility to nosocomial infection than underlying disease. Again, though the concept of caring for critically ill patients in special units equipped to do so is sound, the disadvantages of such a milieu are also being increasingly realized.

The ICU milieu is uniquely conducive to nosocomial infections. It is a closed milieu, constantly full of patients with life-threatening illnesses. It has a constant staff of nurses and doctors who over prolonged periods of time are exposed to and are in contact with an environment contaminated by antibiotic-resistant pathogens. In this closed milieu the major reservoir of nosocomial organisms is the infected or colonized patient. Most bacteria, many viruses, and possibly even fungi are spread primarily via the hands of the medical, paramedical and nursing staff. Mycobacteria, Legionella and, in granulocytopenic patients, *Aspergillus spp.* are transmitted by airborne droplets. Aspiration of infected pharyngeal and mouth secretions, exposure to invasive devices and procedures, surgery, impairment of immune mechanisms or overwhelming illnesses amplify colonization and vulnerability to nosocomial infections, and promote their easy transmission. In most patients, antibiotic use promotes sooner or later antibiotic resistance to a number of organisms that prevail in a particular ICU. These resistant organisms contaminate the whole closed environment of the ICU; they can contaminate the curtains, the walls, floor and ceilings, the side tables, the wash basins and the soap dishes, the detergents used as antiseptics, and the clothing and hands of the ICU staff. Bacteria from colonized or infected patients can also be perpetuated in urine bottles, bedpans, commodes, respiratory therapy equipment, ventilators, chamber domes of transducers used in hemodynamic monitoring, and in bronchoscopes or other endoscopes.

In short, the closed milieu of the ICU provides an environment that is as conducive to the growth and preservation of resistant organisms as is a hothouse conducive to the growth and preservation of exotic flora. It is therefore not surprising

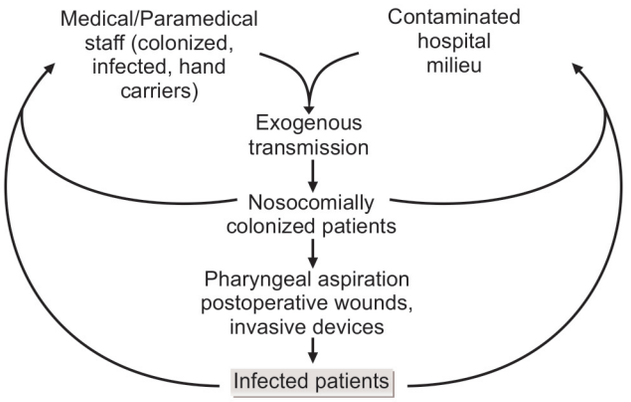

Fig. 1: Epidemiology of nosocomial infection

that two-thirds of reported outbreaks of nosocomial infections have occurred in ICUs, even though less than 10% of all hospitalized patients require ICU care.[2]

The epidemiology of nosocomial infection is illustrated in Figure 1.

INCIDENCE

The more ill the patient, the greater is the incidence of nosocomial infections. The rate of nosocomial infections is highest in burn units, surgical ICUs and ICUs for low birth weight neonates (15–30%). The risk is intermediate in medical and pediatric ICUs (5–10%), and lowest in coronary care units (1–2%).[2]

The risk of nosocomial infections in the ICU is also markedly influenced by the length of stay; the latter varies in different institutions. The Center for Disease Control and Prevention (CDC) has therefore advocated the use of nosocomial infection rates expressed per 1,000 patient days, to enable comparison between different institutions. Again, increasing exposure to invasive devices increases the nosocomial infection rate. The CDC has therefore advocated that device-associated nosocomial infections should be expressed as infections per 1,000 device days.[3-5]

The impact of nosocomial infection on mortality and morbidity in India is unknown but is unquestionably high. Nosocomial infections have been ascribed by the National Nosocomial Infection Surveillance System to be responsible for more than 80,000 deaths annually and in the mid-nineties resulted in 5 billion dollars in excess healthcare costs.[6]

Profile of Nosocomial Infections

Urinary tract infections (UTIs) are the most frequent, accounting for more than 40% of all nosocomial infections. Other nosocomial infections include nosocomial pneumonias, postoperative surgical wound infections, nosocomial bacteremias, gastrointestinal (GI) infections, especially Pseudomembranous colitis due to *Clostridium difficile*.[3]

Different ICUs have different frequency profiles of nosocomial infections. Nosocomial infections and the frequency with which they are observed in the ICU at Breach Candy Hospital, over the last 1 year have been tabled in Table 1.

Table 1: Profile of organisms isolated from patients in the ICUs at the Breach Candy Hospital, 2012

Site	*Common pathogens*
Blood	Klebsiella pneumoniae, Non-albicans Candida, Burkholderia cepacia, Pseudomonas aeruginosa and Acinetobacter baumannii complex
Lower respiratory tract	Acinetobacter baumannii complex, Pseudomonas aeruginosa, Klebsiella pneumoniae and Escherichia coli
Surgical wounds	E. coli, Pseudomonas, Acinetobacter, S. epidermidis, MRSA, MSSA
Urinary tract	E. coli, Pseudomonas, Enterococcus species, Klebsiella pneumoniae and Candida species

Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

Our overall incidence of nosocomial infection over the past 1 year has been 27 episodes. The total number of ICU patients were 679; total patient days—3,823; nosocomial infection per 1,000 patient days was 3.85. Bloodstream infection (BSI) was found to be the most common form with an incidence of 17 episodes, followed by pneumonia with 7 episodes and UTI were only 3 (Fig. 2). Till 1996, UTIs headed our list of nosocomial infections, as in most ICUs all over the world. However, in the last 3 years, there has been a dramatic fall in UTIs due to continuous and active surveillance measures taken by the hospital staff.

Organisms Involved

The majority of nosocomial ICU infections are caused by Gram-negative bacilli, chiefly the Enterobactericaeae, *Pseudomonas aeruginosa* and *Acinetobacter baumannii* complex. Here again the nature and frequency of the Gram-negative organisms varies with different units. Five to ten per cent of nosocomial infections are caused by Gram-positive cocci. Most frequently the *Staphylococcus aureus* or coagulase-negative *Staphylococci* or *Enterococci*.[7] We have been fortunate in having only a small number of infections due to the *S. aureus*. Methicillin-resistant *Staphylococcus aureus* (MRSA) infection for some reason is very uncommon in the unit, compared to the havoc MRSA has wrought in many ICUs and hospitals in the West. Close to 10–15% of infections are due to the *Candida* species. *Aspergillus spp*. and Zygomycetes infection are occasionally reported from units caring for patients with hematological malignancies, or in organ transplant patients.[8,9]

The microbiology of nosocomial infections observed in our unit at the Breach Candy Hospital is given in Figure 3.

Distinguishing between Colonization and Infection

It is extremely important that doctors in the ICU treat patients and not laboratory reports. Thus, a urine culture, or a wound

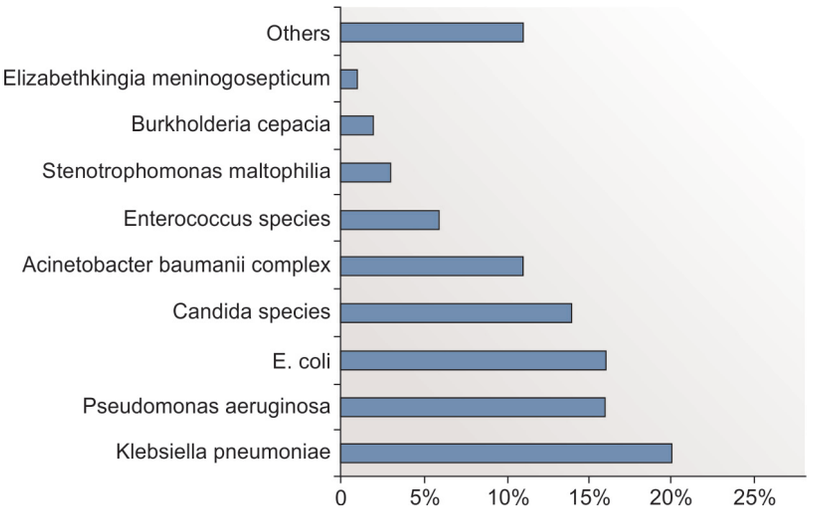

Fig. 2: Profile of organisms causing intensive care unit (ICU) nosocomial infections at Breach Candy Hospital in 2012

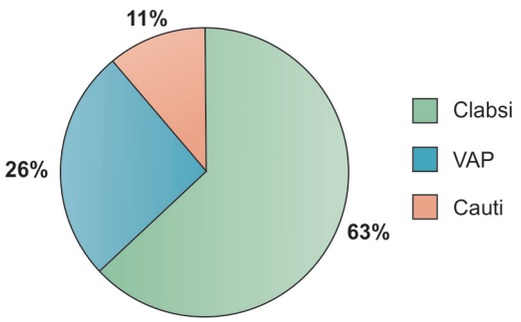

Clabsi—Central line associated blood stream infection
VAP—Ventilator associated pneumonia
Cauti—Catheter associated urinary tract infection

Fig. 3: Percentage (%) distribution of nosocomial infection, 2012

culture, or a sputum culture may show growth of pathogens which may merely represent colonization of the urinary tract or catheter, or of the wound or of the trachea respectively. A close liaison with the microbiology department is essential if correct interpretation of reports is to be made. Culture reports should always be correlated with clinical findings. At times, however, it may be extremely difficult to determine whether a growth of pathogens in an individual patient represents true infection or represents colonization. In many cases, particularly in the ICU, colonization is the precursor of infection, particularly in critically ill individuals, or if the organism is virulent, or resistant to antibiotics, or if the patient has invasive devices which increase his or her vulnerability.[10]

NOSOCOMIAL PNEUMONIA

GENERAL CONSIDERATIONS

Definitions

Nosocomial pneumonia is a pneumonia that develops in patients admitted to the hospital for more than 48 hours.[1] It is a dreaded complication which chiefly afflicts the most critically ill patients in a hospital.

Ventilator-associated pneumonia (VAP) is a pneumonia that develops in a tracheally intubated patient who has been mechanically ventilated for at least 48 hours.

Healthcare-associated pneumonia (HCAP) is a new entity that has been defined by the American Thoracic Society (ATS)[1] for the diagnosis and treatment of nosocomial pneumonia. Risk factors for developing HCAP are residence in a nursing home or extended care facility, hospitalization for 2 days or more within the preceding 90 days, home infusion or antibiotic therapy, chronic dialysis within 30 days, home wound care, and a family member with multidrug resistant (MDR) pathogen colonization or infection. Though these patients are not in hospital, the above stated risk factors predispose to colonization by pathogens present within hospitals including colonization by MDR organisms.

There is some controversy over the etiology of HCAP between American and European data. While American studies report HCAP being caused chiefly by multi-resistant organisms, European data report greater similarities between HCAP and community-acquired pneumonia rather than with hospital-acquired pneumonia.

This chapter chiefly focuses on VAP—undoubtedly the commonest cause of nosocomial pneumonia.

Neiderman and coworkers[2] observed that in an intubated population treated in a surgical ICU, pneumonia developed approximately in 10%, whereas in a medical ICU, 20% of intubated patients developed this complication. Impairment of defense mechanisms of critical ill patients and easy access of dangerous pathogens to the lower respiratory tract are both equally responsible factors. The ICU milieu is therefore an ideal setting for this major complication.

The true incidence of nosocomial pneumonia is difficult to determine, chiefly because of the difficulty in reaching a precise diagnosis, particularly in patients who already have significant radiological shadowing within the lung to start with, as, for example, in patients with acute lung injury and acute respiratory distress syndrome (ARDS).

Cook et al.[3] reported that the risk of VAP is 1% per day on mechanical ventilation. The risk changes over time, being 3% for the first 5 days on mechanical ventilation, 2% from the 5th to the 10th day and 1% for the remaining days. They noted that nearly half of VAP cases occurred during the first 5 days of mechanical ventilation.

Sopena and colleagues[4] reporting in 2005 on a Spanish study on the epidemiology of nosocomial pneumonia in non-ICU patients noted that nosocomial pneumonia was observed chiefly in elderly patients with underlying disease. The mortality rate was 26% and the risk of VAP 1% per day.

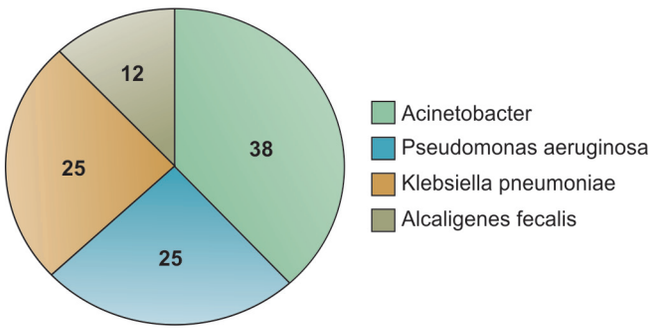

Fig. 4: Percentage (%) distribution of pathogens causing ventilator-associated pneumonia (VAP) in 2012 at the Breach Candy Hospital

Pertinent Data on VAP[5,6]

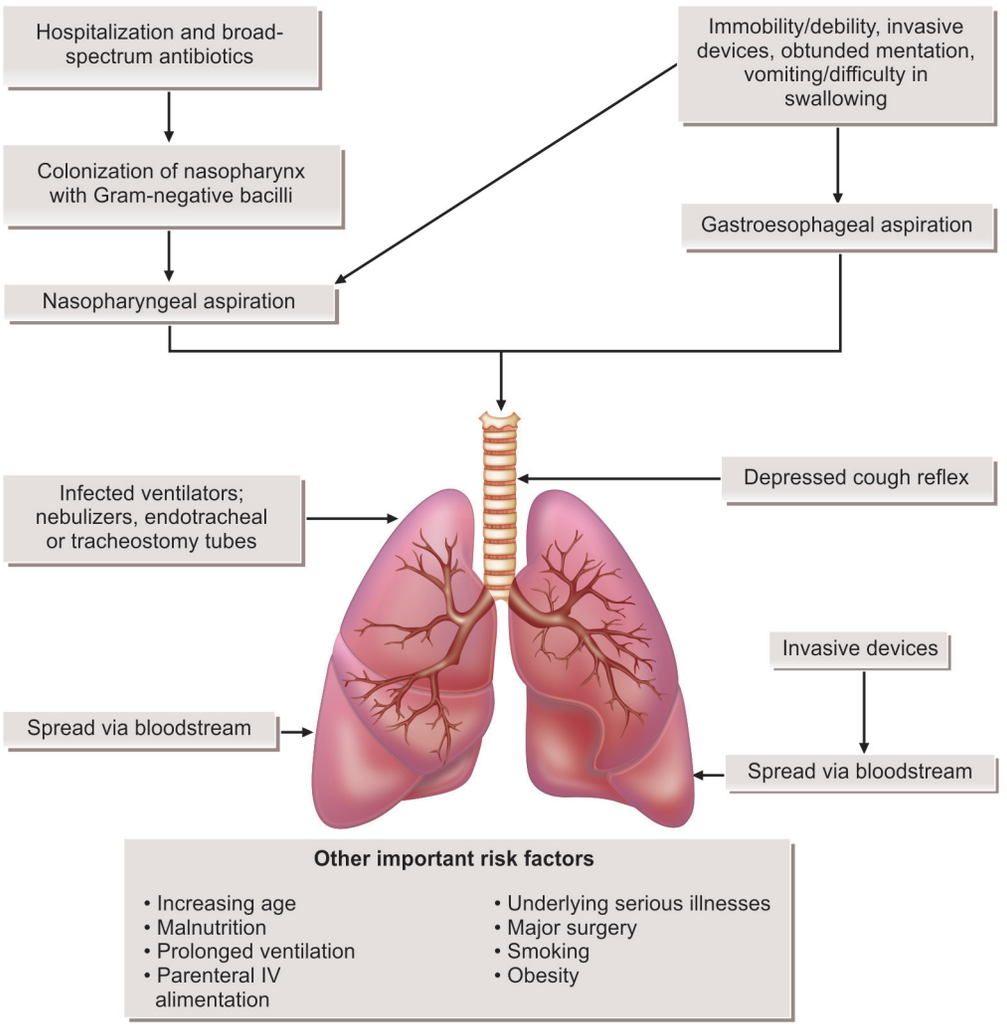
- Ventilator-associated pneumonias are the second most common nosocomial infection in many ICUs often constituting one-third or more of total nosocomial infections.[5]
- Over 90% of ICU acquired nosocomial pneumonias occur during mechanical ventilation and 50% occur in the first 4 days of ventilation.
- Early onset VAPs (<5 days of hospitalization) usually carry a better prognosis and are often caused by antibiotic sensitive bacteria. Late onset VAP (>5 days) are more likely to be caused by MDR pathogens and are associated with increased morbidity and mortality
- Between 10–20% of patients who require ventilation for more than 48 hours will acquire VAP with a mortality of 15–50%.[6]

The incidence of nosocomial pneumonias in various ICUs in our country or for that matter in any of the large metropolitan cities is undetermined, chiefly because no one has bothered to answer this question and little or no data is available. In our unit in Mumbai, nosocomial pneumonias are nowhere as frequent as reported from ICUs in the West, being 1.2–1.3 per 1,000 ventilator days.

The incidence of VAP in an ICU depends on the age of the patient, the severity of the underlying critical illness, comorbid factors, whether the lungs were normal or not at the start of mechanical ventilatory support, and the respiratory and overall critical care offered by a unit. In fact these are also the very factors that influence mortality. The length of ventilator support also influences the mortality; yet younger patients with normal lungs to start with can be maintained for weeks and even months without the course of the illness being complicated by VAP.

The microbial profile at the Breach Candy Hospital for VAP in the year 2012 is illustrated in Figure 4.

Flowchart 1: Pathogenesis of nosocomial pneumonia



13

PATHOPHYSIOLOGY (FLOWCHART 1)

Aspiration

Almost always, nosocomial pneumonia is due to aspiration of infected secretions or particulate matter from the mouth and pharynx into the lower respiratory tract. Retained infected secretions within the large and small airways can also produce nosocomial pneumonia. In most sick patients in the ICU, the oropharynx is colonized by aerobic Gram-negative bacteria within 5–10 days, whereas in healthy adults the normal organisms are anaerobic bacteria, and harmless commensals like *Neisseria pharyngitidis*.

Colonization of patients can occur from exogenous and/or endogenous sources. Exogenous sources include the hands, clothing, equipment of doctors, nurses, healthcare workers and the unhealthy environment of the ICU. Other exogenous sources include colonized bronchoscopes, humidifiers, respiratory equipment, and contaminated nebulizers. Endogenous sources include pathogens contaminating and colonizing the oropharynx, the GI tract, the proximal trachea and the endotracheal or tracheostomy tube.

Tracheal intubation is the most important underlying predisposing condition for the development of pneumonia as it aids aspiration of pathogens and prevents intrinsic respiratory defenses from coming into play. The endotracheal or tracheostomy tube also can further facilitate aspiration, as pathogens often grow on the inner surface and can be aspirated or translocated into the lung. The endotracheal tube is often lined by a biofilm consisting of bacteria embedded in an exopolysaccharide matrix. Embedded bacteria are protected from both antibiotics and the host immune responses and are difficult to eradicate. During tracheal aspiration, mechanical ventilation, bronchoscopy, particles of this biofilm may be dislodged and pushed into the lung leading to lower respiratory tract infection.

The severity of the illness plays an important role in perpetuating this colonization. Invasive diagnostic and therapeutic procedures further promote the aspiration and transfer of infected, colonized oropharyngeal contents into the lower respiratory tract. The upper airway is usually colonized before the lower airway, but organisms such as *Ps. aeruginosa* can colonize the lower airway as a primary event.[7] The reason

for colonization of the mouth, oropharynx and airways by pathogenic bacteria and in particular by Gram-negative organisms, is the subject of research. In healthy individuals a film of fibronectin covers the epithelium lining the mucosa of the mouth and oropharynx, and prevents the Gram-negative bacteria from adhering to the epithelial cells. This protective coating is lost in very ill individuals, so that pathogenic Gram-negative organisms adhere to receptors present on epithelial cells of the mucosa and soon colonize it. The number of these bacterial receptors on both upper and lower airway epithelial cells is increased in many illnesses. This change is associated with increased colonization at these sites. Risk factors for increased colonization due to enhanced adherence of bacteria to mucosal cells in the airways include serious illnesses, smoking, azotemia, surgery and malnutrition.[8]

Gastric Colonization

The acid within the stomach serves as a major deterrent to bacteria swallowed in the saliva. If gastric acidity is suppressed by the use of antacids and H_2 antagonists, the bacteria within the stomach survive, multiply, and soon colonize the upper GI tract. Gastric contents laden with Gram-negative bacteria could easily regurgitate and be aspirated into the lungs, causing aspiration pneumonia. This is particularly frequent in obtunded patients, sedated patients or following a large vomit. Prophylaxis and treatment of bleeding stress ulcers with sucralfate do not significantly increase gastric pH in most patients, and results in a reduced incidence of nosocomial pneumonias.

Hematogenous Pneumonia

Rarely infected emboli from a septic thrombophlebitis can lead to septic infarcts within the lung. Catheter-related sepsis or any other source of sepsis can cause bacteremia with hematogenous spread of infection into the lungs, causing pneumonia.

Inhalation Pneumonia

Contaminated respiratory equipment (nebulizers, humidifiers, ventilator tubing, etc.) as mentioned earlier is a source of infected aerosols. Infected particles 3–5 μm in size can be deposited into the terminal bronchioles and alveoli, thereby causing a lower respiratory tract infection.

Iatrogenic Causes

Lack of aseptic precautions during suction of tracheobronchial secretions, either through an endotracheal tube or tracheostomy is an important cause of lower respiratory tract infection.

FACTORS PREDISPOSING TO NOSOCOMIAL PNEUMONIAS (BOX 1)[3,9]

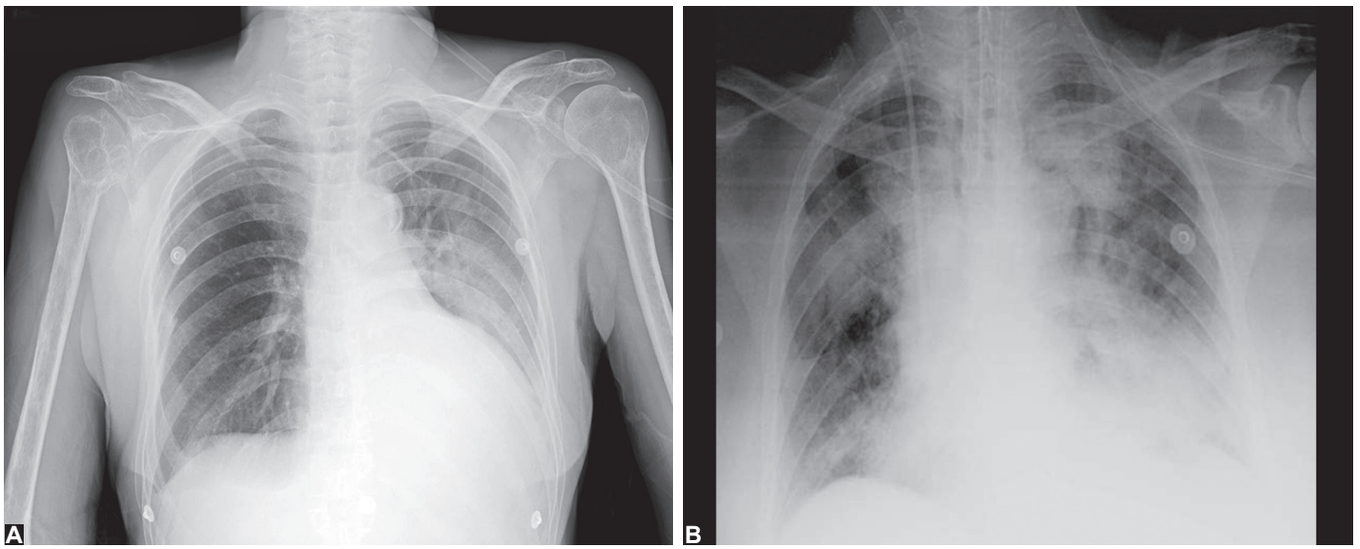
Box 1: Factors predisposing to nosocomial pneumonia (also applicable to other nosocomial infections)

- Host factors—
  - Overwhelming infections or serious illnesses, e.g. severe sepsis, prolonged shock, burns, severe trauma or following major surgery
  - Background factors, e.g. chronic lung diseases, diabetes mellitus, cardiac, renal or hepatic dysfunction, advanced age, underlying malignancy, malnutrition
  - Total parenteral nutrition
- Therapeutic interventions—
  - Endotracheal intubation or tracheostomy with mechanical ventilator support
  - Use of invasive procedures (including central lines)
  - Nasogastric tube
  - Use of corticosteroids or chemotherapy
  - Prolonged use of antibiotics
  - Colonization of upper GI tract with Gram-negative bacteria following use of antacids/H_2-antagonists
  - Use of high FiO_2 whilst on mechanical ventilation
- Environmental factors—
  - Overcrowding
  - Overall unclean environment (unfortunately so frequently seen in developing countries)
  - Transmission chiefly through contaminated hands of ICU personnel
  - Increased prevalence of multiple, resistant organisms

Abbreviations: GI, gastrointestinal; ICU, intensive care unit; FiO_2, fraction of inspired oxygen.

These can be divided into—

- *Host Factors* in which defense mechanisms are suppressed by—
  - Overwhelming infections, serious illnesses, e.g. severe sepsis, extrapulmonary infections, prolonged shock, burns or severe trauma, or following major surgery.
  - Background factors which are associated with a greater propensity to infection. These include underlying chronic lung disease (chronic bronchitis), diabetes mellitus, cardiac disease, renal failure, liver cell dysfunction, underlying malignancy, advanced age, malnutrition prior to the onset of a critical illness or occurring acutely during the course of an illness, and total parenteral nutrition.
- *Therapeutic Interventions* The most important of these are endotracheal intubation, tracheostomy, and mechanical ventilation. Nasogastric tubes encourage gastric colonization with pathogens, and perhaps provide a scaffolding or conduit for these pathogens to reach the pharynx; aspiration of these pathogens or of infected particulate matter results in pneumonia. Corticosteroids or antimitotic agents are immunosuppressants, and their use both encourage and mask infection. As mentioned earlier, there is evidence that excessive neutralization of acid to treat upper GI bleeds by antacids and H_2 antagonists also facilitates upper GI tract colonization with Gram-negative bacteria, and predisposes to pulmonary infection. The use of very high oxygen concentrations in mechanical ventilation over prolonged periods of time may also be



Figs 5A and B: (A) Unilateral nosocomial pneumonia; (B) Bilateral nosocomial pneumonia

detrimental to lung morphology and physiology, and may well predispose to infection. Prolonged antibiotic therapy can induce a superinfection by organisms resistant to conventional therapy, and lead to nosocomial pneumonia resistant to the usual antibiotics.

- *Environmental Factors* Overcrowding, an overall unclean environment (which unfortunately is frequently seen in developing countries), increased prevalence of multiple, resistant organisms, and transmission chiefly through the contaminated hands of ICU personnel, all predispose to the development of nosocomial infections.

CLINICAL DIAGNOSIS[5,10]

The clinical diagnosis of nosocomial pneumonia, including VAP, is difficult and often erroneous. This is proven by a postmortem study showing that the clinical diagnosis of pneumonia was incorrect in 60% of cases.[12] The diagnosis of nosocomial pneumonia requires the presence of the following important features—

- Fever, leukocytosis, purulent sputum or, in the case of VAP, purulent tracheal secretions. At least two of these three clinical criteria should be present.
- A chest X-ray which shows a new or progressive alveolar infiltrate (Figs 5A and B). The presence of an abnormal radiographic infiltrate together with at least two out of three clinical criteria stated above has a high degree of sensitivity but a low specificity. When all three clinical criteria are present in a patient with a fresh alveolar infiltrate on an X-ray chest, the specificity improves but the sensitivity falls to an unacceptable level (<50%).

Diagnostic problems in an individual patient can be formidable for the following reasons—

- A systemic inflammatory response characterized by fever and leukocytosis may be present, but its absence does not exclude the diagnosis of pneumonia. Also, fever and leukocytosis can occur in infections other than pneumonia and in noninfective pathologies in a critically ill patient.
- Absence of sputum or of significant lower respiratory tract secretions in patients with a tracheostomy (with or without ventilator support) does not exclude pneumonia in the presence of a recent infiltrate on an X-ray chest in critically ill patients.
- A shadow on a chest X-ray is not necessarily inflammatory. Localized shadows in one or both lung fields can be due to pulmonary edema, pulmonary hemorrhage, pulmonary infarction, ARDS and other noninflammatory causes. Atelectasis is often mistaken for pneumonia in a critically ill patient. A clearing of the shadow after vigorous physiotherapy differentiates infiltrates caused by atelectasis from those due to infection. The other causes of shadows on the X-ray chest are listed in Box 2.

Box 2: Pneumonia accounts for only one-third of pulmonary infiltrates in the ICU

- Other causes of shadows on X-ray chest—
  - Atelectasis
  - Pulmonary edema
  - Pulmonary infarction
  - Hemorrhage
  - Lung injury (ARDS)
  - Drug reaction
  - Recurrence or spread of mitotic disease
  - TRALI (Transfusion related acute lung injury)

Table 2: The Clinical Pulmonary Infection Score (CPIS)

Criterion	*0*	*1*	*2*
Temperature (°C)	≥36.5 and ≤38.4	≥38.5 or ≤38.9	≥39 or ≤36
Leukocytes, mm^3	≥4000 and ≤11000	<4000 or >11000	<4000 or >11000 + immature neutrophils >50% or >500
Chest X-ray infiltrates	No	Diffuse	Localized
Tracheal secretions	Not purulent or absent	Not purulent	Abundant and purulent
PaO_2/FiO_2	>240 or ARDS		≤240, no ARDS
Microbiology	Negative		Positive

Abbreviations: ARDS, acute respiratory distress syndrome; FiO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen in blood.
Source: Pugin J, Auckentholer R, Mili N, et al. Diagnosis of ventilator associated pneumonia by bacteriologic analysis of bronchoscopic and non-bronchoscopic "blind" bronchoalveolar lavage fluid. Am Rev Respir Dis. 1991;143:1121-9.

It should be remembered that a portable chest X-ray may be difficult to interpret in an intubated critically ill patient. Pneumonia may be difficult to exclude because of the technical quality of the film. Also, the chest X-ray may miss out on subtle features which are quite evident on a computed tomography (CT) of the chest.

In a study of autopsy-proven VAP, no single radiographic sign had a diagnostic accuracy greater than 68%. The presence of air bronchogram or alveolar opacities in patients without ARDS was the only sign that corresponded best with pneumonia, predicting 64% of pneumonias in this study.[11, 13]

A clinical study showed the presence of lung infection in only 42% of patients diagnosed as VAP, proving that there is a poor correlation between clinical features and bacteriological demonstration of VAP.[12]

- Nosocomial pneumonia in a patient with ARDS may be impossibly difficult to diagnose on a chest X-ray. A number of pathologies can cause asymmetric consolidation in patients with ARDS. An air bronchogram on a chest X-ray in a patient with ARDS is not necessarily predictive of nosocomial pneumonia.

Clinical Pulmonary Infection Score (CPIS) (Table 2)[13]

This scoring device is a simple aid to the diagnosis of VAP. It is based on the assessment of six clinical parameters—(1) temperature, (2) purulence of tracheal secretions, (3) total blood leukocyte count, (4) pulmonary radiological findings, (5) oxygenation and (6) semiquantitative culture of the tracheal aspirate. Each of these parameters carries 0–2 points. A value of greater than or equal to 6 was the threshold for a fairly accurate diagnosis of VAP. Studies have shown that the CPIS has a low sensitivity and specificity for diagnosing VAP. The PaO_2/FiO_2 ratio is however a valuable marker; improvement in this marker on treatment signified a better outcome, whilst a lack of response signified a worse outcome.

Newer Streamlined Surveillance Definitions and Guidelines

With the purpose of improving the efficacy and objectivity of VAP diagnosis, the Centre for Disease Control (CDC) has proposed an approach which focuses on ventilator-associated complications, centered on worsening oxygenation and systemic signs of infection.[14] Remarkably, this new approach includes an algorithm which excludes the use of chest radiography. Instead of merely considering VAP versus non VAP, the newer guidelines categorizes patients into three groups—

1. Patients with ventilator-associated complications (VAC). These patients are far more sick than those who do not have VAC.
2. Those with infection-related ventilator-associated complications.
3. Patients with probable versus possible ventilator associated pneumonia.[14] These groups represent patients at various stages in the above spectrum.

The basic features of each of these groups are summarized in Table 3.

Certain questions need to be answered with regard to these new definitions and guidelines. Do these guidelines add greater clarity on our concept of VAP? Do they help improve the management of VAP? If chest radiography is excluded would not one miss a stable VAP which does not significantly alter gas exchange?

Finally, VAC are not always due to infection and the incidence of VAC may not be reduced by measures at VAP prevention. The relation of the quality of patient care to the incidence of VAC is unproven.

We need to wait to see how necessary and useful these new guidelines are, before we set older CDC guidelines of pneumonia and VAP aside.

When considering the older CDC guidelines on nosocomial pneumonia and VAP, it is apparent from the earlier discussion that though clinical features combined with radiological findings are of help, they lack sufficient specificity in the diagnosis of nosocomial and VAP. Bacteriological evidence of pulmonary parenchymal infection is therefore also considered necessary to make a firm diagnosis. The cost-effectiveness of different methods used to obtain this bacteriological evidence and the relation of the evidence obtained to ultimate patient management and patient outcome are matters of continued discussion. These methods are briefly discussed below.

BACTERIOLOGICAL DIAGNOSIS

Noninvasive Modalities

Examination of Expectorated Sputum

Microscopic Examination

This is useful in determining the presence and at times the site of infection (upper airways, lung parenchyma).

Table 3: Newer streamlined surveillance definitions and guidelines

Ventilator associated complication (VAC)	*Any one of the following criteria*	
	Minimum daily FiO_2 increases by 0.2 over baseline and persists for >2 days	Minimum daily PEEP increases by >3 cm H_2O over baseline and persists for >2 days
Infection-related ventilator associated complication	*Includes both the features given below*	
	Temperature >38°C or	A new antibiotic started and continued >4 days
	WBC >12000 or <4000 mm^3	
Possible VAP	*After 3rd day of ventilation and within 2 days of worsening oxygenation, any one of the following criteria is met*	
	Purulent tracheobronchial secretions showing >25 neutrophils and <10 squamous epithelial cells per low power field	Positive culture of sputum/endotracheal aspirate/BAL/ lung tissue or protected specimen brushing (PSB)
Probable VAP	*After 3rd day of ventilation and within 2 days of worsening oxygenation, any one of the following criteria is met*	
	Purulent respiratory secretions from one or more specimen collections and one of the following— 1. Positive culture of endotrcheal aspirate >10^5 CFU/mL or Positive culture of BAL >10^4 CFU/mL or Positive culture of lung tissue >10^4 CFU/mL or Positive culture of PSB >10^3 CFU/mL	One of the following without the need for purulent respiratory secretions— 1.Positive pleural fluid culture (specimen obtained following thoracocentesis or initial placement of ICD only) or positive lung tissue histopathology or positive serology for common viral infections like adeno, RSV and influenza

Leukocytes

More than 25 leukocytes per low power field denote infection, but not necessarily pneumonia. Marino[15] stresses the importance of using the presence of epithelial cells of the oral cavity in a sputum sample as markers of the mouth and upper airways, while alveolar macrophages and elastin fibers are used as markers of the distal airspaces and lung parenchyma respectively. The epithelial cells of the oral cavity are large flattened cells with abundant cytoplasm, and if a sputum sample contains many such epithelial cells, it is not suitable for further examination or culture. On the other hand, alveolar macrophages inhabit only distal airspaces so that their presence denotes that at least a part of the specimen being examined is from the lower respiratory tract. The presence of elastin fibers in the sputum sample is often used as evidence in favor of a necrotizing pneumonia. These fibers are filamentous structures visualized by placing a drop of KOH over the sputum sample. When present, the elastin fibers appear as clumps of interlocking filaments and denote a destructive parenchymal lesion within the lungs.

Sputum culture

It is always necessary to screen sputum samples before doing cultures. Only samples that represent secretions from the respiratory tract (and not from the oropharynx) are suitable for culture.

Endotracheal Aspirates

The noninvasive method of obtaining respiratory secretions for culture and antibiotic sensitivity is through aspiration of endotracheal secretions with a suction catheter either through the endotracheal tube or a tracheostomy tube.

Given below are the methods by which cultures (followed by antibiotic sensitivity reports) can be processed—

1. Qualitative Culture

This is the simplest and easiest to perform and is the usual method followed in developing countries. It is however worth stressing that qualitative cultures of endotracheal aspirates in a suspected VAP may give rise to a number of false positive results (mainly Gram-negative bacilli) and may lead to the over-diagnosis of pneumonia and a misdiagnosis of its cause. Qualitative cultures of endotracheal secretions have a high sensitivity and a low specificity. In patients with pneumonia documented by histopathological examination, the endotracheal aspirate sensitivity was 82% and the specificity only 27%.

Another feature of clinical significance is that secretions aspirated from an endotracheal or a tracheostomy tube which has been in place for 5–7 days often grow Gram-negative organisms (including *P. aeruginosa*) on a qualitative culture because of colonization of the trachea by these bacteria. A positive tracheal qualitative culture therefore does not necessarily indicate infection or pneumonia nor does it necessarily indicate the organism responsible for the pneumonia, if pneumonia is indeed present. The difficulties in interpreting results of qualitative cultures of tracheal aspirates in relation to a possible VAP make one wonder as to how cost-effective these cultures are and how frequently they should be ordered in poor developing countries.

Yet qualitative cultures continue to be performed in most ICUs of poor developing countries when there is a suspicion of a nosocomial pneumonia (including VAP).

The reasons given for this persistence are listed below—

- The diagnostic test is noninvasive, cheap and requires no expertise compared to invasive testing. Even a junior nurse can perform an aspiration procedure at the bedside.

- Qualitative cultures of tracheal aspirates usually identify pathogenic organisms also found by invasive tests. They therefore have a high sensitivity. They however frequently identify nonpathogenic organisms, reducing the specificity and predictive value of the test.[16]
- Most importantly, if cultures are negative for pathogenic bacteria, VAP is very unlikely, unless the patient has received antibiotics prior to the culture test.
- As will be discussed later, a Cochrane meta-analysis suggests that there is no difference between qualitative and quantitative cultures with regard to the final outcome in VAP.

The practical management of a patient with nosocomial VAP may be influenced by tracheal aspirate (qualitative) culture sensitivity tests under the following circumstances—

- If there is an absence of response to empiric antibiotic therapy, a culture sensitivity test of the tracheal aspirate may help in the correct choice of antibiotics.
- If cultures of respiratory tract secretions grow *Staphylococci,* in a unit where this organism is uncommonly found, an appropriate antibiotic against this organism should be used, rather than the usual antibiotic combination against Gram-negative organisms.

2. Quantitative and Semiquantitative Cultures of Endotracheal Aspirates

These methods are being increasingly used to improve the specificity of endotracheal aspirate cultures.

Semiquantitative cultures are done by plating. It is technically easy and many microbiological laboratories in India use this technique.

Quantitative cultures are technically more difficult, laborious and at least in India are generally reserved for research purposes. They have no significant advantage over semiquantitative cultures.

If clinical features lend strong suspicion to the diagnosis of VAP, a culture yielding 10^6 or greater concentration of organisms on the quantitative test supports the diagnosis of nosocomial pneumonia. When quantitative cultures are performed on endotracheal aspirates, the sensitivity falls but specificity increases when compared to qualitative cultures of endotracheal secretions.[16]

Invasive Methods[5]

Role of PSB Sampling

Samples of lower respiratory tract secretions can be collected by special protected brushes through a fiberoptic bronchoscope (PSB sampling). The brush is housed in a catheter that is plugged at the distal end. The protective housing allows the catheter to be advanced through a bronchoscope without coming into contact with the upper airways. Brushings should be obtained from the area of abnormal radiological shadows observed on the X-ray chest. The material should be stained by Gram stain and cultured qualitatively and quantitatively. A culture yielding 10^3/mL or greater concentration of organisms supports the diagnosis of nosocomial pneumonia and identifies the pathogen.[17] The sensitivity for PSB tests ranges from 33% to 100%, with a median of 67%, and the specificity ranges from 50% to 100% with a median of 95%. PSB sampling therefore offers greater specificity and lesser sensitivity in the diagnosis of nosocomial pneumonia.

Bronchoscopic procedures even when performed expertly carry a risk to critically ill patients on ventilator support. The main complication is hypoxia during the procedure; this could lead to hypotension, arrhythmias and even death. Hypoxia may persist for several hours after the procedure, particularly in patients with ARDS.

Role of BAL

Bronchoscopic alveolar lavage has also been used in the diagnosis of VAP. The sensitivity of quantitative BAL fluid cultures ranges from 42% to 93% with a mean of 73%. For quantitative cultures, a CFU (colony forming units) count/mL of 10^4 is considered a positive result. The specificity ranges from 45% to 100% with a mean of 82%.

Role of Blinded Invasive Procedures

The risk and expense entailed in bronchoscopic procedures has led to the development of other tests requiring less expense, expertise and risk. These tests include the following non-bronchoscopic techniques: blinded bronchial sampling (BBS), mini-BAL, blinded sampling with PSB (BPSB). The sensitivity and specificity are reported to be similar to bronchoscopic techniques.

Positive Blood Culture, Positive Culture of a Pleural Exudate

In a patient with clinical and radiological features compatible with nosocomial pneumonia, a positive blood culture is generally a pointer to the nature of the organism causing the infection. However, a patient could develop nosocomial pneumonia, for example by aspiration of infected oropharyngeal secretions and also have a separate bloodstream infection from an intravascular device such as the central venous catheter (CVC). On the other hand, cultures of an organism from a tapped pleural exudate are certain specific bacteriological evidence of nosocomial pneumonia. Unfortunately, pleural effusions or empyemas are infrequent and blood cultures come positive only in a small minority of patients with nosocomial pneumonia.

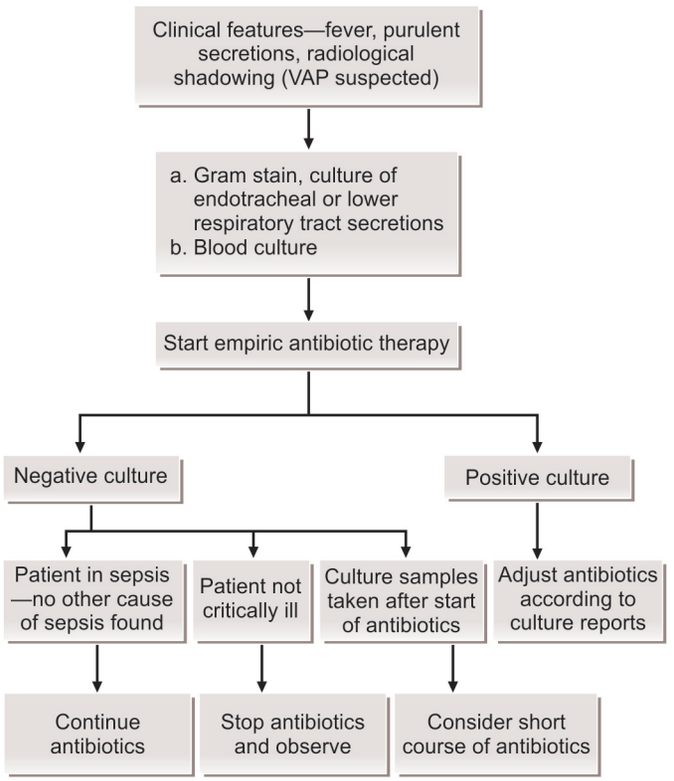
Summary of a diagnostic strategy for a hospital-acquired pneumonia (including VAP) is given in Flowchart 2.

Evaluation of Diagnostic Strategies

Are invasive strategies for culture of lower respiratory tract secretions superior to noninvasive strategies for culture of tracheobronchial secrections?

- There have been four randomized controlled trials[18-21] studying the impact of invasive versus noninvasive strategies on ultimate outcome (mortality), antibiotic

Flowchart 2: Algorithm for the clinical approach to hospital-acquired pneumonia [including ventilator-associated pneumonia (VAP)]



Clinical features—fever, purulent secretions, radiological shadowing (VAP suspected)
a. Gram stain, culture of endotracheal or lower respiratory tract secretions
b. Blood culture
Start empiric antibiotic therapy
Negative culture
Positive culture
Patient in sepsis—no other cause of sepsis found
Patient not critically ill
Culture samples taken after start of antibiotics
Adjust antibiotics according to culture reports
Continue antibiotics
Stop antibiotics and observe
Consider short course of antibiotics

use in patients with clinical suspicion of nosocomial pneumonia. There was no difference in outcome between an invasive strategy (PSB and/or BAL) versus a non-invasive strategy (quantitative endotracheal aspirate culture).

- One larger trial[21] however showed a small reduction in mortality, and morbidity using an invasive strategy (PSB or BAL), as also better sequential organ failure assessment (SOFA) scores and lesser use of antibiotics. This study however compared invasive strategy with a qualitative culture of tracheal aspirates and could not be strictly compared with the other trials.
- Most importantly, Shorr et al.[22] reported on a meta-analysis of pooled data from these randomized studies on 628 patients and observed that the invasive approach did not alter mortality. Invasive testing was however associated with improved antibiotic utilization, or offered a change of antibiotic therapy after sampling.

It is strongly recommended that cultures within the respiratory tract (either invasive or noninvasive sampling) should be sent before starting a new antibiotic or before changing a previous antibiotic regime. If this is not done false negative tests are likely to result.

It would appear from the preceding discussion that quantitative cultures of endotracheal aspirates being more specific are to be preferred to qualitative cultures. This concept though sound in theory, is not necessarily true in practice. Results of a study on qualitative versus quantitative cultures of respiratory secretions for clinical outcomes in patients with VAP are summarized below.[23]

Meta-analysis of five randomized controlled trials (RCTs) with 1,367 patients revealed the following—

- Quantitative cultures did not score over qualitative cultures to reduce mortality among patients with VAP.
- There was no evidence to show that the use of quantitative cultures resulted in a higher rate of antibiotic change, reduction in ICU stay, reduced time on ventilator support, compared to the use of qualitative cultures.
- Mortality was reduced by the use of prompt appropriate microbial agents from the beginning of the therapy.
- The knowledge of local microorganism patterns is important in reducing morbidity and mortality due to VAP.

The evidence present in the above study suggests that (1) invasive modalities for culture of lower respiratory tract secretion are not clearly superior to noninvasive methods for culture of endotracheal secretions; (2) quantitative cultures have no advantage over qualitative cultures in reducing morbidity and mortality in VAP.

In conclusion, the diagnosis of nosocomial pneumonia should be based on an overall perspective of clinical, radiological and bacteriological findings. There is no diagnostic criterion or procedure that serves as a gold standard for the diagnosis of nosocomial (including VAP) pneumonia. There is no definite scientific evidence, or for that matter, expert consensus, to show that antibiotic treatment based on bacteriological examination and cultures of lower respiratory secretions via invasive (special bronchoscopic or other) procedures is superior to empiric treatment aided by culture sensitivity reports on sputum or on tracheal secretions aspirated through a tracheotomy or endotracheal tube.[17-21] Currently, it also cannot be maintained that use of quantitative cultures of endotracheal secretions helps to improve ultimate outcome when compared to qualitative cultures of endotracheal secretions.

The only concession in favor of bronchoscopic diagnostic procedures is that specificity in diagnosis is improved, and perhaps the unnecessary use of antibiotics is avoided for clinically insignificant organisms or in situations where smears and cultures are negative. However, patient outcome has not been altered for the better by the use of diagnostic invasive bronchoscopic or BAL procedures. *In poor developing countries, where cost is important, expertise limited, and when present, not easily available, it is therefore justifiable to treat nosocomial pneumonia (suspected on clinical and radiological evidence) empirically with a suitable planned antibiotic regime. Culture sensitivity of endotracheal secretions in VAP prior to the use of antibiotics is advised.*

Where expense is not in question and the expertise good and available, bronchoscopic BAL or protected BAL, or protected brush specimens are stained and cultured to guide treatment. This option in our opinion is of use only if performed before starting antibiotics. Its efficacy is reduced, if the patient

has already been receiving antibiotics. In any case, empiric therapy with antibiotics should commence promptly after the bronchoscopic procedure. *Treatment should never await culture reports.* A positive Gram stain could however guide initial treatment. Treatment could be later modified, based on culture sensitivity reports.

In our unit, we use empiric antibiotic therapy for nosocomial pneumonia. Bacteriologic examination of tracheal aspirates by semiquantitative culture is done routinely before starting empiric antibiotic therapy, but it is a moot point as to what extent this helps management and patient outcome. We use PSB sampling to obtain more specific bacteriological evidence if a patient on empiric therapy fails to improve. The PSB sampling is done before changing the antibiotic regime. Again, it is doubtful if this protocol influences patient outcome. *Invasive sampling of lower respiratory secretions in nosocomial pneumonia (including VAP) is advised in immunocompromised patients where infection due to opportunistic organisms is a strong possibility. Opportunistic infection is often missed if non-invasive sampling is performed.*

ANTIBIOTIC THERAPY IN NOSOCOMIAL PNEUMONIAS

Though antibiotic therapy to start with is empiric, the selection of antibiotic therapy for each patient should depend on—

- A knowledge and awareness of the prevalence of core organisms and their sensitivity to various antibiotics in a particular ICU setup.
- Clinical background, in particular, the presence of risk factors for MDR pathogens.
- Time of onset of the VAP.
- Whether the patient had received antibiotics prior to the onset of pneumonia.

Awareness of the Prevalence of Core Organisms in a Particular Unit and Their Sensitivity to Different Antibiotics

Core organisms responsible for nosocomial infection in units all over the world are predominantly Gram-negative bacteria. It is the exact prevalence of different Gram-negative organisms and their varying sensitivity to antibiotics that is important. This prevalence and sensitivity to antibiotics may vary from unit to unit. Also, prevalence and sensitivity patterns may vary in the same unit from time to time. A bacteriologic surveillance in every ICU is therefore of crucial importance, and the awareness of the nature of organisms generally responsible for VAP in a unit is of help in choosing appropriate antibiotic therapy.

It needs to be repeatedly stressed that there is a marked increase in the incidence of extended spectrum beta lactamase (ESBL) Gram-negative organisms in many ICUs all over India, particularly in the large metropolitan cities of the country. This is largely due to a lack of antibiotic policy in most ICUs all over the country.

Box 3: Important risk factors for multiple drug resistance (MDR) pathogens

- Antibiotic therapy within the past 90 days
- Current hospitalization of 5 days or more
- Marked severity of the critical illness
- High frequency of antibiotic resistant organisms
- Immunocompromised patients
- Patients with comorbid states
- Multiple invasive procedures

Box 4: Clinical features of severe nosocomial pneumonia

One or more of the features listed below—

- Respiratory failure
- Rapid radiographic progression
- Severe sepsis with hypotension and/or multiorgan failure
- Acute renal failure requiring dialysis

Clinical Background[5,24]

- The feature which is of utmost importance is to determine the presence or absence of risk factors for MDR pathogens. Important risk factors for MDR pathogens are antibiotic therapy within the past 90 days, current hospitalization of 5 days or more, and a high frequency of antibiotic resistant organisms in a particular ICU or hospital. Other risk factors include immunosuppressed patients, patients with comorbid states, in particular, severe chronic obstructive pulmonary disease (COPD). Risk factors for MDR pathogens are listed in Box 3.
- *The severity of the VAP whether mild to moderate or severe* Severe nosocomial pneumonia is characterized by one or more of the following features—respiratory failure, rapid radiographic progression, severe sepsis with hypotension and/or multiorgan failure, acute renal failure requiring dialysis (Box 4).
- In VAP, the time of onset of nosocomial pneumonia—whether early onset or late onset helps guide the nature of empiric therapy.

Use of Antibiotic Therapy Prior to the Onset of VAP

- This factor if present further guides the nature of empiric therapy.
- Principles in treatment strategy in VAP and factors contributing to treatment strategy are listed in Boxes 5 and 6.

In patients with early onset VAP who have not received antibiotic therapy, the etiological bacteria often found are *Enterobacteriaceae*, *Haemophilus sp*, or *S. pneumonia*. Monotherapy with a third generation cephalosporin with no anti-pseudomonal activity (e.g. cefotaxime or ceftriaxone), or the use of clavulinic acid with amoxicillin is appropriate in these patients for about 7 days (Table 4).

In contrast, VAP occurring in patients after prolonged ventilator support (late onset) and after prolonged use of

Box 5: Principles in treatment strategy in VAP

In a suspected VAP—
- Promptly start empiric antibiotic therapy after—
  - Sending respiratory secretions (collected by whichever method) for culture antibiotic sensitivity and Gram stain (see text)
  - Blood culture
- Avoid repeating the same antibiotic class if patient has received it in the past two weeks
- Subsequent modification of antibiotic regime as per culture sensitivity
- Persevere with the same antibiotic regime if there is a good clinical response even if this is contrary to culture reports
- Avoid prolonged use of antibiotics
- Consider de-escalation of therapy in appropriate cases
- Stop antibiotics if no growth reported—unless the patient has severe sepsis and no other cause for sepsis is evident

Box 6: Factors contributing to treatment strategies

- Prevalent microbes and their sensitivity in a particular ICU
- Presence or absence of risk factors
- Previous antimicrobial therapy
- Clinical severity
- Time of onset after mechanical ventilation
- Results of culture sensitivity of lower respiratory tract secretions or endotracheal aspirates
- Clinical response

Table 4: Initial empiric antibiotic therapy in nosocomial and VAP of early onset with no risk factors for MDR organisms

Probable organisms	*Recommended antibiotic (any one of the following may be used)*
S. pneumoniae *Haemophilus influenzae*	Ceftriaxone or Amoxicillin-clavulanic acid
Enterobacteriaceae	Piperacillin + Tazobactum

Table 5: Initial empiric therapy for nosocomial or ventilator associated pneumonia of late onset or with risk factors for MDR infection and any degree of severity

Probable organisms	*Recommended antibiotic*
Enterobacteriaceae *Ps. aeruginosa* *Acinetobacter baumannii* Other Gram-negative bacilli	Cefepime or Piperacillin-tazobactam or Carbapenem (Imipenem/Meropenem)

1. The choice of the antibiotic among those listed will depend on the prevalence of the organisms and their sensitivity in a particular unit and also the severity of the disease.
2. Empiric therapy in severe nosocomial pneumonia or when MDR organisms are suspected should include two or more antibiotics, not to prevent resistance for which there is also no convincing evidence, but to provide a wide coverage for all likely infecting organisms.
3. For a wide spectrum coverage of Gram-positive and Gram-negative organisms, a combination like Piperacillin-tazobactam + vancomycin/teicoplanin OR a carbapenem + vancomycin/teicoplanin is recommended.
4. In case of MDR pseudomonas or acinetobacter, add colistin to any of the above antibiotics, preferably to a carbapenem for maximum synergistic activity.
5. If MRSA is suspected in the unit, add vancomycin to the above antibiotics.

antibiotics is often caused by multi-resistant pathogens such as *P. aeruginosa*, *Acinetobacter spp.*, Klebsiella or methicillin-resistant *Staphylococcus aureus* (MRSA). The appropriate antibiotic choice should be one which acts against ESBL producing Gram-negative organisms and against Pseudomonas (piperacillin/tazobactum or carbapenems). Vancomycin may be added if a staphylococcal infection is suspected (Table 5).

In patients with early onset VAP who have received antibiotics, Gram-negative organisms (*P. aeruginosa* and/or other Gram-negative core organisms), as also *Streptococci spp.* and *H. influenzae* are often responsible for the infection.

Finally, in late onset pneumonia occurring without antibiotic use during 15 days prior to infection, Enterobactericeae, Pseudomonas or Acinetobacter and MRSA are often causative agents.

In both the above groups, i.e. early onset with previous antibiotic therapy and late onset without antibiotic therapy, an appropriate antibiotic choice would be a combination of an anti-Pseudomonal β-lactam with Vancomycin to cover MRSA. If nosocomial pneumonia is thought to result from aspiration of stomach contents, or if there is any other reason to suspect anaerobic infection, metronidazole or clindamycin should be added to the antibiotic regime.

Information obtained from Gram stain of respiratory secretions can guide empiric antibiotic therapy The presence of chiefly Gram-positive bacteria should direct treatment towards *Staphylococcus*, *Streptococcus*, and *Pneumococcus*. The morphology of stained organisms is also of help in identification. Predominant Gram-negative bacilli direct an appropriate choice of antibiotics. Empiric therapy should start promptly without awaiting culture reports.

Information obtained from culture sensitivity reports Though both sensitivity and specificity in identification of the etiological agent in nosocomial pneumonia leave much to be desired, the culture report may be valuable in patient management, particularly if the empiric therapy decided upon does not prove beneficial.

Table 6: Recommended dosage of antibiotics for initial empiric treatment

Antibiotic	*Dose (IV)*	*Infusion time*
Ceftriaxone	2 gm 12 hourly	½–1 hour
Cefotaxime	2 gm 6 hourly	½–1 hour
Ceftazidime	2 gm 8 hourly or 12 hourly	2–3 hours
Cefepime	1–2 gm 8 hourly	2–3 hours
Imipenem	1 gm 8 hourly	1 hour
Meropenem	1 gm 8 hourly	3 hours
Piperacillin tazobactam	4.5 gm 6–8 hourly	3 hours
Amikacin	750 mg	Over 20 minutes
Vancomycin	1 gm 12 hourly	3 hours
Linezolid	600 mg 12 hourly	1 hour
Ciprofloxacin	400 mg 8 hourly	1 hour

Abbreviation: IV, intravenous.

Follow-up of Nosocomial Pneumonia after Initiating Empiric Therapy

Once culture sensitivity results are obtained, the antibiotic regime should be adjusted as per the microbiological results. If the organism is resistant to one of the two antibiotics in use it should be omitted. In critically ill patients another antibiotic which acts against the organism may be substituted for the one omitted. The recommendation to omit aminoglycosides after the first 4 days depends on the gravity of the clinical condition. Monotherapy may be justified in patients who show well marked improvement within 4 days (Table 6).

Duration of Therapy

A large prospective multicenter trial[25] which compared the efficacy of 8 days to 15 days duration of antibiotic therapy in VAP concluded that an 8-day regimen resulted in reduced antibiotic use, and a decrease in the emergence of multi-resistant bacteria when compared to the 15-day regime, without altering the prognosis. It must be remembered that the above is a study on a large group and is not necessarily applicable to an individual patient. Each patient must be considered in relation to several factors which may be applicable to him or her. It is impossible to stop treatment after 7 days or even 15 days in severe *P. aeruginosa* or *Acinetobacter spp.* infections. It is often necessary to continue treatment for several weeks if there is evidence of breakdown of lung tissue with one or more abscesses or in presence of an empyema or in the presence of persistent intra-abdominal sepsis.

If however a sharp clinical improvement occurs within the first 3–4 days of therapy, if PaO_2 and oxygen requirement improve significantly and inflammatory markers [C-reactive protein (CRP)] sharply decline, antibiotics could be withdrawn safely after 7–10 days.

Lack of Response to Antimicrobial Therapy

There are several reasons for a lack of response to antibiotic therapy. These include a wrong diagnosis of pneumonia, or lack of specific antibiotic coverage against the causative organism. At times though the choice of antibiotic therapy is correct, persistence of the etiological agent leads to a persistent or worsening pneumonia. Persistence of the offending microorganism may be due to several factors; an important cause is inappropriate dosing regime.

Superinfection pneumonia is a serious problem that often causes death. Superinfection follows prolonged broad-spectrum antibiotic therapy. Organisms causing superinfection are generally drug-resistant and therefore lethal. They include resistant strains of Pseudomonas and other Gram-negative bacteria, MRSA, *Enterococci*, fungi and MDR *Enterobacteriaceae*.

Nosocomial pneumonia when severe can lead to multi-organ dysfunction and/or septic shock, situations where the mortality is high in spite of adequate antibiotic therapy.

PROGNOSIS AND MORTALITY[26,27]

Nosocomial pneumonia is the leading cause of death due to hospital-acquired infections. Mortality rate ranges from 20% to 70%. High-risk organisms that lead to increased mortality include *P. aeruginosa*, *Acinetobacter spp.*, *Enterobacter spp.*, other Gram-negative organisms, *S. faecalis, S. aureus, Candida* species, *Aspergillus spp.* and polymicrobial infections. The development of VAP is accompanied by a 1.8–4 fold increase in the risk of death. A French study[26] noted that mortality was inversely related to adequacy of the initial empiric antibiotic therapy. Luna and colleagues[27] found an overall mortality of 52.6% in 76 mechanically ventilated patients with bacteriologically confirmed VAP if the choice of the initial antibiotic therapy was not appropriate and there was a delay in the start of therapy. *Substituting a correct antibiotic cover after culture sensitivity reports are available does not reduce mortality if the initial empiric therapy has been inadequate.*

It must be however remembered that nosocomial pneumonia is more common in patients who are critically ill with multiple problems. To what extent death can be attributable to nosocomial pneumonia per se may be impossible to judge. *It is likely that many critically ill patients die with pneumonia rather than die of pneumonia.*

Death in nosocomial pneumonia can result from any one or more of the following—septic shock, multiple organ dysfunction, ARDS, cardiovascular instability, GI bleed. In VAP, it could also be occasionally related to pneumothorax or other forms of barotrauma.

Ventilator-Associated Tracheobronchitis (VAT)

Not all ventilator associated pulmonary infections constitute pneumonia. They could take the form of a tracheobronchitis characterized by the presence of purulent secretions without any parenchymal involvement. The frequency of VAT is less than VAP, but VAT often progresses to VAP. The microbiology of VAT is the same as VAP and can include MDR organisms. Systemic antimicrobial therapy is indicated in VAT.

Box 7: Prevention of nosocomial pneumonia

- Implementation of educational programs for caregivers and frequent performance feedbacks and compliance assessment
- Strict alcohol-based hand hygiene
- Avoidance of tracheal intubation and use of NIV when indicated
- Daily sedation vacation and implementation of weaning protocols
- No ventilator circuit tube changes unless the circuit is soiled or damaged
- Aspiration of subglottic secretions
- Oral care with chlorhexidine
- Avoid stress ulcer prophylaxis in very low-risk patients for gastrointestinal bleed, and consider use of sucralfate when indicated
- Semi-recumbent patient positioning
- Postpyloric feeding in patients who have impaired gastric emptying

Abbreviation: NIV, noninvasive ventilation.

Aerosolized therapy with antibiotics (notably gentamycin) perhaps prevents the occurrence of VAP.

PREVENTION OF NOSOCOMIAL PNEUMONIA (BOX 7)

Effective measures to prevent nosocomial pneumonia would reduce the incidence of a disease which is associated with a high morbidity and mortality. The Institute for Healthcare has recommended that infection control measures of proven efficacy should be grouped and implemented as a bundle rather than being implemented individually. This policy has led to better outcome; significant reductions in the incidence of VAP have been reported following the implementation of VAP preventive bundles.[28]

General Prophylactic Measures

General prophylactic measures play an important role. These in brief include—

- Educating all ICU personnel including residents on various aspects of VAP and on the preventive strategies that reduce its incidence. It is important to constantly maintain this high level of education and ensure that there is perfect compliance in relation to execution of preventive strategies.
- *Handwashing* The World Health Organization (WHO) considers alcohol-based hand disinfection as the single most important strategy to prevent healthcare associated infection[29] and most studies carried out in ICUs have confirmed the marked reduction of nosocomial infection if alcohol based hand hygiene is religiously implemented.
- *Daily Interruption of Sedation* Daily interruption of sedation avoids constant and continuous impairment of respiratory defense mechanisms. It should be practised as a general rule with very few exceptions. Avoidance or a sparing use of neuroparalytic agents has also been recommended.
- Both tracheal intubation and mechanical ventilator support predispose to VAP and the longer the period these interventions are in place the greater the incidence of VAP. As a corollary the patient should be weaned off support and extubated as soon as it is safe to do so. There are a number of intensivists who opine that protocol-driven weaning procedures help early extubation. Yet there are some intensivists who opine that early extubation compatible with good patient outcome and safety may also be achieved without following rigid protocols.
- Noninvasive ventilation has the advantage of obviating the use of an endotracheal tube. The risk of nosocomial pneumonia is thereby reduced. Noninvasive ventilation is particularly useful in acute exacerbations of COPD causing acute respiratory failure, and in respiratory failure due to pulmonary infection in immunocompromised individuals.
- *Improved Design of Tracheal Tube Cuff* Improved design and special material in tracheal tube cuffs have been put into practice with a view to reduce the likelihood of aspiration of infected secretions across the cuff. The new material used for tracheal cuffs include polyurethane, silicone and latex.
  Before the tracheal tube cuff is deflated, it is important to aspirate secretions in the oropharynx. It is equally important to aspirate tracheal secretions through the tracheostomy tube no sooner than when the cuff is deflated.
  Coating the internal surface of the endotracheal tube with antimicrobial agents such as silver has been proposed to prevent biofilm formation within the tube. This is a theoretically sound innovation but we have no experience of its use.
- *Aspiration of Subglottic Secretions* Subglottic secretions are often colonized and aspiration of colonized secretions through colonized endotracheal tubes reduces hydrostatic pressure above the cuff and prevents leakage of infected supraglottic secretions across the cuff. Aspiration could be through continuous or intermittent suction. Current evidence recommends intermittent suction every 4–6 hours over continuous suction, in order to avoid the potential risk of tracheal injury.
- *Endotracheal Tube versus Tracheostomy* Opinions and practices vary in different ICUs. We have always encountered an increased frequency of complications if an endotracheal tube remains in situ for over 10 days. We replace it with a tracheostomy. In patients with voluminous tracheobronchial secretions effective suction through an endotracheal tube is often not very effective. In these patients a tracheostomy is advised as it allows better suction, less retained secretions and less chances of areas of infected atelectasis.
- *Management of Ventilator Circuits* Ventilator circuit changes should not be made frequently. It is recommended that heated humidifiers be replaced by heat and

moisture exchangers as the former are more likely to be contaminated with microorganisms.

Closed tracheal suction systems have no advantage over open suction. In fact, in patients with excess tracheobronchial secretions, closed system suction is ineffective and is likely to lead to an increased chance of infection.[30]

- ❑ *Use of Propped up or Semi-recumbent Position* The patient is best kept with the head of the bed at an angle of 45°. A randomized trial[31] showed a decrease in the incidence of VAP with patients ventilated in a semi-recumbent position compared to patients ventilated in the supine position. This is a simple but important preventive measure against VAP.

Stress Ulcer Prophylaxis

The general consensus is that prophylaxis of stress ulcers should be provided by the use of sucralfate as this does not raise the pH of gastric contents. H_2 receptor antagonists and proton pump inhibitors raise the pH of gastric contents and thereby promote increased colonization within the stomach. Aspiration of colonized gastric contents into the respiratory tract can lead to nosocomial pneumonia.

Enteral feeding has been considered a risk factor for nosocomial pneumonia because of increased risk of alkalization of gastric contents, and aspiration of gastric contents. Yet it is unquestionably preferred to IV alimentation which poses a greater risk for bloodstream infection.

Many critically ill patients have delayed gastric emptying. Placing the feeding tube beyond the pylorus reduces but does not obviate the risk of aspiration nosocomial pneumonia.

13

Care over Orophyngeal Secretions

Oropharyngeal secretions in critically ill patients in the ICU are invariably colonized by pathogenic Gram-negative bacteria which could be aspirated into the lungs. Use of 2% chlorhexidine to clean the oropharynx is a simple but important method to reduce the incidence of aspiration pneumonia. This should be done frequently in all patients and is of particular importance in patients with poor oral and dental hygiene.

Gastric Decontamination

Selective decontamination of the GI tract has been used for many years as a preventive strategy for nosocomial pneumonia. Antibiotics used are non-absorbable—tobramycin, polymyxin, amphotericin B; they are introduced through the nasogastric tube into the stomach in order to prevent gastric colonization with Gram-negative and *Candida spp.*, while preserving the anaerobic flora. Gastric decontamination as a prophylactic measure against nosocomial pneumonia is often used in the ICUs in Europe. The potential risk of breeding antibiotic resistant organisms is genuine and results of randomized trials remain controversial.

General Patient Care

Patients should be turned frequently; physiotherapy to the chest, deep breathing, increased mobility in bed, all help to prevent atelectasis and infection. Meticulous asepsis should be observed during suction of tracheal secretions.

INTRAVASCULAR CATHETER-ASSOCIATED BLOODSTREAM INFECTIONS

Central venous catheters (CVC), Swan-Ganz catheters and intra-arterial catheters are frequently used in the monitoring and management of patients in the ICU. These catheters provide for the infusion of fluids and electrolytes, for the infusion of antimicrobial agents, for short-term hyperalimentation and for hemodynamic monitoring in critically ill individuals.

Besides the use of CVCs, which provide direct access to the large veins in the chest, teflon or other synthetic short catheters are often inserted into peripheral veins for the infusion of fluids and the intravenous administration of drugs and into an artery for monitoring arterial blood pressure. The intravenous and intra-arterial access provided in ICU patients by catheters for purposes stated above is for a short-term period. They are ordinarily removed as soon as the critical phase of the patient's illness is over.

Central venous catheters used over a long period are of the Hickman type. These are used primarily for the administration of chemotherapy, and for total parenteral nutrition that needs to be continued for weeks or even months. Long-term catheters have a subcutaneous tunnel through which the catheter passes after entering the skin, before entering a large central vein.

Though gaining vascular access is often a necessary and essential feature of critical care, it is associated with a substantial risk of iatrogenic bloodstream infection (BSI) originating from infection of the percutaneous intravascular device (IVD), used for vascular access—IVD related (IVD-R) BSI. This is often referred to as line sepsis.

Intravascular devices are responsible for close to 60% of all bacteremias,[1] and studies performed a decade ago showed that IVD-R BSIs are associated with an increased mortality ranging up to 35%.[2] IVD related BSIs are also responsible for increased length of hospital stay and increased costs.[2,3]

The goal of the intensivist is to promptly diagnose and effectively treat these infections. Equally and perhaps more importantly, it is crucial to prevent them. Based on epidemiological research and on increasing knowledge of the pathogenesis of device-related BSI, guidelines for prevention have been formulated.

A central line associated BSI is defined as an infection related to a central line that has been in situ 48 hours prior to the development of the BSI. It is not considered to be secondary to other sources or sites of infection.

PATHOGENESIS

An intravascular device associated BSI can result from one or more of the three sources listed below—

1. Colonization of the IVD, resulting in a catheter-related infection.
2. Infection of the fluid infused through the IVD, i.e. through the catheter.[4]
3. To produce a catheter-related infection microorganisms must gain access to its extraluminal or intraluminal surface. Three possible mechanisms are involved for this to come about—
   a. Skin organisms gain access to the percutaneous tract, possibly by capillary action and colonize the external surface of the catheter.
   b. Microorganisms contaminate the catheter hub and lumen when the catheter is inserted over a guidewire or is then manipulated. The catheter hub and lumen may also be contaminated by an unsterile infusate.
   c. The catheter tip or body or both may be seeded by microorganisms originating from a distant source (e.g. intra-abdominal sepsis, pneumonia).

This seeding could either be a mere colonization of the catheter tip, or it could be the source of secondary sepsis and septicemia. Hematogenous seeding of the catheter tip is common in patients with severe abdominal sepsis (e.g. septic peritonitis) even in the presence of negative blood cultures. More often than not, this merely represents colonization of the catheter tip rather than a catheter-related sepsis. Seeding of the catheter tip could also occur from organisms which gain entry into the bloodstream through the gastrointestinal tract. This translocation of bacteria from the gut into the bloodstream occurs when there is an overgrowth of pathogenic bacteria in the gut. This is observed in critically ill individuals, particularly in patients whose gastric acidity is sharply reduced by H_2 antagonists and antacids. In many such very ill patients the mucosal barrier of the gut is devitalized or has small breaks which allow the overgrowing bacterial flora to enter the blood stream.

Once the catheter is contaminated and colonized either extraluminally or intraluminally, the microorganism becomes incorporated into a biofilm that leads to persistent infection and hematogenous dissemination.[5] A biofilm is a complex matrix consisting of polysaccharides, proteins and nucleic acid which are derived from both the host and microorganisms. The microorganisms are encased in this biofilm and are therefore less susceptible to antimicrobials and host immune responses.[6,7]

Peripheral IV catheters, arterial catheters, non-tunneled central line catheters are IVDs generally used for a short period of time—less than 10 days. Bloodstream infections related to these are usually due to microorganisms gaining access to the extraluminal surface of the catheter through the skin site of insertion. Occasionally, they may gain access intraluminally following insertion with the guidewire.[8,9]

Table 7: Important risk factors for intravascular device related bloodstream infections

Underlying disease	*Catheter-related factor*
Severe illness with high APACHE score	Clumsy or difficult insertion
Neutropenia	Insertion into the femoral vein or artery
Immunocompromised patient	Poor catheter care
Transplant patient	Occlusive dressing
Prolonged ICU stay	Duration of catheter >7 days
Source of sepsis, e.g. Intra-abdominal suppuration	Parenteral nutrition
Massive surgery	
Mechanical ventilation	
Prolonged use of systemic antibiotics	

Abbreviations: APACHE, acute physiology and chronic health evaluation; ICU, intensive care unit.

In contrast, BSIs caused by long-term (>10 days) IVDs such as cuffed Hickman and Broviac-type catheters, hemodialysis catheters, subcutaneous central venous ports are most often due to contamination of the catheter hub and luminal fluid.[10]

It is important to remember that contamination of parenteral fluids, blood products, IV medications can also cause BSIs particularly with arterial catheters used for long-term hemodynamic monitoring, as also with Hickman catheters, central venous hemodialysis catheters and subcutaneous central venous ports.[11,12]

Most nosocomial epidemics of infusion-related BSI are due to contamination of infusate by Gram-negative organisms introduced during manufacture or during its preparation and administration.

RISK FACTORS (TABLE 7)

A number of risk factors can be identified. The severity of the illness influences the risk, patients who are severely ill with high Acute Physiology and Chronic Health Evaluation (APACHE) scores carrying a significantly greater risk for BSIs. Neutropenia, immunocompromised patients, human immunodeficiency virus (HIV) patients, transplant patients all carry a greater risk of IVD-R BSIs. The longer the stay in the ICU, the greater the risk for all nosocomial infections.

A multilumen catheter offers more portals for entry of infection than a single lumen catheter. Also multilumen catheters are generally inserted in more severely ill patients who are subjected to more interventions leading to an enhanced risk of infection.

Catheters introduced into the jugular vein are more frequently associated with infection compared to subclavian vein catheters. This could be related to increased motion at the jugular vein site and the difficulty in keeping this site clean due to soiling with oropharyngeal secretions.

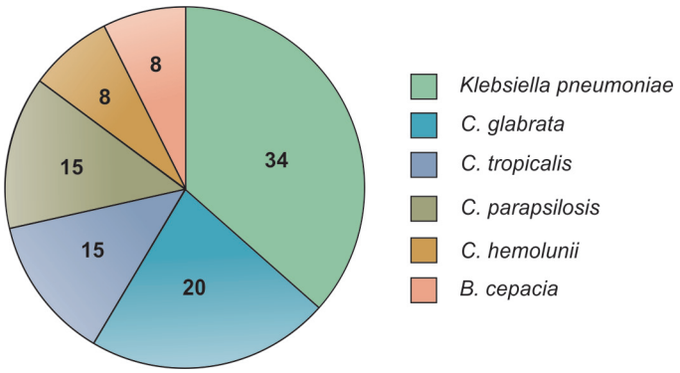

Fig. 6: Percentage (%) distribution of central line-associated bloodstream infection (CLABSI) pathogens in 2012 at the Breach Candy Hospital

The longer a catheter remains within a vein, the greater the risk. Repeated catheterization also increases the risk. It is unwise to change a central line catheter every few days; yet it is equally unwise to keep the catheter in for weeks with intent to change it only when infection occurs. Each ICU may frame its own rules; we prefer to change the central line every 8–10 days.

It has been shown that the features of the IVD, its insertion and maintenance significantly influence the risk of infection. Merrer and colleagues[13] showed that insertion of an IVD in the femoral vein versus the subclavian vein was associated with a far greater risk of infection (20 vs 3.7 BSIs per 1,000 IV device days), and far more thrombotic complications (21.5 vs 1.9%).[13] Risk of catheter-related BSI increases in the presence of a suppurative focus in the body, as it exposes the catheter to bacteremia. Occlusive dressing over the site of puncture for CVC or any IVD can lead to a growth of microorganisms and predispose to infection at the site of entry.

Training, efficiency and care shown by the medical and nursing staff as also the nurse to patient ratio in the ICU (ideally 1:1) and the cleanliness of the environment (so important to consider in developing countries) all play a role in the incidence of blood stream device-related infection in an ICU. Important risk factors for IVD-R BSI are tabled in Table 8.

MICROBIOLOGY

The microbiology of IVD-R BSI varies from one geographic area to another and for that matter in different ICUs in the same city.

The microbial profile of IVD-R BSI based on an analysis of 159 published prospective studies in America[14] showed that the commonest microorganism causing BSI was the coagulase negative *Staphylococcus spp.* (31%) followed by *S. aureus* (18%), enteric Gram-negative bacteria (14%), *Pseudomonas aeruginosa* (8%), *Candida species* (6%), Corynebacterium species (5%), *Enterococcus species* (4%), miscellaneous (4%).

The microbial profile at the Breach Candy Hospital for central line associated bloodstream infection (CLABSI) in the year 2012 is illustrated in Figure 6.

DIAGNOSIS

Before attributing fever or features of sepsis to an IVD-R bloodstream infection, it is important to thoroughly examine the patient and assess the possibility of all other likely sources of infection commonly observed in critically ill patients in the ICU. These include urinary tract infection, nosocomial pneumonia in particularly a ventilator-associated pneumonia (VAP), surgical site infection, colitis caused by *C. difficile,* sinusitis related to a nasotracheal intubation, infected bed sores. Recent evidence-based guidelines provide current information on the evaluation of a patient in the ICU who presents with pyrexia or other signs of sepsis.[15]

If after a thorough clinical examination and relevant tests the cause of pyrexia is not evident, or there are features of sepsis without any identifiable cause, the likelihood of an IVD-R bloodstream infection is strong. In the presence of inflammation at the catheter site insertion, (particularly if there is purulence), together with fever and features of sepsis, an IVD-R bloodstream infection is extremely likely and the intravascular device should be promptly removed.

Another indication of an IVD-R bloodstream infection is blood cultures repeatedly positive for organisms such as *Staphylococci spp., Corynebacterium spp.,* or bacillus species or *Candida spp.,* or *Malassezia spp.*

Blood Cultures

Blood cultures are basic investigations in the diagnosis of IVD-R bloodstream infections. There are several features which need to be stressed in relation to this crucial investigation—

- Empiric antibiotic treatment for a presumed BSI in a critically ill patient should never be started without obtaining prior blood cultures. The blood culture should always be taken from two separate sites, at least one of which is drawn from a peripheral vein by percutaneous venipuncture.
- The sensitivity of blood cultures, which means the greater yield of positive blood culture, is enhanced significantly if a larger volume of blood is drawn for each culture. In adults, 30 mL of blood should be drawn for each blood culture—15 mL being inoculated into aerobic and 15 mL into anaerobic medium.
- Blood cultures drawn through CVCs offer good sensitivity for BSI but are less specific compared to cultures obtained from peripheral veins.[16,17]
- A thorough cleansing of the skin before drawing blood for culture from a peripheral vein is vital, so as to avoid contamination and misleading results. The antiseptic solution recommended is chlorhexidine, tincture of iodine, isoprophyl alcohol, and povidone iodine combined with alcohol rather than povidone iodine alone.
- Up to 30% of blood cultures positive for *S. epidermidis* (an organism commonly present on the skin) represent true infection. However, a single positive culture invariably is due to contamination. This again illustrates the importance of collecting blood cultures (using adequate quantity of blood) from two separate sites whenever BSI is suspected.
- If blood cultures from the IVD (e.g. a central line catheter) and a peripheral vein are positive, the IVD should be removed.
- If either one or the other is positive and no other source of infection is evident, it is again best to remove the IVD.
- In a critically ill individual running undiagnosed fever or having features of sepsis the IVD is best removed, if there is clearly no other source to explain the above findings even if blood cultures from both sites are negative. Abolition of the unexplained fever and regression of sepsis after removal of an IVD such as a CVC may be the only proof of IVD-R bloodstream infection.

Cultures of the Removed Intravascular Device

Culturing the removed intravascular device is the gold standard for IVD-R bloodstream infection, particularly for a short-term (<10 days) IVD. Catheter segments can be cultured semiquantitatively on solid media or quantitatively in liquid media (removing the adherent organisms by sonication).[18,19] The higher the colony count the greater the probability of line sepsis. A growth equal to or greater than 15 colony-forming units (CFU) from a 5-cm catheter segment cultured by semi quantitative method, or growth equal to or greater than 10^2 CFU from a catheter segment cultured by the quantitative method denotes catheter-related infection if the patient had local signs of inflammation or signs of sepsis. If there is significant growth in the absence of local inflammation or sepsis, it denotes colonization of the IVD. If it is necessary to insert a new device it is best to insert it at a new site, rather than inserting one in the same location over a guidewire.

Quantitative or semiquantitative culture methods are generally preferable for detecting infection in IVD that are in place greater than 10 days. This is because the route of infection in long-term devices is generally hub contamination with intraluminal colonization and infection. The quantitative method removes organisms (through sonication) from both external and internal surfaces of the catheter.

The semiquantitative method is often preferred for short-term (<10 days) intravascular devices as the route of infection is generally an ascending infection from the site of skin puncture ultimately colonizing the external surface of the catheter. The semiquantitative method is cheap, less expensive and gives a quicker result.

Gram stain of intravascular catheter segments of removed catheters shows an excellent correlation with results obtained from quantitative methods and allows a quick diagnosis of catheter infection.

Diagnosis of an IVD-R Bloodstream Infection When the IVD Is in Place Longer Than 10 Days

An IVD in place longer than 10 days includes CVC, Hickman and Broviac catheters, hemodialysis catheters and central venous ports. Persistent fever or features of sepsis without any other cause has prompted removal of these devices.

Only 15–45% of these devices removed for suspected infection are found to be colonized or infected at the time of removal. Removal of a Hickman catheter or hemodialysis catheter when they are not infected raises unnecessary difficulties. Quantitative or semiquantitative blood cultures drawn from the IVD (e.g. a central line catheter in place >10 days or a Hickman catheter >10 days) and concomitantly drawn cultures from a peripheral vein allow a diagnosis IVD-R blood stream sepsis—bacteremia or fungal, with a sensitivity and specificity of 80–95%[20] without removal of the catheter, provided empiric antibiotics have not been started.

- If both IVD drawn blood culture and peripheral vein drawn blood culture are positive for the same microorganism and if the growth in blood drawn from the IVD shows at least threefold higher concentration of microorganism per mililiter compared to that grown from the venipuncture an intravascular device-related bloodstream infection is confirmed.
- The other criteria used for diagnosing IVD-R bloodstream infection is the differential time to positivity (DTP) of paired blood cultures—one drawn from the IVD and the other concomitantly from the peripheral vein. If the blood drawn from the IVD comes positive 2 or more hours before that drawn from the peripheral vein a BSI can be confidently diagnosed. The sensitivity and specificity of this test ranges from 82% to 94%.[20]

The differential time positivity test has been tried out in patients with short-term IVDs with disappointing results. This is as expected, since the route of infection in a short-term IVD is extraluminal.

Detection of Contaminated Infusion

If the infusion is suspected to be contaminated the proof lies in demonstrating a growth of the same organism from the infusate and from culture of the peripheral blood.

COMPLICATIONS OF CATHETER-RELATED SEPSIS

Other than varying grades of bacterial sepsis, the two major complications are (1) a septic thrombophlebitis and (2) disseminated fungal infection.

Septic peripheral thrombophlebitis is obvious by the signs of inflammation and thrombosis of peripheral veins. Thrombophlebitis in central veins is often difficult to diagnose. Edema proximal to the phlebitis is common and should promptly arouse suspicion. Localized pain, warmth and tenderness are the important features, particularly when the internal jugular vein is involved. Blood cultures continue to be positive, and features of sepsis persist after removal of the catheter. Venography of a central vein may confirm the diagnosis. Small pulmonary emboli may complicate the picture, and in one of our patients, sudden death occurred from pulmonary embolism, the source of embolism being an infected clot in the subclavian vein.

Disseminated fungal infection is often missed. It should always be suspected when fever and other features of sepsis continue in spite of removal of the catheter and the use of appropriate antibiotics. This is of particular importance in neutropenic or immunocompromised patients. Fever persisting for more than 3 days in spite of the administration of broad-spectrum antibiotics and catheter removal in a critically ill neutropenic patient should prompt a trial with amphotericin B.

TREATMENT

Entry Site Infections

Short-term catheters suspected to be infected should be removed, but it would be unwise to remove a long-term Hickman's catheter as this catheter is often used as a lifeline for chemotherapeutic drugs and/or for hyperalimentation in very sick individuals. Entry site infection of long-term catheters should be treated with local bactericidal ointments and antibiotics given orally or intravenously. The choice of antibiotics depends on the organisms grown, aided by antibiotic sensitivity results.

Tunnel Infection

Patients with tunnel infection (e.g. with Hickman's catheter) require removal of the catheter. The tunnel needs to be surgically opened and the infection drained. One should not wait for culture reports before starting antibiotics. The antibiotic regime should preferably include vancomycin for a possible staphylococcal infection, and a third generation cephalosporin active against *P. aeruginosa* and other Gram-negative infections, or an aminoglycoside.

Catheter-Related Sepsis

Short-term catheters are promptly removed and antibiotics given. We prefer to give antibiotics for a period of 5–10 days depending on the clinical response. Empiric therapy generally includes a third generation cephalosporin (ceftazidime or cefoperazone) with an aminoglycoside. If features of sepsis persist, methicillin or vancomycin is added. The frequency of infection due to methicillin-resistant *Staphylococci* is still low in our unit. In other units, particularly in oncology units, the incidence is high, necessitating the empiric use of vancomycin till blood and catheter tip culture sensitivity reports are available. If catheter sepsis is proven on culture reports, or is strongly suspected, and if the patient worsens in spite of using a broad-spectrum antibiotic cover, a decision to start amphotericin B should be taken.

Septic thrombophlebitis, particularly of central veins, requires the use of IV heparin in addition to an appropriate combination of antibiotics as stated above.

PREVENTION

The Healthcare Infection Control Practices Advisory Committee has recently released guidelines for the prevention

Table 8: Summary of recommendations from guidelines for prevention of intravascular catheter-related infection (2011)

Subject	*Recommendation*
Placement of central venous catheter	Use ultrasound guidance to place central venous catheters to reduce the number of cannulation attempts and mechanical complications (category IB)
Skin preparation	Use 0.5% chlorhexidine for skin preparation and dressing changes. If there is contraindication for chlorhexidine, use tincture of iodine or 70% alcohol (category IA)
Catheter site dressing regimens	Use a chlorhexidine impregnated sponge dressing for temporary short-term catheters in patients older than 2 months of age if CLABSI is not decreasing despite adherence to basic prevention measures (category IB)
Patient cleaning	Use 2% chlorhexidine wash for daily skin cleaning (category II)
Catheter securement device	Use sutureless securement device to reduce the risk of infection for intravascular catheters (Category II)
Antimicrobial lock solutions	Use prophylactic antimicrobial lock solution in patients with long-term catheters who have a history of multiple CRBSI despite optimal maximal adherence to aseptic technique (category II)
Antimicbrobial impregnated central venous catheters	The use of a chlorhexidine or silver sulfadiazine impregnated or minicycline or rifampicin impregnated catheter is recommended in patients whose catheter is expected to remain >5 days, again if the optimal recommended measures have not produced a fall in BSI rates
Needleless intravascular catheter systems	Use a needleless system to access IV tubing (category IC). When a needleless system is used, a split septum valve may be preferred over mechanical valves, due to increased risk of infection with the mechanical valves (category II)
Performance improvement	Use hospital specific or collaborative based performance improvement initiatives in which multifaceted strategies are bundled together to improve compliance with evidence-based practices (category IB)

Abbreviations: CLABSI, catheter line-associated bloodstream infection; CRBSI, catheter-related bloodstream infection.
Source: O'Grady NP, Alexander M, Burns LA, et al. Guidelines for the prevention of intravascular catheter-related infections. Clin Infect Dis. 2011;52(9):e162-93.

of intravascular catheter-related infections. They stress that the program to prevent catheter line associated bloodstream infection (CLABSI) be a multidisciplinary approach.[21] The new guidelines recommend using performance improvement initiatives to decrease CLABSI rates and increase compliance with evidence based practices. Similar to the published guidelines in 2002 the new recommendations emphasize the education of healthcare workers and the assessment of knowledge and adherence to guidelines for those involved in the insertion and maintenance of CVCs. The new guidelines also discuss the use of new technologies to further reduce CLABSI. A statement is also included regarding the importance of ensuring trained, competent and appropriate nursing staff levels, as elevated patients to nurse ratio is associated with an increase in the rate of CLABSI.

Alterations in clinical practice and education interventions have clearly made a very favorable impact on the incidence of hospital acquired infection over the last decade in the West. The Pittsburg Regional Healthcare initiative introduced multiple control interventions to reduce the rate of CLABSI starting from 2001. From 2001–2005, the pooled rate of CLABSI in the participating ICUs reduced by 68%.[22]

The Michigan Health and Hospital Association Keystone ICU project is another large scale quality improvement initiative to reduce hospital acquired infection. During the initial study period starting from 2004 and extending one and a half years the CLABSI rates decreased by 66%. These results were sustained for a further 18 months after completion of the study.[23]

The interventions in both these studies focused on hand hygiene, the use of chlorhexidine for skin preparation, the use of full barrier precautions during insertion, the use of the subclavian vein as the preferred insertion site and the removal of unnecessary CVCs.

There is also an encouraging study carried out by the International Nosocomial Infection Control Consortium (INICC). They studied the effects of the implantation of a comprehensive strategy on CLABSI rates in the intensive care units of twelve developing countries. With an emphasis on education, feedback of outcome, surveillance (infection rate) and process surveillance (adherence to infection control measures) the CLABSI was significantly reduced. It dropped over a period of 24 months from 16.4–7.4 CLABSI per central line days. The number of deaths due to CLABSIs was reduced by 58%. These results are indeed encouraging. With a little more effort, results will hopefully yet improve.[24]

The updated recommendations of the new guidelines are set out in Table 8.

Technology Innovations in the Prevention of CLABSI

New technological innovations have come to the forefront to help further reduce CLABSI. These include—

- Use of real time ultrasound guidance to help insert the central line. Ultrasound guidance reduces the number of cannulating attempts, thereby reducing the risk of mechanical complications, when compared to insertion of central lines using the help of anatomical landmarks.
- Use of antimicrobial and antiseptic impregnated catheters. The lumen of the CVC is filled with an antimicrobial

solution which is allowed to remain when the catheter is not in use. These catheters are expensive and perhaps should be restricted to patients who have long-term CVC in place, and who have repeated BSIs in spite of optimal standard care. The use of a chlorhexidine or silver sulphadiazine impregnated or minicycline or rifampicin impregnated catheter is recommended in patients whose catheter is expected to remain greater than 5 days, again if the optimal recommended measures have not produced a fall in BSI rates.

- The new Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines recommend the use of chlorhexidine impregnated sponge dressing in patients older than 2 months if in spite of optimal efforts the rate of BSI does not decrease.
- A chlorhexidine (≥2%) daily skin wash instead of a soap and water skin wash is a simple strategy that has led to reduced BSI rates in the ICUs.
- The use of sutureless securement devices for intravascular catheters is now recommended as a category II recommendation. Use of these devices may reduce catheter colonization by maintaining the integrity of the surrounding tissues.

URINARY CATHETER-ASSOCIATED INFECTIONS

Till recently, UTIs headed our list of nosocomial infections as in most ICUs all over the world. However, in the last three years, there has been a dramatic fall in UTIs due to the active surveillance measures taken by the hospital staff. The most important predisposing factor for such infections is the presence of an indwelling urinary catheter.[1] Urinary infection is catheter-acquired if it develops while a urinary catheter is in situ or within 72 hours of its removal.[2] The longer a catheter remains in the bladder, the greater the risk of urinary infection. Unfortunately, the use of urinary catheters for long periods of time in very ill individuals is often necessary. The incidence of bacteriuria from urinary catheters varies from 5% to 10% per day.[1] In our experience, a growth of organisms in urine is present in almost every patient who has an indwelling catheter for more than 8 days. Many of these are asymptomatic, but a fair number are symptomatic. As with all nosocomial infections, it is difficult to distinguish between colonization by bacteria and actual infection. The Infectious Disease Society of America[2] has laid down guidelines to distinguish catheter-related asymptomatic bacteriuria from catheter-related urinary tract infections. Urinary infection may take the form of a cystitis or urethritis or may involve the upper urinary tract and produce pyelonephritis.

PATHOGENESIS[2,3]

Bacteriuria

A urinary catheter aids entry of microorganisms into the bladder through several mechanisms. The most common mechanism is the ascension of a biofilm (containing microorganisms) along the catheter which when it reaches the bladder results in a bacteriuria. The bacteriuria is well correlated with the duration of catheterization.[4] Bacterial presence in the periurethral area could allow these microorganisms to be pushed into the bladder during catheter insertion. If these microorganisms persist bacteriuria results. When the catheter is not managed properly, or when contaminated urine in the bag refluxes into the bladder, organisms can again reach the bladder. Organisms may also be introduced when there is a break in the tubing system. Finally, the bulb of the indwelling catheter does not allow a complete drainage of the urine. A small pool of urine remains; once organisms reach this retained pool of urine, or the biofilm on the catheter or bladder wall they persist and multiply.

A biofilm is an inevitable sequel of an indwelling catheter. Host proteins adhere to the surface of the catheter wall forming a conditioning layer. This layer facilitates adherence of microorganisms which generate a polysaccharide coating under which the bacteria grow. They are now less vulnerable both to antibiotics or the host immune response. This biofilm extends both in the inside and outside of the catheter wall and also along the bladder wall. Hydrolysis of urea in the urine by urease producing bacteria such as *P. mirabilis* leads to an alkaline environment with precipitation of calcium and magnesium, so as to result in a crystalline biofilm.[5] This material is similar to urinary bladder and renal stones; it can cause encrustation and block the catheter.

Symptomatic Infection

Factors determining symptomatic catheter-related urinary infection are not clearly understood. Mucosal trauma during catheterization or mucosal bleeding are known to precede fever and bacteremia from a urinary source but symptomatic episodes related to the above are comparatively small in number. Urinary obstruction due to a completely or partially blocked catheter is one other factor leading to symptomatic infection. Nicolle[3] believes that though the virulence of organisms in the bladder, which has an indwelling catheter cannot be disregarded, this does not play a pivotal role. She noted that *E. coli* grown from bacteriuria resulting from a catheter-related bacterial infection as also that grown from the blood in patients with asymptomatic bacteriuria show an attenuation of virulence properties.

MICROBIOLOGY[2,3]

An analysis of urine cultures in individuals with catheters in our ICU showed that the commonest organism grown was *E. coli* followed by *Enterococci spp.*, *Klebsiella spp.*, *P. mirabilis*, *P. aeruginosa* and Enterobacteriaceae. A growth of *Candida spp.* is not at all uncommon in very ill patients with indwelling catheters who have been deluged with powerful broad-spectrum antibiotics.

Gram-positive organisms, such as coagulase negative *Staphylococci* and *Entercoccus* species are isolated frequently but are not usually associated with symptomatic infection. Bacterial isolates from critically ill patients are generally characterized by increased bacterial resistance. Extended β-lactamase producing Gram-negative bacteria are commonly found.

Polymicrobial infections are also fairly frequent in catheterized patients. The presence of polymicrobial infections in the urine in non-catheterized patients, or in those who have not had any instrumentation done on their urinary tract, is likely to be due to contamination.

The microbial profile at the Breach Candy Hospital for urinary tract infection (UTI) in year 2012 is illustrated in Figure 7.

RISK FACTORS

Risk factors for catheter-induced bacteriuria (often accompanied or followed by infection) are prolonged duration of catheterization, a break in the closed system drainage with colonization of the urinary bag, poor catheter care, urethral trauma, a raised serum creatinine, diabetes, preuretheal

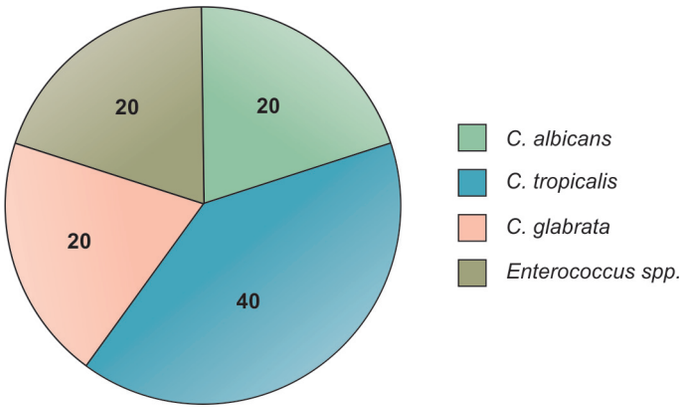

Fig. 7: Percentage (%) distribution of catheter-associated urinary tract infection (CAUTI) in 2012 at the Breach Candy Hospital

colonization with potential pathogenic bacteria and immunocompromised states.

CLINICAL FEATURES[2,6]

Signs and symptoms of catheter-associated urinary infection include new onset or worsening of fever, rigors, delirium, lethargy, suprapubic pain or discomfort. Hematuria, pain and/or tenderness over the costovertebral angle may also be observed.

In patients in whom the catheter has been removed, dysuria or urgency and frequency of urine or suprapubic pain denote a catheter-associated urinary infection.

A search for a possible urinary tract infection is mandatory in a patient with clinical features of sepsis, or in one who has pyrexia for which there is no other apparent cause.

Infection may be mild, moderate or fulminant in nature. Fulminant Gram-negative infections produced by catheter-related *P. aeruginosa* or *Klebsiella spp.*, or any other Gram-negative infections may take the form of high fever with severe rigors, and may quickly progress to a state of mental obtundation, hypotension, septic shock and renal failure. A rapidly progressive renal insufficiency may be the sole clinical manifestation of a severe catheter-related urinary tract infection, both in very critically ill patients and in immunocompromised states.

COMPLICATIONS

These include pyelonephritis, emphysematous pyelonephritis, renal abscess, perinephric abscess, Gram-negative bacteremia with septic shock. Progressive renal failure may complicate urinary tract infections, and this is often compounded by the use of nephrotoxic drugs (e.g. aminoglycosides) used to treat such infections.

DIAGNOSIS[2,3]

Catheter-associated urinary tract infection (CA-UTI) must be distinguished from catheter-associated asymptomatic bacteriuria. The International Clinical Practice Guidelines from the Infectious Disease Society of America give the following definitions for catheter associated urinary infection and catheter associated asymptomatic bacteriuria (CA-ASB).

CA-UTI in patients with an indwelling urethral catheter is defined by the presence of symptoms or signs compatible with UTI with no other identified source of infection, along with more than or equal to 10^3 CFU/mL of more than or equal to 1 bacterial species in a single catheter urine specimen, or in a midstream voided urine specimen from a patient whose urethral or condom catheter has been removed within the previous 48 hours.

CA-ASB in patients with an indwelling urethral catheter is defined by the presence of more than or equal to 10^5 CFU/mL of more than or equal to one bacterial species in a single catheter urine specimen in a patient without symptoms compatible with UTI.

Criteria for symptomatic catheter-related urinary tract infection have also been laid down by the National Healthcare Safety Network (NHSN).[6]

NHSN Criteria for Catheter-Related Urinary Infection

At least one of the following signs or symptoms with no other recognized cause—

Fever >38°C, suprapubic tenderness, costovertebral angle pain or tenderness,

OR

For patients <1 year of age, one spike of fever (>38°C core), hypothermia (<36°C core), apnea, bradycardia, dysuria, lethargy or vomiting,

AND

Urine culture with ≥10^5 CFU/mL with no more than two species of organisms,

OR

Urine culture with ≥10^3 CFU/mL with no more than two species and a positive urine analysis [positive dipstick for leukocyte esterase or nitrite, pyuria (≥10 WBC/mm^3 or ≥3 white blood cells/HPF unspun urine)], microorganisms in Gram stain of unspun urine.[6]

Guidelines from the Infectious Society of America and from NHSN are not exactly similar. This is perhaps an illustration of trying to gather, equate and practice all clinical medicine solely from the available evidence.

What Should the Practicing Intensivist or Physician Do?

I would consider that in the presence of clinical features of urinary tract infection, the presence of a urine culture showing a 10^5 CFU/mL could indicate a catheter-related UTI. There is an important proviso to the above statement. In critically ill patients with fever, patients with ongoing or increasing sepsis where no other cause is evident, the presence of pus cells in urine and a urine culture with greater than 10^5 CFU/mL warrant treatment. It is perfectly possible for a urinary infection in the above circumstances to be the cause of sepsis and we have witnessed this in critically ill patients with the above-mentioned features.

Urine Examination[2,3]

Pyuria[2]

A patient with a catheter-associated UTI must have pyuria. The absence of pus cells in a symptomatic patient should suggest a diagnosis other than a UTI. The presence, absence or degree of pyuria by itself should not be used to distinguish CA-ASB from CA-UTI.

In CA-UTI the urine should show greater than or equal to 3 WBC/HPF in unspun urine. Pus cells can be quantified by using a hemocytometer. Pus cells greater than or equal to 10 WBC/mm^3 are significant. The NHSN criteria suggest that a positive dipstick for leukocyte esterase or nitrite is also significant as is the presence of microorganisms in a Gram stain of unspun urine.

Culture[2,3]

Empiric antibiotic therapy should never be given before sending for a urine culture. One however must not await culture reports in critically ill patients to start treatment.

If a short-term indwelling catheter is in place the urine for culture should be collected through puncture of the sampling port. Urine collected through the catheter will show a higher colony count if the catheter is lined by a biofilm. For the same reason if the urinary catheter has been in place for a long time, greater than 2–3 weeks, the catheter should be replaced by a new catheter and urine specimen for culture should be sent from the newly inserted catheter.[7]

Patients with a short-term indwelling catheter who have symptoms of urinary infection have quantitative counts greater than or equal to 10^5 CFU/mL.[8] Lower quantitative counts may be observed when patients are having diuresis or receiving antimicrobial therapy. Lower counts may occasionally represent early biofilm contamination of the catheter.

For patients with a long standing indwelling catheter who have symptoms of urinary infection, a quantitative count of greater than 10^5 CFU/mL of one or more organism is also appropriate for a diagnosis of culture-associated infection.

When urine culture shows a colony count of less than 10^5 CFU/mL in a patient with an indwelling chronic catheter attribution of fever to a UTI is in doubt and the diagnosis should be critically reassessed.

Urine cultures for bacteria or fungi submitted to the microbiology laboratory should be processed promptly. Alternatively, the specimens should be stored at 4°C; at this temperature the organisms remain viable for about 24 hours. If urine sent to the laboratory is kept standing for over 2 hours before being cultured, the urinary bacterial count increases significantly, thus making the diagnosis of urinary infections increasingly difficult. Sensitivity tests to antibiotics are routinely performed whenever the colony count is greater than 100,000 CFU/mL. When a polymicrobial flora is grown, sensitivity tests for different organisms may need to be performed separately.

Other Laboratory Investigations

A blood count may show leukocytosis and blood cultures may detect bacteremia, the source being an infected urinary tract.

Imaging Studies

Patients in the ICU with urosepsis, whether catheter-related or not, often require evaluation for upper urinary tract disease. Ultrasonography (USG) is useful to establish the anatomy of the kidneys, and to exclude an obstructed ureter. Occasionally, an IV or retrograde pyelography may be necessary. A computed tomography (CT) scan may establish the diagnosis of a suspected renal or perinephric abscess and may yield further evidence of any ureteric obstruction.

Differential Diagnosis

It is important as stated earlier to distinguish urinary tract colonization manifested by asymptomatic bacteriuria from a true UTI. Prostatitis, pelvic inflammatory disease and diverticulitis may mimic a catheter-related urinary tract infection in a very ill individual. Not uncommonly, a septic state in a moribund patient in the ICU is mistakenly attributed to the presence of a comparatively mild to moderate urinary infection, whereas the actual cause is more sinister, e.g. an intra-abdominal abscess or a peritonitis resulting from a bowel perforation or infarction.

TREATMENT

Bacteriuria in Asymptomatic Patients[9]

Antibiotic therapy should not be used as bacteriuria will often recur after antibiotics are stopped, or superinfection with more virulent organisms may occur. There is also the fear and concern of selection of antibiotic resistance.[9]

Prophylactic use of antibiotics in patients having an indwelling urethral catheter is not recommended in the guidelines but is often used in many ICUs in the hope of preventing UTI.

Bacteriuria in Symptomatic Patients[2,3]

In symptomatic patients, the catheter is removed and suitable antibiotics commenced. If the patient needs an indwelling urinary catheter, a new one is inserted. In serious UTIs, it is important to commence therapy promptly after sending urine cultures in patients who appear very ill, without waiting for the culture reports. Empiric therapy for urinary infection should also be given in those patients who are hemodynamically unstable, in the immunocompromised and neutropenics, in poorly controlled diabetics, in patients with damaged or prosthetic valves (for fear of complicating bacterial endocarditis), and in patients with deteriorating renal function. The optimal duration of antimicrobial therapy is debatable. If the catheter remains in situ, a 7-day course is recommended to avoid the emergence of resistant organisms.

Selection of Antibiotics

A Gram stain of the urine may help decide the nature of the infection (whether Gram-negative as is common, or Gram-positive in occasional cases), well before culture reports are available.

The choice of antibiotics for Gram-negative infections in most units is usually amoxicillin-clavulanic acid or ceftazidime or cefoperazone, combined with an aminoglycoside. It is best to avoid the latter if renal function is impaired, more so as facilities for determining aminoglycoside levels are not available in all medical centers in the country. Ciprofloxacin is added to ceftazidime or cefoperazone in severe UTIs with renal insufficiency if sensitivity reports support its use. An alternative regime for severe Pseudomonas or other Gram-negative infection is the use of piperacillin-tazobactam combination or of merepenem.

Currently, there has been a great increase in ESBL producing organisms resistant to penicillins and third generation cephalosporins, so that in many patients one has to resort to the use of carbapenems, or even colistin if cultures show the presence of carbapenem-resistant organisms.

In Gram-positive infections, amoxicillin-clavulanic acid is generally used till such time as a culture report is available. Resistant staphylococcal infections are not common in our unit. If however infection with resistant *Staphylococci* is suspected, the drug of choice is vancomycin, which covers both resistant *Staphylococci* as well as *Enterococci*. Gentamicin may be added for mixed staphylococcal and Gram-negative infections.

Candiduria[10]

The presence of candida in the urine requires careful interpretation.

Asymptomatic candiduria in an immunocompetent patient generally indicates mere colonization without infection. It clears when the catheter is removed and particularly when the antibiotics are stopped.

Symptomatic candiduria in immunocompetent patients or severe candiduria, even though asymptomatic in immunocompromised individuals, often spells danger. It could signify fungal infection of the bladder, an ascending fungal pyelonephritis, or disseminated candidiasis. The presence of disseminated candidiasis is difficult to diagnose as blood cultures are not necessarily positive. Fluffy white retinal exudates protruding from the retinal surface into the vitreous, and an endophthalmitis have been reported in 40–50% of patients with disseminated candidiasis, but we have never had the opportunity of observing these lesions. Clinical features that should make one suspect disseminated candidiasis are—

- A deterioration in the general condition with worsening renal function in a patient with persistent and profuse candida in the urine.
- Growth of *Candida spp.* from two other sites (e.g. sputum, vascular catheter), besides the urine. In neutropenic patients who are septic, growth of *Candida* from just two sites is sufficient evidence to start systemic antifungal therapy.
- Profuse growth of *Candida* in the urine in a patient who has no indwelling catheter or pus cells in the urine of a patient who is deteriorating clinically at a very rapid rate.

Treatment

Suspected Candida infection of the upper urinary tract or suspected disseminated candidiasis requires the use of IV fluconazole or IV amphotericin B (see Chapter Invasive Fungal Infections in the ICU). The indwelling catheter should be removed and a new one inserted, if a catheter is vital for patient management.

Candidiasis confined to the bladder should be treated with oral fluconazole and/or irrigation of the bladder with amphotericin B. Sobel[10] describes the following method for irrigation of the bladder with amphotericin B solution. 50 mg amphotericin B is mixed with 1 L of sterile water and infused at a rate of 40 mL/hour, using a three-way bladder catheter. The response is generally good and the irrigation can be stopped after 3–4 days. Systemic candidiasis or fungal involvement of the kidneys or the perinephric space requires the prompt use of amphotericin B.

PREVENTION OF URINARY CATHETER-RELATED INFECTIONS[2,6,11,12]

Measures to prevent catheter-related infection, if assiduously practiced, can sharply reduce the incidence of these infections. This reduction can also happen in poor developing countries of the world as is shown by a study of catheter associated urinary tract infection rates in adult intensive care units of 15 developing countries.[13] A multidimension infection control strategy consisted of a "practice bundle" with details on education and training on the insertion, care and maintenance of the urinary catheter, outcome surveillance, process surveillance, hand hygiene compliance, urinary catheter care monitoring and performance feedback. In phase I of this study (before intervention) the CA-UTI rate was 7.86 per 1,000 urinary catheter days. In phase II after intervention the CA-UTI decreased to 4.95 per 1,000 catheter days—a significant 17% reduction.[13]

The reader is referred to the 2009 International Practice Guidelines for the details on the prevention of catheter-associated urinary tract infection (Boxes 8 and 9). A few important and relevant aspects are given below—

- Insert an indwelling catheter only if absolutely necessary. If condom drainage of the urine is satisfactory, and there is no urinary retention, it is wiser not to insert the catheter. The catheter should be removed as soon as it is not needed.[2]

  About 20–50% of indwelling catheters in patients in ICU do not meet the appropriate indications for catheter insertion, and 30–50% of catheter days are reported to be unjustified because the catheter remains in situ beyond which is necessary.[12]

  Strategies to reduce the use of catheterization have been shown to be effective and have a greater impact on reducing nosocomial UTI than any other strategy advised in the guidelines.
- A urinary catheter must be inserted under complete aseptic conditions, and should be meticulously cared for once inserted.

Box 8: Indications for indwelling catheter (Healthcare Infection Control Practices Advisory Committee)

- Acute urinary retention or bladder outlet obstruction
- Accurate measurement of urine output in critically ill patients
- Selected perioperative use—
  - Urologic or genitourinary surgery
  - Prolonged duration of surgery
  - Large volume infusions or diuretics during surgery
  - Intraoperative monitoring of urine output
- Assist in healing open sacral or perineal wounds in incontinent patients
- Prolonged immobilization for spine or pelvic fractures
- Comfort for end-of-life care

Source: Gould CV, Umscheid CA, Agarwal RK, et al. Guideline for prevention of catheter-associated infections. [online] CDC website. Available from http://www.cdc.gov/hicpac/ [Accessed September 2013].

A closed catheter drainage system with ports in the distal catheter for needle aspiration of urine should be used to reduce CA bacteriuria and CA-UTI in patients with an indwelling urethral or suprapubic catheter. Disconnection of the catheter junction should be minimized and the drainage bag and connecting tube should always be kept below the level of the bladder.

The catheter should not be pulled upon during nursing, and the sterile system should not be broken by obtaining samples of urine for examination from the urine collection bag. Urine samples should always be obtained from the proximal portion of the catheter or through the sample port of the catheter system. The urethral meatus should be coated with a bactericidal ointment—neosporin, soframycin or bacitracin. Care should be taken that the catheter is not contaminated by fecal matter or secretions on bedsheets or bedclothes.

- Antibiotic coated catheters were proposed to reduce the incidence of CA-UTI. Current studies show that the use of antibiotic coated or silver oxide coated catheter do not reduce the incidence of UTI.[14]
- Complex catheter systems continue to be devised. They have yet to prove their use and the expense plus close attention and supervision necessary, render their use impractical in developing countries.

Box 9: Recommended practices for indwelling catheter insertion and maintenance

- Catheter insertion—
  - Properly trained personnel
  - Hand hygiene
  - Smallest-bore catheter
  - Aseptic technique and sterile equipment
- Catheter maintenance—
  - Sterile, continuously closed drainage system
  - If breaks, replace catheter, collecting system, and connection
  - Consider using preconnected, sealed catheter-tubing junction
- Maintain unobstructed urine flow from bladder to drainage bag—
  - Avoid tube kinking
  - Keep bag below bladder
  - Empty bag regularly
  - Separate collecting containers from each patient
- Standard precautions for catheter and collecting system manipulation

ANTIBIOTIC-ASSOCIATED COLITIS

GENERAL CONSIDERATIONS

Diarrhea in a patient under critical care is most often due to antibiotics, to overzealous enteral feeding, or following chemotherapy for malignancy or myeloproliferative diseases. In hospitals and ICUs in poor countries, where kitchen hygiene leaves a lot to be desired, outbreaks or isolated instances of intestinal infection due to *E. coli, Shigella spp.*, *Salmonella spp.*, or trophozoites of *E. histolytica* may also be occasionally observed.

Antibiotic-associated diarrhea is due to an overgrowth of various organisms in the gut. An overgrowth of *C. difficile* in the colon can lead to a potentially serious form of diarrhea due to a *C. difficile* infection causing a colitis.[1,2]

C. difficile is a spore bearing anaerobic bacillus that produces Toxin A and Toxin B. A few strains produce only Toxin B. All strains including those only producing Toxin B can cause the same spectrum of illness characterized by an intestinal pathology. Nosocomial hospital outbreaks due to *C. difficile* are assuming increasing importance in hospitals in the West. In our part of the world *C. difficile* infection is fairly frequent but outbreaks of nosocomial infection are uncommon. The increasing incidence of *C. difficile* infection in ICUs in the East is largely due to increasing awareness of the infection.

Non-toxigenic strains of *C. difficile* also exist—they do not produce disease. The difference in the ability to produce toxin is important as some diagnostic tests detect *C. difficile* whether it produces toxin or not, and others test only for Toxin A. The sharp increase of *C. difficile* infection in the West over the last 10 years is due to the emergence of a new strain of *C. difficile,* the BI/NAPI/027 strain. This strain produces more toxins A and B than the usual strain. It also produces a third toxin, a binary toxin which is highly resistant to fluroquinolones.

Exposure to antibiotics is the most common cause of *C. difficile* infection. This is particularly prevalent in ICUs where patients often receive multiple classes of antibiotics. The most common antibiotic associated with *C. difficile* infection is clindamycin, but all broad spectrum antibiotics—ampicillin, augmentin, third generation cephalosporins, and almost all other antibiotics can trigger it. In the West, fluoroquinolones are increasingly associated with it due to the emerging strain BI/NAPI/027 which is highly resistant to this drug. Other risk factors include increasing age, severity of a critical illness and suppression of gastric acid by H_2 antagonists and by proton pump inhibitors. Patients in the same ward, unit or ICU as those suffering from *C. difficile* infection are at greater risk for also acquiring the infection. *C. difficile* infection can thus spread from patient to patient and this fact is crucial in relation to preventive measures to curb spread of the disease.

CLINICAL FEATURES[3]

A low-grade fever and watery diarrhea of varying severity are observed. This may occur during antibiotic therapy, or may occur some weeks after antibiotics have been stopped. The diarrhea may be mild or profuse causing both hypovolemia, and fluid and electrolyte disturbances. Mucus, blood and shreds of colonic mucosa that have sloughed off from the colon, may be present in the stools. The clinical features may be indistinguishable from acute dysentery. Pseudomembranous colitis occurs only in 50% of cases. In severe pseudomembranous colitis, all the features of a toxic megacolon may occur, culminating in perforation of the large bowel. This is more likely if the association of the above clinical features with the antibiotic used is not realized, and the drug is not immediately withdrawn.

DIAGNOSIS[2-5]

The diagnosis is made by detection of *C. difficile* or its toxin in patients with diarrhea. The presence of pseudomembranous colitis is confirmatory for *C. difficile* infection but as mentioned earlier this entity occurs only in 50% of cases. The most commonly used test is a toxin A or B enzyme immunoassay (EIA). Unfortunately this test has variable sensitivity and specificity. Also the Eliza test only detects toxin A and will therefore miss strains that produce toxin B. An EIA test has been advocated in the West for *C. difficile* glutamate dehydrogenase. To the best of my knowledge it is not performed in India except perhaps in special labs. Other lab tests for confirmation are polymerase chain reaction (PCR), or toxigenic culture.

Differential diagnosis includes infective diarrhea or dysentery due to various organisms—*E. coli*, *Shigella*, *Campylobacter jejuni*, *Salmonella* and *E. histolytica*. These nosocomial infections of the gut may be rare in Western countries, but are not so uncommon in our part of the world. In the elderly, a differential diagnosis of ischemic colitis must also be considered. Cytomegalovirus infections in immunocompromised patients may present with diarrhea or with a hemorrhagic colitis. Noninfectious causes of nosocomial diarrhea include enteral feeding, drugs increasing intestinal motility and alteration of the normal bowel flora following antibiotic use.

MANAGEMENT[5,6]

Most patients improve quickly after withdrawing the antibiotic responsible for the diarrhea. Specific therapy must be used in patients with severe diarrhea, or in those whose diarrhea continues after stopping the antibiotic. Drugs useful in

pseudomembranous colitis are metronidazole[5] 400 mg thrice daily for 14 days, or vancomycin 250 mg thrice a day orally for 14 days. Excellent results are generally obtained with metronidazole.

In severe infections associated with hemodynamic instability vancomycin 500 mg qds is given through a nasogastric tube and metronidazole is administered intravenously in a dose of 500 mg 8 hourly. Vancomycin retention enemas 250 mg in 250 mL normal saline four times a day are advised if the patient has an ileus. Intravenous immunoglobulin in a dose of 500 mg/kg for 1–3 doses has also been recommended for fulminant colitis. A surgical consultation should always be sought as some fulminant cases may need a subtotal colectomy.

In patients who have recurrent *C. difficile* infection, the initial oral dose of vancomycin 125 mg 6 hourly should be tapered very slowly over a period of 6 weeks.

C. difficile, at least in Western countries, has been known to survive for prolonged periods on a variety of surfaces—walls, carpets, beds, etc. It is also easily transmitted to patients through the hands of doctors, nurses and other paramedical personnel working in the ICU. Hospital outbreaks can spread from one infected patient to the other in an ICU.[6] Meticulous care—handwashing in particular as also other preventive measures including the implementation of isolation procedures are necessary to prevent this spread.

PREVENTION AND CONTROL OF NOSOCOMIAL INFECTIONS

(Also see Prevention of Nosocomial Pneumonia, Device related Bloodstream Infections and Urinary catheter–associated Infections)

INFECTION CONTROL AND PREVENTION PROGRAMS[1]

Ideally every hospital should have an Infection Control and Prevention Committee consisting of heads of major clinical services, pathologists, microbiologists, hospital matron, senior sisters of the ICU, registrars and physiotherapists. The basic function of such a committee is outlined in Box 10 and comprises of maintenance of surveillance of nosocomial infections, with special reference to the ICU, and formulation of policies and procedures for prevention and control of such infections. It is imperative to lay down a standard policy for sterilization of instruments and other invasive gadgetry used in the ICU. Frequent checks should be carried out to ensure that strict standards once formulated are meticulously followed.

Frequent educational updates for nurses and house doctors on the correct use and management of invasive devices, or of other devices responsible for nosocomial infection, are of great help. These devices include urinary catheters, all varieties of intravascular catheters, equipment for hemodynamic monitoring and for hemofiltration, tracheostomy and endotracheal tubes, mechanical ventilators, nebulizers and other gadgets used for respiratory therapy.

Box 10: The role of a nosocomial infection control committee

- Surveillance of nosocomial infection, particularly in the ICU
- Formulation of policies and procedures for prevention and control of such infections
- Laying down of a standard, strictly followed policy for the effective sterilization of instruments and other gadgetry used in the ICU
- Holding educational updates for nurses and house doctors on the correct use and management of invasive devices, or of other gadgetry contributing to nosocomial infection (see Text)
- Formulation of a broad policy on the use of antibiotics in the ICU
- Investigation of a nosocomial outbreak
- Implementation of immunization programs (particularly against Hepatitis B virus), and protection against infection (all fulminant infections and HIV infection) of medical, nursing, paramedical and other hospital staff. Special emphasis should be laid on protection of those working in the ICU and other high-risk areas within the hospital

Abbreviations: ICU, intensive care unit; HIV, human immunodeficiency virus.

Instructions on the correct use and handling of gadgetry should be extended to the operating theater staff, with special reference to the cardiopulmonary bypass machine, and the use of the intra-aortic balloon pump.

A policy should be formulated on the use of antibiotics in the ICU, though sufficient latitude needs to be given to the treating consultant within the framework of such a policy.

The Infection Control Committee should shoulder the responsibility of promptly investigating a nosocomial outbreak. Finally, it should supervise and implement immunization programs and protective measures against infection, for the medical, paramedical, nursing and other personnel working in the ICU and other high-risk areas of the hospital.

It is beyond the scope of this chapter to cover and discuss at length the various factors contributing to nosocomial infections in the ICU. Nevertheless, some basic practical points need to be emphasized (Box 5).

Hand Hygiene[2]

Hand hygiene is perhaps the most important measure for preventing nosocomial infection and includes the use of alcohol rubs as well as soap-based agents for handwashing. Hands should be thoroughly washed with soap and water, followed by a hand rub with an alcohol-based agent with or without chlorhexidine before touching or handling a patient in the ICU. Bar soaps easily get contaminated with microorganisms and hence their use must be discouraged. Liquid soap containing dispensers are preferred in the ICU. Washing hands is also imperative before examining or dressing a wound, performing an invasive procedure, or touching invasive devices used in patient care. Hand hygiene should always be performed with an alcohol-based antiseptic when one has finished with the patient, as contamination of the hands with pathogenic organisms will almost certainly have occurred. ICU personnel, in our experience, frequently carry Gram-negative bacilli and *Staphylococci* either on the skin, or nares or within the throat. Yet the habit of handwashing seems extremely difficult to inculcate in all workers (including doctors) in the ICU. Alcohol rubs are advantageous in that they are fast acting (15–20 sec) and have the widest spectrum of activity against various microorganisms. Alcohol rubs are the best in settings where the quality of water cannot be relied upon. When using an alcohol rub, one needs to ensure that the hands are rubbed dry for the rub to be effective in killing the microorganism. As per the WHO recommendations, it is mandatory to wash hands with soap and water when the hands are visibly soiled with organic matter like blood or body

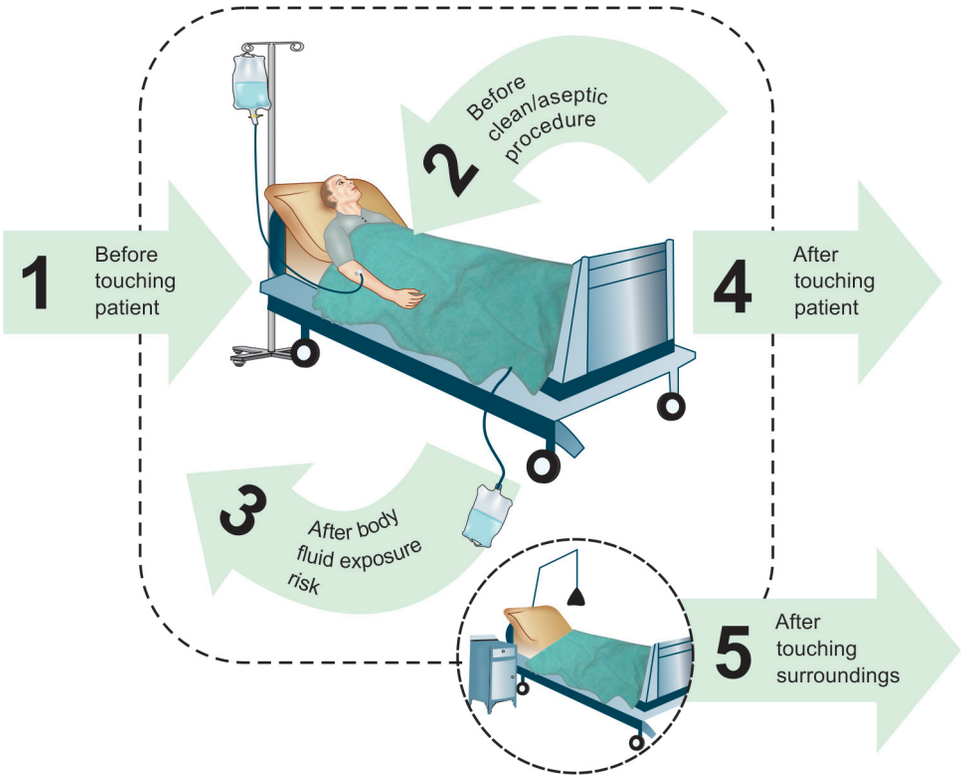

Fig. 8: Five moments of hand hygiene
Source: World Health Organization.

fluids and when caring for patients who are carrying spore bearing organisms like *C. difficile, C. tetani* and others.

The World Health Organization (WHO) recommends the "five moments of hand hygiene" at all times of patient care (Fig. 8).

Use of Reliable Chemical Disinfectants and Antiseptics

Perfect sterilization and disinfection encompass almost all measures aimed at preventing nosocomial infections. The failure of a disinfectant to disinfect reusable respiratory apparatus, ventilator tubings, or a patient's skin prior to an invasive procedure can be responsible for serious outbreaks of nosocomial infection. Contamination of disinfectants and antiseptics leading to nosocomial outbreaks is a well-known phenomenon all over the world.[3] Povidone iodine, a common antiseptic agent used in the ICU has been responsible for four nosocomial outbreaks due to *P. aeruginosa* in the USA.[4] Hence, when suspecting a common source outbreak in the ICU, sampling disinfectants and antiseptics is very important.

Careful Use of Invasive Devices and Other Gadgetry Known to Cause Nosocomial Infections

A few points need to be emphasized—

- It is tempting to use invasive gadgetry just because it is waiting to be used! Developing countries are fortunate in a way because not all ICUs are very well-equipped and invasive monitoring equipment like Swan-Ganz catheters are expensive. With greater experience, invasive monitoring is done only in selected problem patients, in whom diagnostic assessment is difficult, and whose management is therefore uncertain.
- Ventilator tubings should not be changed frequently as was thought earlier. Bacterial filters in ventilators should be changed every 48–72 hours. Every precaution should be taken to prevent nosocomial infections through nebulizers. Nebulizing solutions may sometimes be contaminated and cause nosocomial pneumonia. It is wrong to use nebulizers unless they are of clear benefit to the patient; routine use of nebulizers should be strongly discouraged.
- Central venous lines are removed as quickly as possible. It is best to remove a catheter in the radial artery (used for monitoring blood pressure) by the 5th day. When central lines are suspected to cause nosocomial infection, catheter tips should be cultured in a correct manner (see subsection on Catheter-Related Infections). Blood cultures through a CVC and simultaneously through a peripheral vein help in the diagnosis of device-related blood stream infections.
- Urinary catheters are the commonest cause of nosocomial infections. They should be meticulously cared for.
- Tracheostomy tubes should be changed every 7 days. The no-touch technique for tracheal aspiration through

a tracheostomy tube or through an endotracheal tube is vital. Every single suction should be carried out like a surgical procedure. It is not necessary to wear gloves for suction, but the hands should be thoroughly scrubbed. Sterile gloves however should be worn for changing a tracheostomy tube or for dressing a tracheostomy wound.

Carefully Planned Use of Antibiotics (Also See Use of Antibiotics in the ICU)

An indiscriminate use of antibiotics can cause an ecological disaster, characterized by the multiplication of resistant bacteria in the ICU. This has been observed all over the world. Resistant organisms include methicillin-resistant Staphylococci, Gram-negative bacilli including Proteus, *Klebsiella spp.*, *Enterococci* and *P. aeruginosa* resistant to third generation cephalosporins and aminoglycosides, and fungi, in particular, *Candida*. These resistant organisms cause great problems in management, and are the source of serious nosocomial infections that can wreak havoc in an ICU setting.

Circumspection and Care in Use of Antacids and H_2 Antagonists for Upper GI Bleeding

Since increasing the pH of gastric acid contents by antacids and H_2 antagonists promotes colonization of the stomach, it is wise not to use H_2 antagonists routinely in all critically ill patients as prophylaxis for GI bleeding. Severe GI bleeding due to acute or chronic gastric or duodenal ulcers can however pose a serious hazard to life, and H_2 antagonists with sucralfate are indicated. Some ICUs prefer to use sucralfate alone, as it prevents a significant change in the pH of gastric contents.[5,6]

Good Nutritional Support

This is vital if nosocomial infections are to be successfully treated. In our country, and in all other developing countries, critical illnesses manifest against a background of poor nutrition. Survival for example in severe tetanus or in nosocomial infections complicating severe tetanus, is absolutely impossible without adequate nutritional support.

Isolation of Patients with Fulminant Infections and of Patients Infected by Resistant Bacteria

Barrier nursing and contact isolation are vital features to combat outbreaks of infection.

Cleanliness of ICU Environment

It is vital to keep the ICU environment as physically clean as possible. The practice of changing shoes and wearing special slippers before entering the ICU is an eyewash, and perhaps contributes to additional nosocomial infections. It is more important to have the floor swabbed with a disinfectant every 3–4 hours through the day and night, to keep bedside tables clean and uncluttered, to keep ceilings, walls and curtains meticulously clean, and to have as little equipment as possible cluttering the unit.

Box 11: Prevention of nosocomial infections

- Thorough hand washing
- Use of reliable chemical disinfectants and antiseptics
- Care over central lines or urinary catheters (care bundle strategy) and other invasive devices
- Tracheostomy care and care of ventilator tubings, nebulizers, and all other respiratory equipment
- Judicious use of antibiotics
- Careful use of antacids and H_2-antagonists
- Isolation of patients with resistant bacteria or fulminant contagious infections
- Keep ICU environment as clean as possible
- Good nutritional support

Abbreviation: ICU, intensive care unit.

The incidence of nosocomial infections in an intensive care unit is also dependent on trained nursing staff and the nurse-patient ratio which ideally should be 1:1. The comparatively low incidence of nosocomial infection in our ICU could partly be due to the fact that in our unit, patient care in relation to washing and cleaning is entrusted only to the nurses, who have been indoctrinated and trained to wash hands promptly after touching a patient. IV lines or other invasive and noninvasive gadgets used for patient care are never touched without first scrubbing the hands. Bedpans and urinals are also solely handled by the nursing staff. In contrast, in all or almost all other units urinals and bedpans are handled by a special group of untrained men and women whose standards of hygiene, to say the least, are deplorable.

Selective Decontamination of the GI Tract

(See Prevention of Nosocomial Pneumonia) (Box 11).

CHAPTER 45

Community-Acquired Fulminant Infections Requiring Critical Care

INTRODUCTION

Important community-acquired fulminant infections requiring critical care in poor developing countries include diseases peculiar to these countries as also diseases which are common to both to the East and West. Important examples of the latter group of diseases are fulminant pneumonia, bacterial sepsis and infections of the neuraxis, all of which have been dealt with in other sections of this book. This section deals with fulminant tropical infections; of these *Pasmodium falciparum* infection leads the list. Other fulminant infections that have been dealt with in this section are tetanus, disseminated hematogenous tuberculosis, complications of severe typhoid fever, fulminant amebic infections, dengue hemorrhagic fever, severe leptospirosis, severe scrub typhus and melioidosis. Each one of these infections presenting in a severe form has a high morbidity and a significant mortality. Prompt diagnosis, early treatment (which to start with is often empiric) and good critical care are crucial for survival.

Fulminant Plasmodium Falciparum Infection—Cerebral Malaria[1]

GENERAL CONSIDERATIONS

Plasmodium falciparum malaria is now unfortunately endemic in many parts of India. It has even become endemic in the city of Bombay (now Mumbai) and its suburbs, and in other major cities of Maharashtra and Gujarat. What is worse; strains resistant to chloroquine are frequently encountered. In certain cities of Gujarat, like Navsari, Surat and Ahmedabad, *P. falciparum* is more often than not resistant to chloroquine.

The global case fatality rate of falciparum infections is around 1% or 2 million deaths per year.[1] *P. falciparum* is the predominant malarial infection in highly endemic areas of Africa,[2,3] and has a high prevalence in South America and Southeast Asia, including India and Thailand.[1-3] Cerebral malaria is the most severe manifestation of *P. falciparum* infection, and is responsible for 80% of 2 million global deaths. If unrecognized and not correctly treated, cerebral malaria is almost certainly fatal. It must however be realized that severe *P. falciparum* infection can also cause death through a fatal involvement of other organ systems, without necessarily producing a significant involvement of the central nervous system.

PATHOPHYSIOLOGY[1,4]

The pathological and clinical manifestations of severe *P. falciparum* infection are caused exclusively by the intraerythrocytic asexual form of the parasite. The parasite exerts a twofold action—

- It induces the formation of protein-rich knobs on parasitized red blood cell (RBC) surface membrane, causing these cells to adhere to the endothelial lining of the microvasculature, through proteins such as thrombospondin, intercellular adhesion molecules and CD36. This cytoadherence leads to a sequestration of the parasitized RBCs in the capillaries and postcapillary venules in the brain and other organs of the body. Obstruction to microcirculation in the brain and other organ systems leads to tissue hypoxia and lactic acid acidosis.
- The interaction between the parasite and the host RBCs is believed to result in the liberation of tumor necrosis factor α, interleukins and other potentially toxic or pharmacologically active compounds such as reactive oxygen species and nitric oxide. These have deleterious local-cum-systemic effects.

It is a combination of the above two factors which is responsible for severe multiple organ dysfunction observed in fulminant falciparum infections. This obstruction to the microcirculation within the brain produces cerebral hypoxia and features of cerebral malaria. Cerebral edema develops in some patients as a terminal event, and is not the chief cause of coma. Global cerebral blood flow is reduced in cerebral malaria, and there is increased cerebral anaerobic glycolysis with an increase in the cerebrospinal fluid lactate concentration.

Widespread damage to endothelial cells can perhaps trigger disseminated intravascular coagulopathy. Decreased antithrombin levels are noted in severe cases, and generally signify a poor prognosis.

Massive intravascular hemolysis with hemoglobinuria is due to heavy parasitemia; hemolysis also occurs in patients with G6PD deficiency, particularly after the use of quinine.

Damage to the alveolar-capillary membrane due to parasitized RBCs obstructing pulmonary capillaries and due to release of cytokines leads to acute lung injury and noncardiogenic pulmonary edema.

Renal failure is an important feature of fulminant infection. Factors producing renal failure include sluggish circulation due to parasitized erythrocytes, renal vasoconstriction, hemoglobinuria and acute glomerulonephritis.

Hypoglycemia is due to parasitemia as also to quinine therapy. Children and pregnant women are particularly susceptible to hypoglycemia which is often asymptomatic. The increased susceptibility in pregnancy is because of pancreatic islet cell hyperplasia, and other metabolic changes associated with the pregnant state.

Translocation of bacterial flora from the gut may be related to mesenteric ischemia produced by parasitized erythrocytes. Gram-negative bacteremia with secondary sepsis may occur. This is especially observed in the "algid" form of *P. falciparum* malaria.

Box 1: Features of severe falciparum infection [World Health Organization (WHO)]

Clinical features—
- Prostration
- Impaired consciousness
- Respiratory distress (acidotic breathing)
- Multiple seizures
- Circulatory collapse
- Pulmonary edema (radiological)
- Abnormal bleeding
- Jaundice
- Hemoglobinuria

Laboratory features—
- Severe anemia (Hb <5 g/dL) or hematocrit less than 15%
- Hypoglycemia (blood glucose <40 mg/dL)
- Acidosis (plasma bicarbonate <15 mmoL/L) or arterial pH less than 7.25
- Renal impairment (urine output <12 mL/kg/hour) or serum creatinine above age-related normal range; persisting after rehydration
- Hyperlactemia [plasma lactate (>5 mmoL/L)]

CLINICAL FEATURES AND COMPLICATIONS[1,5,6]

Severe falciparum infection is characterized by any one or more of the following features—
- A parasite count greater than 15%.
- Cerebral malaria.
- Hematocrit less than 20%.
- Total serum bilirubin greater than 5 mg per cent.
- Gross fluid and electrolyte abnormalities.
- Evidence of multiple organ dysfunction syndrome.
- Temperature greater than 39°C.
- Complicating infection.

The World Health Organization (WHO)[5] has defined severe disease by the clinical and laboratory features shown in Box 1.

CEREBRAL MALARIA

Cerebral malaria can strike with dramatic suddenness, or may be preceded by unremittent fever accompanied by chills or rigors. Usually 10 days after the fever, the patient has a generalized seizure followed by progressive coma. High fever alone can cause delerium and mental obtundation. The term cerebral malaria should be reserved for an encephalopathy due to *P. falciparum* infection, which leads to mental obtundation, often progressing to coma. *P. falciparum* infection can also induce coma which is post-ictal or is due to severe hypoglycemia.

Hyperpyrexia, frequent or rarely continuous seizures, and increasing coma form a triad of symptoms observed in this dreadful disease. Mild neck stiffness is present at times,

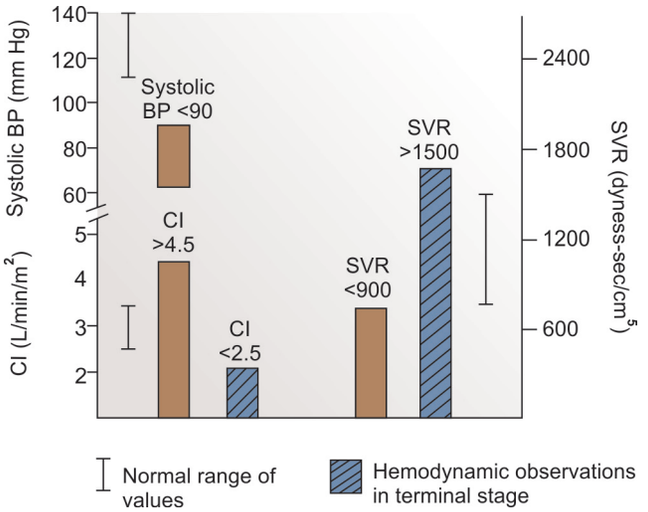

Fig. 1: Hemodynamic observations in fulminant falciparum infections
Abbreviations: CI, cardiac index; SVR, systemic vascular resistance.

Box 2: Pulmonary complications of fulminant falciparum infection

- A fall in PaO_2—inappropriate to the X-ray changes observed
- Acute lung injury of varying severity—
  - Chiefly a V/Q abnormality
  - A marked right to left shunt
- Aspiration pneumonia
- Fulminant pulmonary edema due to hyperpyrexia
- Pulmonary edema due to fluid overload
- Tachypnea with respiratory muscle fatigue
- Nosocomial pneumonia
- Pulmonary embolism

and Kernig's sign may be positive. There is generally no focal neurological deficit. Papilledema is generally absent, but retinal hemorrhages may be seen. Dysconjugate gaze disturbances and in particular skew deviation of the eyes are common, but except in terminal cases the pupillary and corneal reflexes are preserved. Doll's eye movements and oculovestibular reflexes are also generally preserved. Muscle tone is increased, deep jerks are exaggerated, abdominal reflexes are absent, and the plantars are often bilaterally extensor. Extensor thrusts resembling decerebrate rigidity, associated oculogyric crisis, and stertorous breathing may occur in patients who are severely hypoglycemic.

A rare presentation of falciparum malaria is cerebellar ataxia, without disturbance in consciousness. Similar cerebellar signs may be observed in patients recovering from cerebral malaria.

Malarial psychosis is on rare occasions a presenting feature of the disease, though more often than not psychosis follows upon the use of mefloquine or chloroquine.

Fundus examination in adults with cerebral malaria may show retinal hemorrhage, exudates and papilledema. In African children with cerebral malaria retinal changes include macular and retinal peripheral whitening, vessel changes (orange vessels and capillaries whitening) collectively termed malarial retinopathy.[7] We have never observed these changes described in African children in our part of the world.

Fulminant *P. falciparum* infection often produces multiple organ dysfunction, and in our experience 80% of patients with cerebral malaria have complications pointing to other organ system involvement. As has already been pointed out, some patients have severe multiple organ dysfunction without significant cerebral encephalopathy.

Hypoglycemia is very frequent and can occur spontaneously in severe infections with heavy parasitemia, or can occur within a few hours to a few days of starting quinine. Pregnant women and children, as mentioned earlier, are very prone to this complication. Complicating bacteremia also contributes to and worsens the condition.

Patients admitted to ICUs following *P. falciparum* infection occasionally present with hypotension and shock (algid malaria). Diarrhea and severe gastrointestinal (GI) bleeds are often associated features. This state is believed to be due to Gram-negative endotoxemia, probably due to translocation of bacteria from the gut.

The cardiovascular manifestations[8] are often similar to those observed in endotoxin shock, and are typically characterized by hypotension, a lowered systemic vascular resistance (SVR) and an increased cardiac index (CI). A low CI with an increased SVR may be observed in terminally ill or in fulminant cases and is of ominous significance (Fig. 1).

The pulmonary manifestations[8,9] of the fulminant form of the disease are characterized by the evolution of acute lung injury which may be mild, moderate or severe in intensity. The severe form of the disease is associated with a large right to left shunt in the lungs and is generally fatal. Acute pulmonary edema sometimes occurs suddenly and is observed with hyperpyrexia greater than 107°F; this is generally fatal within a few hours. Pulmonary edema also occurs terminally in a number of patients dying of falciparum infection.

Aspiration pneumonia is frequently seen in fulminant infections; nosocomial pneumonia may also occur particularly in patients on ventilator support. Other pulmonary complications include pulmonary edema due to fluid overload and the occurrence of marked tachypnea even in the absence of acute lung injury or acute respiratory distress syndrome (ARDS). Tachypnea in old, feeble and malnourished patients with hyperpyrexia invariably leads to respiratory muscle fatigue and respiratory arrest. Elective intubation and respiratory support is life-saving in these patients. Rarely death may occur from pulmonary embolism. The pulmonary complications of fulminant falciparum infection are listed in Box 2.

The renal manifestations include oliguria, a rise in serum creatinine, and a mild-to-moderate renal insufficiency. Acute tubular necrosis with renal shutdown is occasionally observed, particularly in the presence of hemolysis.

Acute hemolysis can also occur in patients who do not have a G6PD deficiency, and who have not received quinine. It is probably due to heavy parasitemia. Classical blackwater fever is the association of hemoglobinuria with severe manifestations of *P. falciparum* infection in a non-immune patient, who is not G6PD deficient.

Spontaneous bleeding from gums and the GI tract may be encountered. Fulminant malaria can also produce generalized bleeding due to a disseminated intravascular coagulopathy.

Jaundice is frequently present with the serum bilirubin being generally elevated to about 5 mg/dL, and this is accompanied by a modest rise in the serum transaminases. Deepening jaundice (serum bilirubin >15 mg/dL), with a disseminated intravascular coagulopathy initially mistaken as viral hepatitis or obstructive jaundice, is an occasional presentation.

Splenic rupture is an uncommon complication; it can occur even after minor trauma, and is rarely spontaneous, perhaps due to sudden acute splenic enlargement.

Hyponatremia [due to inappropriate antidiuretic hormone hypersecretion (SIADH)], and a lactic acid acidosis are seen quite frequently in severe infections.

Multiple organ systems are often involved with increasing dysfunction, failure and ultimate death. In hyperfulminant cases, death may ensue within 24 hours.

Diagnosis[1,10]

The clinical picture of an encephalopathy or of an encephalopathy with multiple organ dysfunction, should point to cerebral malaria particularly in an area endemic for *P. falciparum* infection. The spleen may or may not be palpable. In fulminant cases, there is probably no time for the spleen to enlarge. A palpable liver and spleen in the presence of the clinical features described above are useful pointers to the correct diagnosis. Repeated blood smears for malarial parasites should be done, and when a clinical diagnosis is highly suspect, specific treatment for falciparum infection should be promptly started. Diagnostic tests to confirm or establish any other diagnosis producing a similar clinical picture must be persisted with. It must be remembered that at times (on rare occasions), no parasites can be found in peripheral blood smears from patients suffering from fulminant falciparum infection. This may be related to partial antimalarial treatment, or due to sequestration of parasitized cells in vascular beds of different organ systems. The importance of starting empiric treatment in critically ill patients with an illness compatible with fulminant *P. falciparum* infection is obvious. Time is of essence in severe infections; a delay of 24 hours or even less spells the difference between life and death.

When treatment is delayed to a point in time when multiple organ systems are already dysfunctional, death can occur from progressive multiple organ failure even when specific therapy has eliminated parasites from the blood. There is therefore a point of no return in some patients even with the best critical care if specific therapy is offered late in the natural history of the disease.

Enzyme-linked immunosorbent assays (ELISA) and radioimmunoassays (RIA) can detect 0.0001% of parasitemia.[3] Recently developed probes using genomic or synthetic *P. falciparum* deoxyribonucleic acid (DNA) can detect as little as 0.01 mg of parasite DNA after just 1 week's exposure. These are basically for research and epidemiological surveys, and have no role in the management of acutely ill patients in ICUs of poor developing countries.

Laboratory investigations should always include blood glucose levels; they should also include laboratory tests which monitor the function of different organ systems of the body. Fluid, electrolyte and acid-base studies are important, as derangement of these parameters can be easily rectified.

Though leucopenia or a normal leucocyte count is the rule in fulminant falciparum infections, a mild neutrophilic leucocytosis does not exclude the diagnosis. Blood cultures for bacteremia should always be done in the presence of a neutrophilic leucocytosis.

Differential Diagnosis

Mistakes in diagnosis are frequent, and would probably include consideration of a large cross-section of emergency medicine. Fever, hepatosplenomegaly, jaundice with increased liver enzymes and an increased bleeding tendency can also occur in dengue, leptospirosis, typhoid and other hemorrhagic fevers. Typhoid though is not generally accompanied by purpura or an increased bleeding tendency. Heat stroke in the hot summer months in North India bears a close resemblance to cerebral malaria. Acute pyogenic meningitis can be easily differentiated by a cerebrospinal fluid (CSF) examination. The association of fever with convulsions is also observed in encephalitides, metabolic encephalopathy, status epilepticus, cerebrovascular accidents, poisonings and eclampsia.

The algid form may be mistaken for heat exhaustion or food poisoning. Nonspecific abdominal pain in fulminant infections has convincingly mimicked an acute abdomen. Icterus with fever may be mistaken for viral hepatitis. The presence of fever with multiple organ system dysfunction may be mistaken for Gram-negative sepsis. Fulminant *P. falciparum* infection in fact constitutes protozoal sepsis.

Fulminant falciparum infection presenting with or soon evolving into disseminated intravascular coagulation (DIC) can be mistaken for overwhelming bacterial sepsis or DIC due to other causes. Fever with shock (algid malaria) may mimic dengue, septic shock, cardiogenic shock, hypovolemic shock or shock caused by an intra-abdominal catastrophe.

In fact fulminant falciparum infection may mimic almost every medical emergency that finds its way into a critical care unit. The differential diagnosis of severe fulminant *P. falciparum* infection is listed in Table 1.

MANAGEMENT[1,11]

Patients with fulminant *P. falciparum* infection, and, in particular, with cerebral malaria, require prompt admission to the ICU. A central venous line should be quickly secured

Table 1: Differential diagnosis of severe fulminant *P. falciparum* infection

Clinical presentation of severe (fulminant) P. falciparum infection	*Differential diagnosis*
Fever, splenomegaly, jaundice with increased liver enzymes with or without purpura or bleeding tendency	Dengue, leptospirosis, salmonella infection
High fever or hyperpyrexia with mental obtundation	Heat fever in hot summer months Pyogenic meningitis
Fever with convulsions	Encephalitides, metabolic encephalopathy, status epilepticus, cerebrovascular accident, poisoning and eclampsia
Algid form	Heat exhaustion and food poisoning
Nonspecific severe abdominal pain	Acute abdomen
Fever with jaundice	Viral hepatitis
Fever with multiorgan dysfunction	Bacterial sepsis
Fever with pulmonary edema [acute respiratory distress syndrome (ARDS)]	Leptospirosis, dengue, salmonella infection, other causes of noncardiogenic pulmonary edema
Fever, hemolysis with hemoglobinuria	Hemolytic uremic syndrome—other causes of hemolysis and hemoglobinuria
Fever with shock	Dengue, cardiogenic shock, hypovolemic shock, shock due to an intra-abdominal catastrophe
Fever with disseminated intravascular coagulation (DIC)	Fulminant dengue, DIC due to bacterial sepsis; other causes of DIC

and all vital signs carefully monitored. If a clinical diagnosis is made, a careful search for malarial parasites by an experienced pathologist in thin and thick peripheral smears is almost always rewarding. Blood cultures, blood glucose, serum electrolytes and arterial pH and blood gas analysis are done. If in an area endemic for malarial infection, early investigations reveal no clear cause for a clinical picture strongly suggestive of cerebral malaria, specific treatment against *P. falciparum* infection should be promptly started and continued, unless another definite cause for the illness is established.

Specific Therapy[1]

Many patients with *P. falciparum* malaria in India, Africa, Southeast Asia and in other endemic areas of the world are resistant to chloroquine. The drug should therefore not be used in *P. falciparum* infection, more so in fulminant falciparum infection where urgency of appropriate treatment is vital for survival. Specific antimalarial chemotherapy detailed below should be given not only to those with severe proven falciparum infection, but also to those living in endemic areas where a critical illness is compatible with or indistinguishable from fulminant falciparum infection.

The drug of choice at present is artesunate, treatment being initiated by an intravenous (IV) bolus injection. Artesunate given parenterally has replaced quinine as the drug of choice both in patients with severe falciparum infection and in patients who are vomiting and unable to retain swallowed tablets.[12,13]

The dose of artesunate is 2.4 mg/kg IV (loading dose) on the 1st day, followed by 1.2 mg/kg IV daily for a minimum of 3 days and preferably 5 days or until the patient can take oral therapy. The drug can also be given in the above dosage by intramuscular (IM) injection, though the IV mode of administration is clearly preferred.

Artemether®by IM injection or quinine by intermittent or continuous IV infusion is less effective when compared to artesunate.

The recommended dose of Artemether® is 3.2 mg/kg IM as the loading dose followed by 1.6 mg/kg IM daily for a minimum of 3 days and preferably 5 days or even more days until the patient can take oral therapy.

The recommended dose of quinine is 20 mg salt/kg loading dose diluted in 10 mL isotonic saline/kg given IV over 4 hours, followed by 8 hours after start of the loading dose with 10 mg/kg over 2 hours every 12 hours until the patient can swallow.

The 7-day course should be completed with quinine tablets 10 mg slat/kg (maximum 600 mg) every 8–12 hours.

In patients admitted to the ICU where they are under close observation the recommended dose of quinine is 7 mg of the salt/kg IV as the loading dose by an infusion pump over 30 minutes, followed immediately with 10 mg salt/kg IV over 2 hours every 12 hours till the patients can swallow.

Quinidine can be used in place of quinine but dangerous arrhythmias can occur. We have never used quinidine even when it was available in India. At present the drug is not available either for oral or IV use.

If facilities for giving IV injection or infusion are not available either artesunate or Artemether® can be given intramuscularly, the dose of each being the same as stated above.

Quinine can also be given intramuscularly if IV infusion for some reason is not possible. The dose is 20 mg/kg diluted

to 60–100 mg/mL as the loading dose, followed by 10 mg salt/kg every 8 hours until the patient can swallow. Quinine when given intramuscularly can cause severe tissue necrosis leading at times to abscess formation. Tetanus is a known complication following IM quinine. It can be avoided by scrupulous sterile precautions.

If it is not possible to give drugs by IV infusion or by IM injection, or if it takes time for parenteral therapy to be arranged, artemisinin can be used in the suppository form—40 mg/kg loading dose as an intrarectal suppository, followed by 20 mg/kg at 4, 24, 48 and 72 hours, followed by an oral anti-malarial drug.

Outside large cities, particularly in smaller districts of India, artesunate is often unavailable, the only drug for systemic parenteral use being quinine. It is therefore important to be aware of the side effects and toxic effects of quinine.

Hypoglycemia is the most important complication of quinine therapy. Quinine also produces cinchonism, characterized by tinnitus, impaired hearing, blurred vision, tremors and giddiness. The most dangerous side effect of quinine, particularly when used intravenously, is the occurrence of arrhythmias—in particular, ventricular tachycardia. A prolonged QTc interval is a warning of the possible occurrence of such arrhythmias. ECG monitoring is therefore very necessary in critically ill patients. Rarely hemolysis, thrombocytopenia and granulomatous hepatitis are observed. High blood concentrations can cause deafness; blindness and CNS depression, are very rarely seen in patients treated for malaria. In patients who are G6PD deficient, quinine can cause severe hemolysis.

13

FEATURES OF NOTE IN PARENTERAL THERAPY OF SEVERE FALCIPARUM INFECTION

1. The malarial parasite continues to outwit human ingenuity. Drug resistance remains an ever worrying problem. There is documentation of in vitro resistance of the *P. falciparum* parasite to artemisinin with delayed clearance of the parasite in Pailin, western Cambodia and possibly in neighboring countries.
2. The use of anti-malarial drugs is poorly controlled; availability of drugs in areas of the world where the disease is highly endemic is uncertain.
3. Fake drugs continue to penetrate the markets of Asia and Africa.
4. It is not sufficiently realized that since most deaths with falciparum infection occur within 4 days of starting therapy it is vital to achieve parricidal levels of the parenteral drug used as quickly as possible. As in severe sepsis from other causes "time" is crucial if patients are to be salvaged.
5. In fulminant infection, there are some who prefer to use parenteral *artemisinin and quinine*. There is no evidence that the use of both is synergistic and is better than the use of either one or the other.

Table 2: A parenteral chemotherapy schedule for severe falciparum infection

Drug	*Dose*
Artesunate	2.4 mg/kg IV (loading dose) on the 1st day, followed by 1.2 mg/kg IV daily for a minimum of 3 days and preferably 5 days or until the patient can take oral therapy. The drug can also be given in the above dosage by IM injection
	OR
Quinine	20 mg salt/kg loading dose diluted in 10 mL isotonic saline/kg given IV over 4 hours, followed by 8 hours after start of the loading dose with 10 mg/kg over 2 hours every 12 hours until the patient can swallow. Later 600 mg tds orally for 7 days
	OR
Artemether®	3.2 mg/kg IM as the loading dose followed by 1.6 mg/kg IM daily for a minimum of 3 days and preferably 5 days or even more days until the patient can take oral therapy

6. In the treatment of falciparum malaria which is not severe or fulminant, artemisinin-based combined therapy (ACT) has been advocated to prevent resistance. ACT consists of the use of artemisinin derivatives combined with drugs such as mefloquine, amodiaquine or pyrimethamine—sulphonamide. The WHO (2006) now recommends that combination therapy replaces monotherapy in the treatment of uncomplicated *P. falciparum* infection.[1] This has proved effective except in Southeast Asia (Cambodia, Thailand and Burma) where resistance to artemisinin has been reported.

The drugs combined with artemisinin depend on the resistance of local strains of *P. falciparum*. In Southeast Asia lumefantrine or mefloquine may be added; in Africa lumefantrine, amodiaquine or pyrimethamine-sulfonamide may be added. The drugs and their dosage commonly used in severe falciparum infection are listed in Tables 2 and 3.

CRITICAL CARE[14,15]

Overall critical care is of vital importance. The central venous pressure is best maintained around 5–7 mm Hg, as overhydration carries the risk of inducing ARDS in these patients. Hyperpyrexia must be controlled with tepid sponging, cooling blankets and paracetamol. Fluid, electrolyte and acid-base balance must be meticulously maintained.[15] Intravenous dextrose is generally continued during quinine therapy to counter hypoglycemia.

In obtunded or comatose patients with cerebral malaria, it is important to protect the airway by elective intubation; every effort must be made to prevent aspiration pneumonia. Intravenous mannitol is used if there is an increase in intracranial pressure. Seizures are controlled by 20–40 mg diazepam given as a titrated infusion in 5% dextrose or by IV 2 to

Table 3: Chemotherapy for chloroquine sensitive P. falciparum or P. vivax, P. ovale, P. malariae, or when the patient cannot swallow

Drug	*Dose*
Chloroquine	The initial dose of 10 mg/kg should be administered over a period of not less than 8 hours, preferably by very slow intravenous infusion. Subsequent infusions of 5 mg/kg should be administered every 8 hours until a total dose of 25 mg/kg has been given
	OR
Quinine	20 mg/kg IV loading dose in 5% dextrose over 4 hours, followed by 10 mg/kg over 2–4 hours q8 h (maximum 1800 mg/d)—20 mg/kg IV loading dose in 5% dextrose over 4 hrs, followed by 10 mg/kg over 2–4 hrs q8h (maximum 1800 mg/d) until PO therapy can be started. Later 650 mg TDS × 7 days

4 mg lorazepam. Dilantin sodium may be given intravenously in addition. Delirious patients must be carefully restrained through good nursing care. A fall from the bed can precipitate a splenic rupture, a rare but recognized complication.

Ventilator support is always indicated in comatose patients particularly in the presence of seizures. It is also indicated in patients with ARDS or in severely tachypneic patients even when there is no evidence of acute lung injury.

Splenic Rupture

Sudden abdominal pain, often associated with pain over the left shoulder should arouse suspicion of a splenic rupture particularly if there has been possible trauma—as, for example, a fall from the bed. Hemodynamic instability or deterioration strengthens this suspicion. An ultrasonography (USG) of the abdomen or a computed tomography (CT) of the abdomen can confirm a splenic rupture with hemorrhage into the peritoneal cavity. Treatment depends on the extent of rupture and the clinical features. Conservative management with blood transfusions and careful observation in a critical care unit may be successful. Surgery may be imperative in difficult situations characterized by a large splenic tear causing hemodynamic deterioration.

Hypotension

Hypotension can be due to hypovolemia, blood loss, hemolysis, septic shock or hypoxia. Management consists of volume expansion with colloids, crystalloids and if necessary with packed cells. Inotropic and vasopressor support are invariably necessary. Suitable antibiotics are used against complicating bacterial sepsis. Proper arterial oxygenation and oxygen transport are important features of critical care.

Renal Failure

Renal failure should be addressed by correcting prerenal factors that can cause oliguria and azotemia. Use of hemofiltration or dialysis may be necessary till kidney function has sufficiently recovered.

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy is a dreaded complication. It should be treated with IV vitamin K, infusions of fresh frozen plasma, cryoprecipitate, prothrombin complex and platelet infusions.

Support to all organ systems is necessary for survival in critically ill patients.

MANAGEMENT OF PREGNANT WOMEN WITH SEVERE FALCIPARUM INFECTION[1]

WHO (2006) has recommended artesunate and Artemether® in preference to quinine in the second and third trimesters of the pregnancy because they do not cause recurrent hypoglycemia. However, blood glucose must be checked daily in pregnant women whether or not they have been prescribed quinine. In the first trimester WHO recommends quinine in preference to artemisinin derivatives as the risk of hypoglycemia with quinine is lesser than the potential greater risk to the fetus following the use of artemisinin.

Induction of labor, cesarian section, accelerating the second stage of labor should receive prompt serious consideration in pregnant women with severe falciparum infection.

HYPERPARASITEMIA AND EXCHANGE BLOOD TRANSFUSION

Hyperparasitemia (>500,000/μL) or greater than 20% in nonimmune patients is believed to be associated with a high mortality. Exchange blood transfusion, hemopheresis and even plasmapheresis have been used with success in these circumstances, particularly when there is a poor response to specific chemotherapy. The above procedures would not only sharply reduce parasitemia, but also remove cytokines, other noxious mediators and restore RBC mass, platelets, clotting factors and albumin.

We have however never been advocates of exchange transfusions even before the introduction of artemisinins. Artemisinins now get rid of parasitemia very quickly, so that it is doubtful whether additional reduction of the parasitic load is of significant help.

MORTALITY[16]

In good units, severe *P. falciparum* infections should not carry an overall mortality greater than 20–25%. The mortality in our unit for just single organ failure is less than 10%. The mortality for two organs failure approximates 20%; it increases to 50% when three or more organs fail. Krishnan and Karnad[16] in an excellent study on 301 patients with severe *P. falciparum* infection observed a mortality of 48.8% with two or more organ failure. Even so, this is one tropical condition where multiple organ dysfunction and failure is not necessarily associated with as forbidding a mortality as that reported in western literature. We have observed that

in patients seeking early admission, prompt treatment with an artemisinin or quinine and good critical care can lead to survival even when SOFA scores are as high as 12–15 [see Chapter Multiple Organ Dysfunction Syndrome (MODS)].

Mortality is frequently but not necessarily related to the degree of parasitemia; yet, a parasite count greater than 500,000 mL is believed to carry a 50% mortality. Severe ARDS carries a bad prognosis, as does complicating bacterial infection. Fulminant disseminated intravascular coagulopathy in association with severe ARDS is invariably fatal. Persistent lactic acid acidosis, profound persistent hypotension are associated with a high mortality.

ACUTE VIVAX, OVALE, MALARIAE MALARIA[1]

Acute vivax malaria is associated with symptoms of fever with severe rigors followed by drenching sweats; but the mortality is very low. Certain forms of vivax malaria pose life-threatening emergencies. These are briefly mentioned below—

- Vivax malaria can lead at times to severe anemia which may be life-threatening in debilated individuals.
- Splenic rupture is more common in vivax infection rather than in falciparum infection. It can occur following even minor trauma, or spontaneously following sudden rapid enlargement of the spleen.
- Acute respiratory distress syndrome is now a well-recognized complication of vivax infection and carries a significant mortality, particularly if not correctly treated.
- Cerebral vivax malaria has occasionally been reported though some of these patients may have an associated undetected falciparum infection.

P. ovale malaria causes negligible mortality but *P. malariae* can lead to chronic morbidity and mortality by causing nephrotic syndrome and the tropical splenomegaly syndrome. Cerebral malariae malaria has been reported; it is rare and the possibility of an associated *P. falciparum* infection cannot always be excluded.

Treatment of *P. Vivax, P. Ovale, P. Malariae* Malaria

Chloroquine is the treatment of choice. Severe infection will require parenteral treatment. Chloroquine resistant *P. vivax* infection is treated by increasing doses of oral chloroquine. The oral dose of chloroquine is 600 mg base on the 1st and 2nd day; 300 mg on the 3rd day.

TETANUS

INTRODUCTION

Tetanus is a killer disease afflicting the poor underprivileged people of the developing third world countries. It is caused by contamination of a wound by *Clostridium tetani (C. tetani)*, which is a Gram-positive, anaerobic and spore-forming organism. The spores gain entry through any wound; only the wound may be so minor that it may escape notice. Patients with tetanus require critical care, and in the larger cities of India are admitted either to special tetanus wards (equipped as ICUs) or to general medical ICUs. The fulminant form of the disease is a challenge to all that critical care medicine stands for. Successful management necessitates the application of every basic tenet of critical medical and nursing care.

The mortality of neonatal tetanus worldwide is close to 1,000,000 deaths each year. In our country, as also in other third world countries, the disease chiefly afflicts the younger age group between 17–30 years. In the west, the disease is extremely rare, and is nearly extinct in some countries. When it does occur, it is commoner in people older than 50 years, in whom the effects of immunization have worn off, in the non-immunized, in the impoverished and in drug addicts.

Tetanus is a disease of wounds; any wound however trivial can result in the disease. In fact 20% of patients have no evidence of a wound, nor do they give a history of injury. Contamination of wounds by manure, garden soil, or rusty implements is particularly dangerous. In our part of the world, tetanus can complicate burns, middle ear infections, septic abortions, childbirth and surgery. Tetanus neonatorum is most often due to non-sterile obstetric techniques, and to the dreadful habit of application of infected material such as cowdung to the umbilical stump.

PATHOPHYSIOLOGY[1,2]

Under anaerobic conditions, tetanus bacilli within a wound produce a neurotoxin called tetanospasmin. This toxin spreads to underlying muscles and is bound to receptors containing gangliosides on the neuronal membranes of the presynaptic nerve terminals. It is then internalized and transported intra-axonally and retrogradely within the peripheral nerves to the motor horn cells of the segment of the cord supplying the muscles. The toxin also invariably enters the bloodstream. It does not cross the blood-brain barrier, but via the blood it reaches and is bound to numerous nerve terminals in muscles throughout the body. It is then transported intra-axonally and retrogradely along numerous peripheral nerves to reach the alpha motor neurons of the whole spinal cord and brainstem. It also reaches the sympathetic ganglia, the lateral horns of the spinal cord and the parasympathetic centers. After reaching the cell bodies in the spinal cord and the brainstem, the toxin crosses the presynaptic cleft, and is bound to receptors on presynaptic nerve terminals of inhibitory interneurons (Fig. 2). Tetanus toxin now blocks the release of inhibitory neurotransmitters (chiefly glycine and gamma aminobutyric acid) from nerve terminals of inhibitory neurons.

The motor and autonomic neurons are now devoid of inhibitory control which lead to an uncontrolled, disinhibited efferent discharge from motor neurons of the spinal cord and brainstem to both agonist and antagonist muscles, causing muscle rigidity and reflex muscle spasms that characterize the generalized forms of the disease. Disinhibited autonomic discharge leads to excessive sympathetic activity with increased catecholamine levels in the blood, as also to excessive parasympathetic activity. Medullary and other centers in the brainstem and the hypothalamus may also be affected by tetanus toxin. The direct action of tetanus toxin on organ systems has not been proven, but remains a distinct possibility.

ALTERED HEMODYNAMICS[1-3]

Severe tetanus is characterized by a hypermetabolic, hyperdynamic, hyperkinetic circulatory state with tachycardia and an increased cardiac output. The details of the hemodynamics in patients with severe uncomplicated tetanus are illustrated in Figure 3.

Autonomic nervous system disturbances can profoundly affect the circulatory state. Autonomic storms described under complications are characterized by a paroxysmal seizure-like discharge causing marked tachycardia and hypertension. A cessation of this discharge leads to bradycardia and hypotension. Increased parasympathetic activity is as integral a feature of tetanus as sympathetic overactivity. The imbalance between the sympathetic and parasympathetic systems, with fluctuations in tone and activity, leads to marked cardiovascular instability.

Our studies on tetanus suggest that though the myocardium responds well to volume load, the response is not as good as in control subjects.[1-3] Myocardial function is thus suspect; whether this is related to tetanus toxin per se, or is related to factors common to any critical illness, is uncertain. Our experience also suggests that tetanus toxin may have a direct depressant effect on infranodal conduction causing infranodal block and arrest.[1-3]

CLINICAL FEATURES AND DIAGNOSIS

Generalized Tetanus

The two basic clinical features of tetanus are increased muscle tone and spasms. Fulminant tetanus is also invariably associated with autonomic disturbances.

Rigidity or increased muscle tone generally first involves the masseters, resulting in difficulty in opening the mouth—

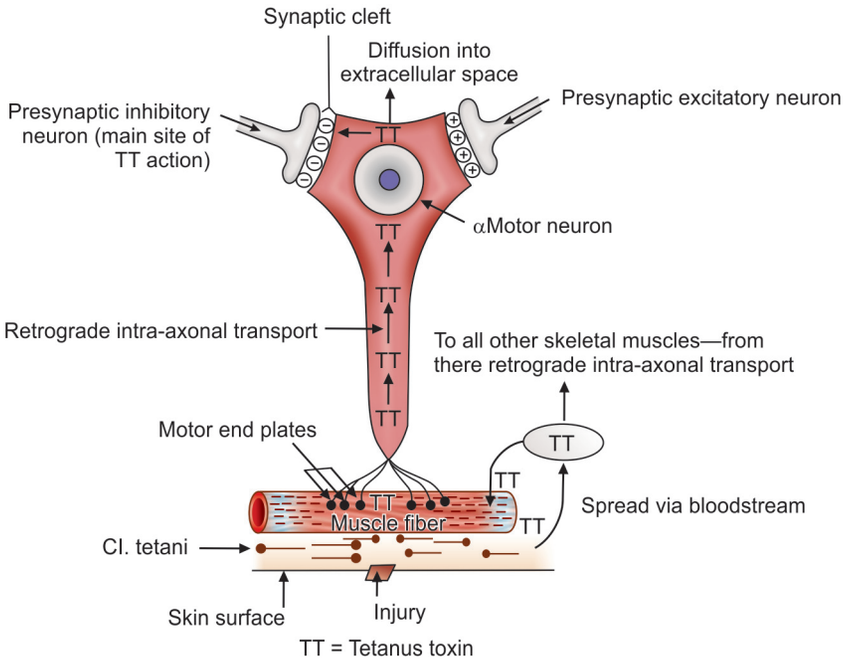

Fig. 2: Retrograde intra-axonal transport and main site of action of tetanus toxin (TT) in the central nervous system. The toxin ascends retrogradely along axons of the peripheral nerves to reach the alpha motor neuron cell bodies. It then crosses the synaptic cleft to reach the terminals of the presynaptic inhibitory neurons where it exerts its main action by binding to receptors on the presynaptic membrane. Tetanus toxin also acts on the neuromuscular junctions of the peripheral nerves, as well as on the presynaptic excitatory neurons. The clinical picture of tetanus is however largely related to its main site of action

13

trismus or lockjaw. It soon involves the muscles of the face giving rise to the typical tetanus facies, with a "risus sardonicus". The muscles of the neck, trunk, back and extremities are all involved. The limbs are ramrod stiff, the abdomen may show board-like rigidity, and increased tone in the muscles of the neck and back can cause opisthotonos with retraction of the head, closely simulating meningitis.

Muscle spasms or seizures form the hallmark of severe tetanus. Seizures are easily induced by touch, noise or emotional stimuli. They often occur spontaneously, and vary in frequency and severity. Spontaneous seizures in the very severe forms of the disease occur at very brief intervals, so that the patient often is in a perpetually convulsed state. Protracted spasms often involve the pharynx, rendering swallowing impossible. Laryngeal spasms can lead to asphyxia. Powerful frequent spasms of the respiratory muscles render breathing impossible, so that the patient becomes hypoxic and even cyanosed.

Severe tetanus is a painful, febrile disease associated with tachycardia, sweating and an unstable cardiovascular system. Unless expertly managed, the patient succumbs to respiratory complications, circulatory failure, cardiac arrest, or to complications causing multiple organ failure.

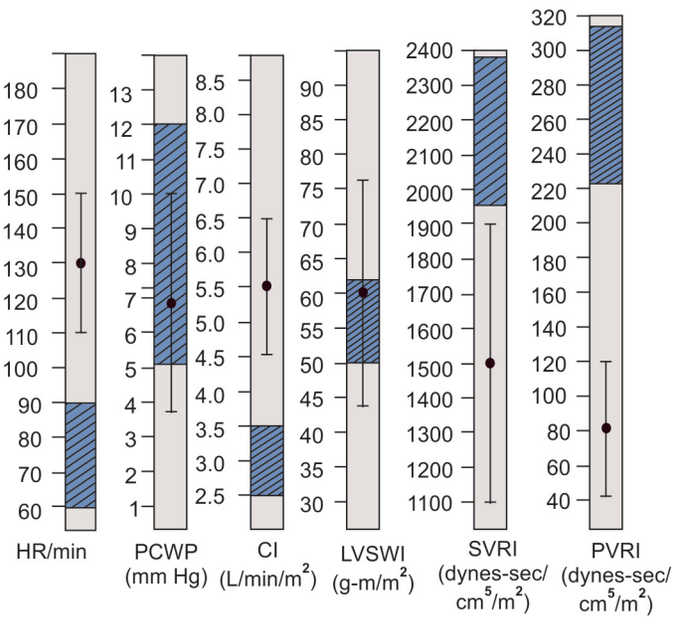

Fig. 3: Hemodynamic observations in 19 patients with severe uncomplicated tetanus (I = mean + SD). Shaded areas show range of normal values. *Abbreviations*: HR, heart rate; PCWP, pulmonary capillary wedge pressure; CI, cardiac index; LVSWI, left ventricular stroke work index; SVRI, systemic vascular resistance index; PVRI, pulmonary vascular resistance index.

Autonomic Nervous System Disturbances

These are intrinsic to severe tetanus. Tachycardia (ranging 150–180/minute) persisting for days on end, drenching sweats, frequent elevations in systolic and diastolic blood pressure, increased salivary and tracheobronchial secretions, and evidence of increased vagal tone and activity are the usual features pointing to autonomic disturbances in severe tetanus.

Grading the Severity of Tetanus

This is not just an academic exercise; it helps in both the prognosis and the management of the problem. The criteria described below are arbitrary, but have been used by us over many years, and have stood the test of time.

Grade I (Mild)

Mild to moderate trismus; general spasticity; no respiratory embarrassment; no spasms; little or no dysphagia.

Grade II (Moderate)

Moderate trismus; well-marked rigidity; mild to moderate, but short-lasting spasms; moderate respiratory embarrassment with tachypnea greater than 30–35/minute; mild dysphagia.

Grade III (Severe)

Severe trismus; generalized spasticity; reflex and often spontaneous prolonged spasms; respiratory embarrassment with tachypnea greater than 40/minute; apneic spells; severe dysphagia; tachycardia usually greater than 120/minute; a steady moderate increase in autonomic nervous system activity.

Grade IV (Very Severe)

Features of Grade III plus violent autonomic disturbances often resulting in what may be aptly termed "autonomic storms" involving the cardiovascular system. These include episodes of severe hypertension and tachycardia alternating with relative hypotension and bradycardia, or severe persistent hypertension (diastolic pressure >110 mm Hg), or severe persistent hypotension (systolic pressure <90 mm Hg).

Cephalic Tetanus[1]

This occurs after wounds to the face or head and is typified by unilateral facial paralysis, trismus and facial stiffness of the unparalyzed side. Pharyngeal spasms causing dysphagia and frequent laryngeal spasms are generally present. Rarely, facial palsy is bilateral. Occasionally there is also paresis of the glossopharyngeal, vagal and rarely the oculomotor nerves. Cephalic tetanus often graduates to generalized tetanus.

Tetanus Neonatorum[1]

Even in the best of units this has a high mortality. The earliest symptom is a difficulty in suckling and swallowing due to stiffness of the masseters and the muscles of the pharynx. Stiffness extends to the face causing the classic tetanus facies. Skeletal muscle stiffness produces flexion at the elbows with the fists clenched and drawn to the thorax, extension of the knees with plantar flexion at the ankles and toes. There is retraction of the head with marked opisthotonos. Muscle spasms render breathing difficult. Autonomic disturbances occur and death results from cardiorespiratory failure.

Local Tetanus

Rarely tetanus is confined to a group of muscles adjacent to a wound, or confined to one limb.

NATURAL HISTORY

The incubation period of tetanus averages 7–10 days, but may range from 2 days to 2 months. The shorter the incubation period, the more severe the disease.

The period of onset is the time interval between the first symptom and the occurrence of muscle spasms or seizures, and it ranges from 1–7 days. The shorter the period of onset, the more severe the disease. The period of onset is a more reliable prognostic guide than the incubation period. The disease increases to its maximum intensity over a period of 7–10 days, then plateaus over the next 1–2 weeks, and then gradually declines over the next 2 weeks. The natural history of the disease is punctuated by numerous complications which have been briefly outlined later. Tetanus is a severely catabolic disease, with the patient remaining in a hypermetabolic state for 3–4 weeks. Significant weight loss is observed even in those who recover, and even when every aspect of nutrition is assiduously cared for.

COMPLICATIONS[1]

The natural history and management of moderate and, in particular, severe tetanus are bedevilled by numerous complications. As mentioned at the outset, any or every organ system can be involved. Respiratory and cardiovascular complications and those involving the autonomic system are inherent to the disease. Others are related to the prolonged management of critically ill individuals who have been paralyzed by curare-like drugs, and maintained on ventilator support for periods extending from 4–6 weeks.

Respiratory Complications[1,4]

These include atelectasis, aspiration pneumonia and bronchopneumonia. Infection is generally due to Gram-negative organisms, chiefly *Klebsiella* and the *Pseudomonas* species. Prolonged laryngeal spasm can produce death from asphyxia. Episodes of acute respiratory distress with tachypnea occur in both moderate and severe tetanus, and are probably related to release of inhibitory control over the respiratory center, induced by the tetanus toxin. Unrelenting continuous spasms render breathing impossible, and unless correctly managed, produce death from acute hypoxia. The adult respiratory distress syndrome is now increasingly

observed—it is chiefly due to iatrogenic sepsis, but can be due to tetanus per se. Complications related to tracheostomy and to prolonged ventilator support (chiefly pneumothorax and nosocomial pulmonary infections) are also observed.

Autonomic Cardiovascular Complications[1,3]

Marked tachycardia, as high as 180/minute has already been commented upon. Severe hypotension, labile hypertension, or persistent severe hypertension are all observed. Hypertensive patients are almost always extremely sensitive to beta-blockers. Severe peripheral vasoconstriction with a shock-like state resulting in rapid death is observed in a few fulminant cases. Autonomic storms are characterized by episodes of sudden severe tachycardia with severe hypertension (BP = 180–220/110–130 mm Hg), alternating within minutes with bradycardia (50–60/minute) and a fall in systolic blood pressure to less than 100 mm Hg. Marked cardiovascular instability results in, and is the forerunner of cardiac arrest and sudden death.

Increased vagal tone is invariably present and is manifested by increased tracheobronchial secretions, by sudden severe bradycardia and hypotension, and even arrest during suctioning of the trachea through the tracheostomy tube.

Cardiac arrhythmias are frequent and include supraventricular tachycardias, ventricular extrasystoles, junctional rhythms and short spontaneously reverting bursts of ventricular tachycardia.

Sudden hyperthermia (rectal temperature >41°C) can occur and result in cardiovascular collapse and death. Hypothermia may also be rarely observed. Sudden fluctuations in temperature are probably related to hypothalamic disturbance.

Sudden Death[1,4]

Sudden death remains the most dreaded complication of tetanus. In our experience, it constitutes the commonest cause of death in patients managed in well-equipped and well-staffed ICUs. Sudden death is related to the following factors—

- Marked cardiovascular instability due to fluctuating sympathetic tone.
- Excessive vagal tone causing reflexly induced bradycardia, hypotension and cardiac arrest.
- Hypoxia due to unremitting seizures or to prolonged laryngeal spasms.
- Hyperpyrexia, often unsuspected and sudden, causing cardiovascular collapse and death.
- Impaired infranodal conduction, probably related to the tetanus toxin per se.
- Massive pulmonary embolism.
- An unrecognized iatrogenic complication, as for example, tension pneumothorax.
- No obvious reason.

Multiple Organ Dysfunctions (MOD)

MOD is frequent in severe fulminant tetanus; it was observed in 22% of our cases. The system most frequently involved is of course the respiratory system, followed by the cardiovascular system, the GI system, the liver and the kidneys. Changes can also occur in the hematopoietic system. Hypotension with systolic blood pressure less than 70 mm Hg necessitating inotropic support may persist for days. GI dysfunction is evinced by ileus and massive bleeds. A rise in the liver enzymes to well above 100 IU, and of serum bilirubin up to 5 mg/dL is frequent. Mild elevations in the prothrombin time to one and half times the control value are also observed. Renal insufficiency is characterized by a rise in serum creatinine up to 3 mg/dL. Rarely acute renal failure requiring dialysis is observed. It is indeed remarkable and noteworthy that multiple organ dysfunction, when not induced by obvious sepsis, does not carry the grim prognosis reported in western literature, and recovery ensues provided excellent care is available.

Other Complications

These are chiefly iatrogenic and related to prolonged ventilator support in critically ill patients. These include sepsis, GI complications (GI bleeds, diarrhea, ileus), renal dysfunction, fluid and electrolyte disturbances, compression fractures of vertebrae, anemia and hypoproteinemia.

Miscellaneous complications include peripheral neuropathy, infected bed sores, thrombophlebitis, corneal ulcers and deep vein thrombosis in the lower limbs; this can result in death due to pulmonary embolism.

A list of respiratory, cardiovascular, autonomic and other complications observed in 233 patients at the JJ Hospital, and in 32 patients with severe tetanus at the Breach Candy Hospital is given in Tables 4 to 6.

DIAGNOSIS

The diagnosis is based on the clinical features; there is no laboratory test that can confirm tetanus. To the experienced eye, tetanus admits of no differential diagnosis. The tetanus facies is unmistakable. It occurs in no other disease, and it simply cannot be mimicked by even a trained malingerer for any length of time. Rarely, trismus may be an early feature of meningitis. A CSF examination clinches the diagnosis, as in tetanus the CSF is normal. Dystonic reactions produced by phenothiazines and metoclopramide bear no resemblance to tetanus, and can be easily distinguished from it. Cephalic tetanus may be mistaken for rabies because of dysphagia; however, hydrophobia is never present in tetanus.

MANAGEMENT[2]

Whenever possible, all patients with tetanus should be admitted to an ICU, or a specially equipped tetanus ward that functions as an ICU. Mild or Grade I tetanus poses no problems except when complicated by a serious or septic wound, which by itself can result in death. However, mild (Grade I) tetanus can graduate over a few days to moderate (Grade II) or even severe (Grades III and IV) tetanus. Even

Table 4: Respiratory complications in 265 patients with tetanus

	Number of patients
• Bronchopulmonary infections—	
– Pneumonia and bronchopneumonia	36
– Lung abscess	1
– Pyopneumothorax with bronchopleural fistula	1
• Significant pulmonary atelectasis	26
• Pneumothorax (iatrogenic)	5
• Pneumomediastinum	5
• Episodes of unexplained respiratory distress	29
• Adult respiratory distress syndrome	9
• Significant stridor	5
• Accidental disconnection of ventilator	1

Note: Atelectasis (segmental or subsegmental) is an invariable feature of severe tetanus. "Significant pulmonary atelectasis" includes only those patients where atelectasis persisted over a day in spite of repeated attempts to open up the involved segment or lobe.

Use of Antiserum

Immediately on admission to our unit the patient is given antiserum. Human tetanus immunoglobulin (HTIG) is superior to the equine antiserum as it does not produce a hypersensitivity reaction, and should be given in the dose of 3,000–5,000 international units intravenously or intramuscularly. However, in poor developing countries, equine antiserum is the only one generally available and 10,000 units are given intravenously after doing a skin sensitivity test. Fatal anaphylaxis can occur even in the absence of a positive skin test. Some workers infiltrate 3,000 units of the antitoxin locally around the wound, but this is of doubtful efficacy.

Antibiotics

Two mega units of crystalline penicillin are given IV for 8 days. Metronidazole, 500 mg IV 8 hourly for 5–7 days, has been currently recommended.

Management Strategies (Table 7)

Grade I or mild tetanus should be treated conservatively with the use of sedatives and muscle relaxants.

Grade II or moderate tetanus should have a tracheostomy done in addition to the use of sedatives and muscle relaxants.

Grade III and Grade IV or severe tetanus require sedation, tracheostomy, neuromuscular paralysis with curare-like drugs, and ventilator support till such time as the disease resolves and recovery ensues.

Table 7: Management strategies according to severity of tetanus

Mild or Grade I tetanus	Sedatives + Muscle relaxants
Moderate or Grade II tetanus	Sedatives + Muscle relaxants + Tracheostomy
Severe or Grades III and IV tetanus	Sedatives + Tracheostomy + Induced neuromuscular paralysis + Ventilator support

Source: Udwadia FE. Tetanus. Oxford University Press, Mumbai; 1994.

Use of Sedatives and Muscle Relaxants

This constitutes the traditional conservative management of tetanus. Even today, sedatives and muscle relaxants continue to be the only therapy available, even for severe cases, in many tetanus units in developing countries all over the world.

In good ICUs and in well-equipped tetanus wards, sedatives and muscle relaxants continue to form the basis of therapy for Grades I and II tetanus. We almost exclusively use diazepam as the drug of choice. The dosage in children and adults is 5–20 mg thrice daily and in neonates 2 mg thrice daily. In moderate (Grade II) tetanus, the drug is used as an IV infusion over 24 hours. We prefer not to exceed a dose of 80–100 mg IV over 24 hours, even in the presence of marked rigidity. Many units both in India and in the West and South America continue to use doses as high as 250–350 mg IV over 24 hours. In our wide experience with this disease over the years, we remain unconvinced that doses more than 80–100 mg/day, given over many days, confer any further benefit, or reduce the mortality associated with this disease. In fact, we feel that very high dosage schedules, as explained later, may do more harm than good, and particularly in the absence of ventilator support, always seriously depress respiration.

Other muscle relaxants in use include chlorpromazine, phenobarbitone, paraldehyde, mephenesin and meprobamate. The last two drugs are hardly ever used. A few units use chlorpromazine, or a combination of diazepam with chlorpromazine or phenobarbitone, or prefer to use all three drugs to help to achieve better control of severe rigidity. The dose of chlorpromazine is 50 mg intramuscularly, four times daily in adults, 25 mg in children and 12.5 mg in neonates. The dose of phenobarbitone is 200 mg in adults, 100 mg in children and 30 mg in neonates, given intramuscularly every 8–12 hours. Dantrolene is a relatively new muscle relaxant which has been used in tetanus; we however have no experience with this drug, but doubt that it has any significant additional advantage over diazepam.

Baclofen, a centrally acting muscle relaxant, has been used intrathecally by some workers, with satisfying results.[5,6] It has no special advantage[7] and, in our opinion, its use is not practical for poor third world countries.

Sedatives and muscle relaxants are of symptomatic use. The ideal sedative and muscle relaxant schedule for each patient should be so tailored as to ensure sedation, muscle relaxation and sleep, but should yet allow the patient to be aroused to obey commands. A practical, objective guide to the degree of muscle relaxation desired in moderately severe tetanus is the tone of the abdominal muscles which should feel relaxed and much less stiff on palpation.

Laryngeal spasm should be countered by an IV injection of 10–20 mg of diazepam, or 50 mg chlorpromazine, or by IV succinylcholine.

Tracheostomy

We consider this necessary even for Grade II or moderate tetanus and absolutely mandatory for Grades III and IV tetanus. In Grade II tetanus, an important cause of death, even in intensive care settings, is sudden, prolonged laryngeal spasm, which causes death by asphyxia. This is easily preventable by doing a tracheostomy. Inability of patients with moderately severe tetanus to swallow well, combined with the use of heavier sedation, are also indications for an elective tracheostomy.

Induced Paralysis with Ventilator Support

Severe tetanus should not be managed conservatively, solely with the use of sedatives and muscle relaxants. Conservative management in these patients carries an appallingly high mortality. These patients not only require an elective tracheostomy, but also need to be paralyzed by neuroparalytic agents and kept on ventilator support. Pancuronium is the neuroparalytic agent generally available in poor countries. Pancuronium 2–4 mg is given IV, and the dose is so titrated for each patient, that the neuromuscular paralysis achieved allows for efficient ventilator support. This is checked by serial measurements of arterial pH and arterial blood gases. The PaO_2 should be maintained greater than 70 mm Hg, and the $PaCO_2$ between 35–40 mm Hg. The initial requirement of the neuroparalytic drug may be as frequent as half to 1 hourly. With time the requirement falls to 2 hourly, and later still to even 6–8 hourly schedules. We prefer to use bolus injections in the manner stated above (as in our opinion these are better tolerated) rather than using a continuous IV infusion of the drug. Newer neuroparalytic drugs include vecuronium used in the dose of 6–8 mg/hour and atracurium (loading dose 0.23 mg/kg followed by an infusion of 5 µg/kg per minute).[8] The high cost of these two drugs however precludes their use in poor developing countries where tetanus is still rampant.

The average period of ventilator support in severe tetanus in our experience varies from 10 days to 6 weeks. Once spasms abate, pancuronium is stopped; ventilator support is however continued till the patient is deemed fit to be weaned. Premature weaning in the presence of excessively stiff chest muscles is unwise, and leads to problems necessitating reintroduction of ventilator support. The tracheostomy tube is removed only when the patient can cough well, swallow satisfactorily, and can handle his upper respiratory secretions without difficulty.

Treatment of Autonomic Circulatory Disturbances

A number of drugs have been used to treat autonomic storms producing severe cardiovascular instability in fulminant tetanus. These include beta-blockers,[9] heavy sedation,[10] IV morphine sulfate,[11] IV clonidine[12] and IV infusions of

magnesium sulfate.[13] However, these drugs do not alter the high mortality in fulminant disease. Our studies on the hemodynamics of severe tetanus have convinced us that it is best to rely on efficient cardiorespiratory support, and to avoid drugs that strongly depress the central or autonomic nervous systems. Hypotensive spells are treated with a volume load, and if this is inadvisable or ineffective, we use a titrated dose of dopamine sufficient to raise the systolic blood pressure just above 100 mm Hg. Hypertensive spells with systolic blood pressure greater than 200 mm Hg or a diastolic blood pressure greater than 110 mm Hg are best treated with 5–10 mg of oral propranolol, the dose being titrated to achieve an effective control over the heart rate and the blood pressure, or sublingual nifedipine (5 mg), or a combination of the above two. The use of IV beta-blockers is best avoided as these patients are extremely sensitive to these drugs, particularly when used intravenously. Bradyrhythms below 50/minute are treated with IV atropine, and severe sinus tachyrhythms greater than 170–180/minute with verapamil 40 mg twice or thrice daily. In patients with a shock-like state with increased SVR and a reduced CI, 2–5 mg morphine given intravenously helps sometimes in effectively reducing the SVR, and improving the cardiac output and tissue perfusion. The dose again needs to be titrated as per the patient's response, and the dose may be repeated, if necessary. Patients with the above-mentioned hemodynamic abnormality, who do not respond to morphine, should be given a trial with a slow titrated infusion of sodium nitroprusside, so as to reduce the SVR. We invariably combine this with simultaneous dopamine inotropic support.

Severe tetanus is often associated with hypotension (systolic blood pressure <70–80 mm Hg). Unless the intravascular volume is definitely depleted, it is unwise to use large fluid challenges to increase the arterial blood pressure. The compliance of both the systemic and pulmonary vasculature is markedly increased in these patients, and volume replacements are literally swallowed up in the compliant vessels, or tend to produce noncardiogenic pulmonary edema and ARDS. The CI may still be markedly raised in the presence of a low arterial blood pressure. Even so, the use of dopamine inotropic support is advocated so as to maintain the systolic blood pressure in young individuals between 90–100 mm Hg, and in older patients close to 120 mm Hg. This ensures adequate oxygen transport and allows for an increased oxygen uptake by hypermetabolic tissues.

In our opinion, high doses of diazepam (150–300 mg/day IV) in severe tetanus are unwise, and may well contribute to a high mortality. Such high doses by strongly depressing the autonomic and CNSs, may predispose to cardiac arrest during episodes of bradycardia and hypotension, or could well prevent successful resuscitation following cardiac arrest. We advocate only 30–50 mg/day of IV diazepam in patients who are paralyzed and on ventilator support.

The management principles enunciated and discussed above have resulted in a mortality as low as 6% in our ICU in patients with severe fulminant tetanus.

Box 3: Summary of the management protocol in tetanus

- Antiserum—Equine antitoxin 10,000 units IV after test dose. If available, 3,000–5,000 IU of human tetanus immunoglobulin (HTIG) preferred
- Antibiotics—Crystalline penicillin 2 mega units IV for 8 days + metronidazole 500 mg IV 8 hourly
- Care of the wound according to general surgical principles
- Sedatives and muscle relaxants—used for all grades of tetanus. The sedative most commonly used is diazepam, 20 mg 8 hourly IV, in adults. We do not exceed a dose of 100 mg/24 hours
- Tracheostomy—done in Grades II, III and IV tetanus
- Induced paralysis + ventilator support—used in Grades III and IV tetanus. Pancuronium 2–4 mg IV as and when required (to start with, every half to 1 hour)
- Treatment of autonomic circulatory disturbances—
  - Hypotensive spells treated with volume load, or if this is ineffective or inadvisable, a titrated dose of dopamine is used for inotropic support. Maintain BP around 100–120/80 mm Hg
  - Hypertensive spells treated with 5–10 mg oral propranolol, or 5 mg sublingual nifedipine, or a combination of both drugs. Avoid IV propranolol. Morphine 2–5 mg IV is used in patients with low CO and high SVR. Morphine in an IV infusion may also be used
  - Bradyrhythms less than 50/min treated with IV atropine
  - Sinus tachycardia greater than 180/min treated with verapamil 40 mg thrice a day
- Treatment of other complications
- Overall critical care and nursing
- Nutrition—maintain a caloric intake of 2,500–3,000 cals/day, with 75–100 g of proteins/day

Treatment of Other Complications

Prevention, prompt recognition and treatment of the numerous complications that can involve almost each and every system, is vital if mortality is to be reduced.

Critical Care and Nursing

No other illness makes greater demands on a critical care unit than severe fulminant tetanus. Critical care of the patient as a whole and expert nursing are of crucial importance. Special emphasis should be laid on meticulous care of the tracheostomy and on good physiotherapy. In addition to maintaining the arterial blood gases within the normal range, adequate oxygen transport must be ensured. Packed cells should be transfused to correct anemia; cardiac output is enhanced by inotropic support, if necessary.

Nutrition

Tetanus is a severely catabolic disease, and generally occurs in patients with a poor nutritional state. Good nutrition is

imperative for survival. A caloric intake between 2,500–3,000 calories/day, with at least 75–100 g of protein is given in the form of liquid or semiliquid food through the nasogastric tube.

A summary of the management protocol in tetanus has been tabulated in Box 3.

PREVENTION

Tetanus is a dreadful disease which is almost totally preventable by proper active immunization and proper care of wounds. An attack of tetanus does not confer immunity from another attack. Immunization with tetanus toxoid should begin during convalescence. Some prefer to administer the first dose of toxoid soon after admission to the ICU. It is fortunate that the overall incidence of tetanus has declined over the last 15 years, probably due to a more efficient immunization program.

MORTALITY

Mortality depends on the severity of tetanus. A short incubation period (<4 days) and a short period of onset (<2 days) signify severe disease and prognosticate a high mortality, often over 50%. Tetanus neonatorum carries a mortality of 60–80%. The overall mortality in tetanus, reported from different countries, ranges from 20% to 60%. In Mumbai till 10 years back, overall mortality in a large teaching hospital was 30%, and the mortality in fulminant tetanus was between 70% and 100%. This high mortality was due to a failure to grasp the principles of critical care and ventilator support. With the management strategies outlined above, the overall mortality in the same teaching hospital fell to 12%, and mortality in severe tetanus to 23%.[4] With better intensive care facilities, the mortality of severe tetanus has been brought down to around 6%.[3] These results amply justify our management strategies discussed above.

ACUTE DISSEMINATED HEMATOGENOUS TUBERCULOSIS

GENERAL CONSIDERATIONS

The problem of acute disseminated hematogenous tuberculosis is of importance in critical care medicine in India, and in other developing countries. This is because of the wide prevalence of tuberculosis in poor countries, and the certain increase in incidence likely to occur with the spread of AIDS in these countries.[1] According to the WHO report (2009) on tuberculosis, the incidence of tuberculosis in India is 168/100,000 population per year.[2] The diagnosis of acute disseminated hematogenous tuberculosis is easy in a patient with known tuberculosis in the recent past. When the problem presents de novo, or when it occurs in immunocompromised patients who are extremely prone to both community acquired and opportunistic pathogens, the diagnosis can be extremely difficult.

CLINICAL FEATURES AND DIAGNOSIS (BOX 4)

Fever of unknown origin is the presenting feature. Clinical deterioration can occur over a period of months, but is observed in a matter of days in immunocompromised individuals.[3] Pulmonary lesions are invariably present, but can be easily missed. Miliary shadows may be undetectable on a portable chest X-ray, and the sputum examination may not be possible, as the patient either has no expectoration, or is too ill to expectorate. At times, the disease manifests with fever and bilateral diffuse shadows in both lungs on an X-ray of the chest. There may be little or no cough and there is generally no sputum. Tachypnea is an important feature; the clinical picture is that of ARDS with well-marked hypoxemic respiratory failure, necessitating intubation and mechanical ventilator support. The relation of these "shadows" within the lung to tubercle can only be proven by examination of the BAL fluid obtained through fiberoptic bronchoscopy. The BAL fluid shows acid-fast bacilli and a transbronchial biopsy often shows ceseating granulomas.

Box 4: Features suggestive of disseminated hematogenous tuberculosis

- Fever of unknown origin lasting over a few weeks, with sudden deterioration especially in immunocompromised patients
- Tachypnea
- Sputum scanty or absent
- Hypoxemic respiratory failure—ARDS
- Initially a hyperdynamic circulation as in sepsis, soon followed by a fall in cardiac output and shock
- Miliary or scattered shadows within the lung
- Diagnosis most often made by fiberoptic bronchoscopy
- AFB present in BAL fluid; caseating granulomas may be seen in transbronchial biopsies
- CT chest or abdomen may show evidence of lymphadenopathy
- Frequent evidence of liver cell dysfunction
- Multiple organ dysfunction indistinguishable from sepsis
- Recovery possible if diagnosed early and treated promptly

Over a varying period of time (15 days to 1 month), patients who are critically ill invariably develop dysfunction of multiple organs. The liver and the spleen may both be palpable, and liver functions are frequently deranged with a rise in serum bilirubin to well beyond 5 mg/dL, a significant increase in the transaminases, and a prothrombin time more than one and a half times the control value. A liver biopsy may show ceseating granulomas. Very ill individuals have a fall in systolic blood pressure below 90 mm Hg (often as low as 70 mm Hg), and require inotropic support. GI bleeds and ileus make maintenance of nutrition difficult. Anemia and hypoproteinemia are both invariably present; the former is due both to blood loss and to infection. The white blood cell (WBC) count may not be of much help. Normal counts, leucopenia, or a mild to moderate leucocytosis may be observed. The ESR however is invariably raised, and is in the region of 100 mm/hour by the Westergren method. There may however be exceptions to this rule, particularly in the early phase of the natural history of the disease.

The patient may be obtunded even when the CSF examination is normal, and even with no evidence of tuberculomas in the brain on a CT examination of the head. The clinical picture in the fully evolved disease is often indistinguishable from sepsis with multiple organ dysfunction.

The presentation with multiple shadows within the lung evolving into the ARDS with multiple organ dysfunction is generally observed in immunocompromised patients, including those on corticosteroids. Rarely, it may occur in immunocompetent individuals as well.

The diagnosis may be difficult and at times impossible to establish. Repeated blood cultures in the early phase of the illness for Gram-negative infections, and peripheral smears to exclude *P. falciparum* infection should be done. As has already been mentioned, a fiberoptic bronchoscopy with bronchoalveolar lavage and a transbronchial biopsy are, in our experience, probably the most useful investigations.[4] Acid-fast bacilli can be demonstrated in bronchial aspirates or grown on culture. Biopsies (including liver biopsy) may show ceseating granulomas. CT examination of the chest and abdomen may provide tell-tale clues by demonstrating the presence of enlarged necrotic glands. A CT of the head may unexpectedly reveal tuberculomas in the brain.[5] If the patient is not too ill and if the above investigations are negative, an open lung biopsy is of great help in the presence of pulmonary shadowing of undetermined etiology. Tuberculosis may manifest in the most bizarre fashion, particularly in countries where the disease is common. It should never be forgotten

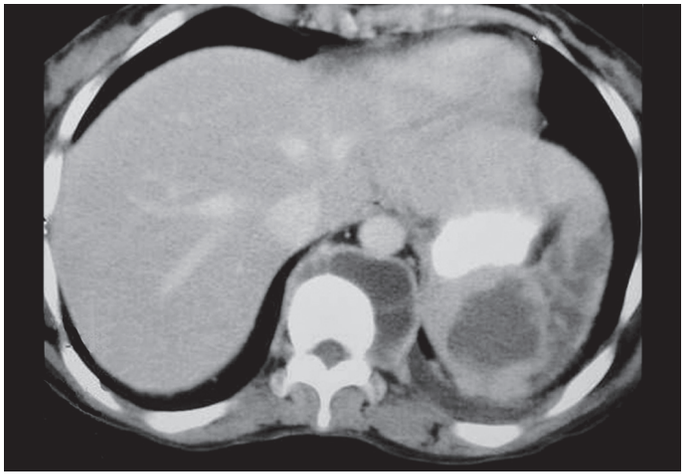

Fig. 4: Hematogenous disseminated TB—CT scan following contrast reveals focal hypodense lesions in the spleen as well as a preparavertebral abscess. There is splenic as well as vertebral involvement in this patient having disseminated hematogenous tuberculosis

as an important differential diagnosis in an acute, life-threatening obscure illness (Fig. 4).

MANAGEMENT

The management is with all five antituberculosis drugs— (1) streptomycin 0.75–1 g intramuscularly, (2) rifamycin 450–600 mg, (3) isoniazid 300 mg, (4) pyrazinamide 1.5 g, and (5) ethambutol 800–1200 mg/day. Unfortunately, the presence of liver dysfunction complicates management. Very often it is impossible to use rifamycin and/or isoniazid as liver function deteriorates further; pyrazinamide may also worsen liver function and may have to be stopped. One is then left with second line drugs like ethionamide, clarithromycin, PAS or cycloserine. Quinolones should be added to the drug regime in patients who cannot tolerate the first line drugs.

Critical care in these patients involves efficient ventilator support, inotropic support for the circulation, maintenance of pH and arterial blood gases, and maintenance of fluid and electrolyte balance. Repeated packed cell transfusions are necessary to keep the hemoglobin at more than 9 g/dL. Nutrition is of utmost importance, and patients with GI dysfunction may need IV alimentation till oral feeds can recommence.

It is remarkable that even with significant multiple organ dysfunction, the prognosis is not as bad as is observed with Gram-negative bacterial sepsis. If patients can tolerate the first line drugs, if liver function does not progressively deteriorate, and if expert critical care is available, the mortality is around 50%. Mental obtundation, iatrogenic infection and persistent lactic acid acidosis are important features that point to a poor prognosis and a fatal outcome.

SEVERE TYPHOID (ENTERIC) FEVER

Typhoid and paratyphoid fevers are caused by specific species of the Gram-negative bacillus, *Salmonella enterica*. Typhoid fever is caused by contamination of food or water by the *S. typhi*. This bacillus is excreted in stools and urine of acutely infected individuals and by chronic and convalescent carriers. Bad hygeine allows effluents containing infected stools and urine to contaminate food and water. Though the disease is well-nigh eliminated in the developed countries of the West, it is endemic in all poor developing countries. There are an estimated 12 million cases of enteric fever in the world each year with about 200,000 deaths.[1]

On ingestion of contaminated food or water, the typhoid bacillus is first localized in the Peyer's patches of the small intestine. It then reaches the mesenteric lymph nodes and gains entry to the bloodstream through the thoracic duct. A transient initial bacteremia occurs and the bacilli are seeded within reticuloendothelial sites where intracellular multiplication of the bacillus occurs during a 7–14 day incubation period. A second bacteremia is now observed with the bacilli again reaching the Peyer's patches in the intestine as also other reticuloendothelial sites, as in the liver, spleen, bone marrow and reticuloendothelial cells in the other organ systems. This second bacteremia is associated with fever and other systemic features that characterize the disease. The multiplication of bacilli occurs chiefly within macrophages. Inflammation within Peyer's patches leads to necrosis with formation of multiple ulcers in the ileum which are responsible for GI symptoms such as diarrhea, GI bleeds and perforation.

The reader is referred to another text for a full description of typhoid which is typically characterized at the end of the first week by continuous fever (with little and no diurnal variation), headache and malaise. Rose spots on the chest so frequently described in Western texts are only rarely observed in dark-skinned individuals. Hepatosplenomegaly is generally present.

COMPLICATIONS REQUIRING CRITICAL CARE[2]

Gastrointestinal Bleeds

The typhoid ulcers in the region of the Peyer's patches of the ileum are due to inflammation (macrophages, mononeuclear and lymphocytic infiltration) with ischemic necrosis. Ulceration of a vessel within the ulcer can produce severe GI bleeds characterized by melena or fresh blood through the rectum. It is easy to recognize this complication in the presence of fever. However, many patients today are treated within the first 4–5 days of typhoid fever (without realizing that the fever is typhoid) with antibiotics, which act against typhoid. The fever subsides but typhoid ulcers once formed run their natural course—they either heal, or bleed or perforate. When a GI bleed or perforation occurs many days after fever has disappeared, the relation of these complications to typhoid is often missed.

Typhoid GI bleeds can be severe, but rarely exsanguinating. Packed cell infusion may be necessary together with the antibiotic regime described later.

Perforation[3]

Typhoid ulcers have a greater chance of perforation compared to tuberculous ulcers or ulcers due to other pathologies. This is because ulceration due to typhoid fever is characterized by inflammation and a degree of vasculitis without any evidence of fibrosis.

Perforation is characterized by a sharp increase in pain, tenderness and guarding over the abdomen. It may be difficult to diagnose as many patients have a constant degree of abdominal discomfort with soreness on palpation of the abdomen.

Once clinically suspected and confirmed by imaging, surgery is the answer. The perforation is closed with appropriate sutures and a peritoneal toilet performed. Very often a number of other ulcers in the ileum which appear to be on the verge of perforation are also oversewn to prevent subsequent perforation. Even so, perforation may recur and in one patient three laparotomies were necessary before the patient eventually recovered.

Severe Sepsis

This is occasionally observed and can occur abruptly after the fever has lasted for 8–10 days without specific treatment. Sepsis is characterized by multiple organ dysfunction—chiefly hypotension, ARDS and severe mental obtundation with lactic acid acidosis. Recovery is generally possible if the appropriate antibiotics are given together with critical care and support to all organ systems.

Typhoid State

This is rarely seen today and was generally observed in the pre-antibiotic era in the third week of typhoid. It is still occasionally met with in patients who have not sought treatment or in those treated with indigenous drugs. The patient has high fever and displays the typhoid facies. The face is thin, flushed, with a dull apathetic expression and staring eyes. Apathy may progress to or is interspersed by muttering delirium; tremors of the hands and a tremulous often incoherent speech are observed. Osler has beautifully described the terminal stage characterized by twitching of the fingers and wrist (subsultus tendinium), plucking at bedclothes and at imaginary objects and an unrousable stupor going into coma with eyes open and staring (coma vigil). Death results from circulatory failure.

Complications Involving Other Organ Systems

The two important complications occasionally seen in severe typhoid are: (1) typhoid myocarditis and (2) typhoid cholecystitis. The latter may necessitate surgery.

Complications may however involve any organ system and a full range of complications were observed in the pre-antibiotic era. The often-repeated dictum in the Oslerian era was that if you knew typhoid, syphilis and malaria you knew your medicine. Fortunately the numerous complications of typhoid described in that era are hardly ever observed.

In children, there is a greater incidence of diarrhea, nephritis and typhoid meningitis when compared to adults.

Reports from Indonesia and Papua New Guinea have reported a subgroup of patients with severe typhoid, who present with shock (systolic BP <90 mm Hg) and poor skin, cerebral and renal perfusion with a fatality of about 50%. The criteria for what was termed severe typhoid were mental confusion and shock.[4] These are almost certainly patients with fulminant sepsis caused by *S. typhi*.

Interestingly, it was observed that in addition to chloramphenicol these patients responded to high doses of dexamethasone—3 mg/kg infused over 30 minutes followed by 8 doses of 1 mg/kg every 6 hours. The mortality in those receiving the above treatment was reported to be 10% compared to 56% in the group not receiving dexamethasone.

DIAGNOSIS

The definitive diagnosis of enteric fever is a positive culture of *S. typhi* or *S. paratyphi* organisms from the blood. Cultures are positive in 80% of cases if enough blood is taken for culture and if the patient has not received specific antibiotics. Marrow cultures yield a slightly higher incidence of positive cultures compared to blood cultures.

S. typhi can also be cultured from the urine and the stool. Stool cultures should be interpreted with caution in the areas known to have many careers.

A strongly positive Widal test in relation to the O antigen generally indicates typhoid, but the test has many pitfalls. A fourfold rise in titer of antibodies to *S. typhi* or *paratyphi* suggests enteric fever but is too delayed to help clinical diagnosis. False positive tests are seen in patients with previous infection, vaccinated individuals and in infections with cross-reacting organisms.

Other laboratory findings include a normocytic anemia and thrombocytopenia. Leucocytosis does not occur except in the presence of perforation. The WBC count is normal, but may be leucopenic. The liver enzymes are invariably slightly raised. Hyponatremia and hypokalemia may also be observed.

DIFFERENTIAL DIAGNOSIS

The commonest cause of fever extending for more than 8 days in endemic zones is enteric fever. Differential diagnosis includes malaria, dengue, leptospirosis, scrub typhus and amebic infection. Non-infective disorders, like lymphoproliferative disease, vasculitides, should also be considered.

TREATMENT

Till recently, ciprofloxacin was the first line drug against typhoid, but there is now an increasing resistance to the drug. If the positive blood culture shows resistance to nalidixic acid it implies also a significant resistance to the quinolone group of drugs.

The current drug of choice is ceftriaxone 2 g IV twice daily for 8 days. Azithromycin 500 mg twice daily orally for 5 days also acts well.

The organism seems to have now regained its sensitivity to ampicillin, chloramphenicol and cotrimoxazole.

FULMINANT AMEBIC INFECTION

Amebiasis is caused by the protozoan *E. histolytica* and is probably the most common cause of mortality among parasitic infections after malaria and schistosomiasis. Amebiasis is responsible for 50,000–100,000 deaths annually. The disease is endemic in tropical and subtropical regions, having a high prevalence rate in India, Asia, Africa, South America and Mexico. It spreads by the orofecal route; contamination of food and water, poor hygiene, poor sanitation and overcrowding help in its dissemination. Globally, 10% of the world's population is infected with *E. histolytica* causing significant morbidity and mortality. There are two more points worth noting—

1. Host immunity is negligible in the virginal host. The host antibody response is however useful in preventing subsequent invasive episodes.
2. Amebic infection can be fulminant in the very young, in the malnourished, in those on corticosteroids and in the immunosuppressed. We have observed fulminant amebic infections in some patients with HIV disease.

PATHOPHYSIOLOGY

The pathophysiology of amebic ulcerations of the large bowel, of amebic liver abscess and the pulmonary complications observed in amebiasis are briefly given below.

Following the ingestion of cysts chiefly through consumption of contaminated vegetables, the trophozoites develop in the small gut and are carried with the intestinal contents into the cecum and the large bowel. The trophozoites are motile amebae which attach themselves anywhere along the mucosa of the large gut (particularly in the rectosigmoid and cecum). They produce an ulceration of the mucosa because of the proteolytic enzymes secreted by them. Large flask-shaped ulcers are formed which could bleed or perforate. The trophozoites at the base of these ulcers may enter the portal circulation and reach the liver. Here the proteolytic enzymes secreted by the trophozoites produce a lytic necrosis of the liver cells resulting in one or more abscesses. A hepatic abscess is most often in the posterosuperior aspect of the right lobe of the liver. Pulmonary manifestations occur as a direct extension of the hepatic abscess through the diaphragm into the pleural space, or into the lung or into both. A left lobe hepatic abscess may extend through the diaphragm into the pericardium and rarely into the left pleural space. Rarely, trophozoites may enter the systemic circulation via the rectal venous plexus so that there is a hematogenous spread of infection to the lung and, very occasionally, to other organ systems, particularly the brain. There are some who believe that hematogenous spread could also occur if the trophozoites of a liver abscess gain access to the hepatic veins or the inferior vena cava. Lymphatic spread of amebic infection from the liver through the diaphragm into the thorax remains a theoretical possibility.

In our series, more than 60% of patients with a large liver abscess had serious pulmonary manifestations. It is uncommon to find overt manifestations of amebic ulcerative colitis in patients who have pulmonary manifestations of amebiasis.

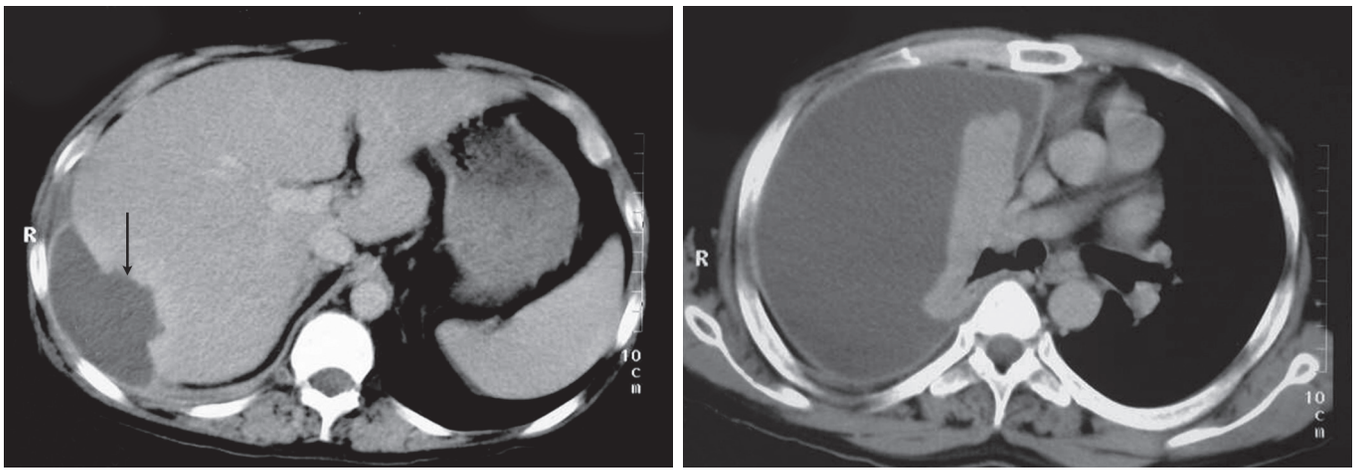
Amebic infection requiring critical care is an acute necrotizing ulcerative amebic colitis, and amebic liver abscess or abscesses which produce life-threatening complications.

ACUTE NECROTIZING ULCERATIVE AMEBIC COLITIS

Acute necrotizing ulcerative amebic colitis carries a high mortality, particularly in poor malnourished elderly patients admitted to ICUs of large teaching hospitals in the country. Death in these patients is due to perforation of the large bowel; more than one perforation may be present.

Clinical Features

Watery diarrhea and abdominal cramps with blood and mucus in the stools are the prelude to colonic perforation. The clinical manifestations of sudden severe abdominal pain, tenderness, rigidity, with an evidence of a painful inflammatory abdominal mass, or of spreading peritonitis with gas under the diaphragm are easy to recognize. However, in a number of instances, the clinical signs of perforation are atypical. This is particularly observed in poorly nourished, immunocompromised, or old debilitated patients. Such a patient looks ill; his sensorium is often clouded; he is dehydrated and complains of vague abdominal discomfort. He usually gives a history of loose watery stools for some days, but poverty, ignorance and apathy may sometimes combine to make him deny a history of significant diarrhea. Clinical examination reveals a distended abdomen with diffuse tenderness on palpation. Distension in acute amebic colitis is always to be viewed with suspicion as it is often a sign of impending perforation. When perforation occurs, distension increases and bowel sounds become feeble or absent. Watery diarrhea from a necrotic large bowel may however persist and fool the unwary into complacence. A toxic look, not unlike that observed with a toxic megacolon complicating nonspecific ulcerative colitis, is observed terminally in some patients. Fluid and electrolyte disturbances are always present. Increasing tachycardia, hypotension, shock and death ensue. A leucocytosis may not always be present. One has often wondered why the clinical features of amebic perforation of the large bowel are so atypical in some patients. The probable answer lies in the host-parasite relationship. A fulminant infection in dehydrated, malnourished, or immunocompromised patients literally swamps the body defenses and does not allow any worthwhile defense reactions to manifest themselves. The presence of a mild icterus and a palpable tender liver further strengthen the diagnosis. An associated liver abscess is easily picked up



Figs 5A and B: Ruptured liver abscess: (A) CT scan through liver demonstrates ruptured liver abscess (arrow); (B) the ruptured abscess has extended into right pleural space and caused shift of the mediastinum to the left

by an ultrasound or CT of the abdomen. A sigmoidoscopy is invaluable as amebic ulcers are always seen; amebae can be demonstrated in scrapings of these ulcers.

Management

Treatment for a perforated amebic ulcer of the large bowel or rectum is surgery for the perforation, together with specific antiamebic treatment. The prognosis in perforation is indeed poor. The friability of the large bowel adds to the surgeon's difficulties, the sutures often cutting through when the perforation is sealed. The possibility of multiple perforations must always be brought to the surgeon's attention. Remarkably enough, amebic liver abscess is uncommon in patients with necrotizing colitis. Postoperative complications are frequent and require overall critical care.

Specific Treatment

Metronidazole 500 mg IV 8 hourly is administered for 10 days. This drug is an extremely valuable amebicidal drug, and is also effective against anaerobes. Side effects include a metallic taste in the tongue, disturbances in higher functions and occasionally seizures.

Dehydroemetine 60 mg IM daily for eight injections was the drug used before metronidazole came on the scene. It is perhaps more toxic than metronidazole but was reasonably effective. Unfortunately, the drug is no longer available. Perhaps a combination of dehydroemetine and metronidazole may work better than either one or the other in fulminant amebic infections.

Tetracycline 250 mg 6 hourly is a useful adjunct in the treatment. It acts by modifying the bacterial flora necessary for the survival of *E. histolytica*. Suitable broad-spectrum antibiotics need to be given to counter the peritonitis produced by a colonic leak.

Fluid and electrolyte imbalance must be promptly rectified.

AMEBIC LIVER ABSCESS

Amebic liver abscess is an extremely common pathology in tropical countries. There are however two groups of patients with amebic liver abscess who require critical care.

(1) Those with a large undiagnosed solitary abscess, or multiple liver abscesses causing a life-threatening illness. Fever may be high and spiking, or may be low grade. The diagnosis is promptly made in a good unit, both on clinical examination and on an ultrasound of the abdomen. A tender liver, intercostal tenderness, signs of a pleural rub or pleural effusion on the right side with a raised right dome of the diaphragm, segmental or plate atelectasis in the lower lobe of the right lung are all pointers to the clinical diagnosis. A large centrally placed abscess or multiple small abscesses not approaching the diaphragm may not produce signs in the chest. A left lobe abscess may cause involvement of the left pleural space. Multiple liver abscesses or a single huge abscess can produce increasing jaundice and progressively increasing liver cell dysfunction. This is particularly seen in the malnourished, in alcoholics, and always in the cirrhotic. The patient becomes increasingly dull, apathetic and finally moribund, from a combination of sepsis and liver cell failure.[1,2]

Diagnosis[5-8]

The amebic nature of the liver abscess is proven by the indirect hemagglutinin test which is strongly positive in almost all patients with an amebic abscess. A positive test may persist even well after the abscess has completely healed. An aspirate only rarely shows vegetative form of *E. histolytica* as these forms are generally present along the walls of the abscess rather than in the anchovy sauce pus. However, *E. histolytica* can be detected from the pus of a liver abscess by the PCR technique.

Imaging with USG and CT scan help to give the exact size, number and location of the amebic abscess or abscesses (Figs 5A and B).

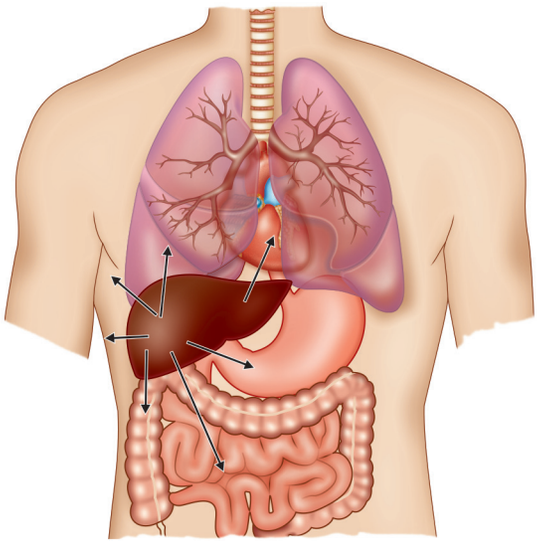


Fig. 6: Possible site of rupture of an amebic liver abscess (see text)
Source: Vakil RJ, Udwadia FE. 1982. Diagnosis and Management of Medical Emergencies. Mumbai: OUP;1982.

Box 5: Indications for aspiration of a liver abscess

- An abscess greater than 10 cm in size—aspiration allows early resolution
- A left lobe abscess greater than 7 cm; a left lobe abscess abutting on the dome of the diaphragm; presence of signs of impending rupture into the pericardium
- Lack of clinical improvement after 4–5 days of specific therapy even if abscess is less than 10 cm in diameter
- Impending rupture into the pleural space
- Seronegative liver abscess (often a pyogenic liver abscess)
- Percutaneous drainage may be necessary when—
  - The abscess is very large
  - Fills repeatedly after tapping
  - Thick pus which is not easily aspirated through a needle, as in patients with a pyogenic liver abscess

Management[9-11]

Management lies in the CT-guided aspiration of one or more large abscesses (>8 cm in diameter) and the use of specific antimicrobial treatment described earlier.

(1) Abscesses less than 8–10 cm in diameter often heal satisfactorily following the use of IV metronidazole and may not need to be aspirated.

General supportive care toward circulatory respiratory and other organ systems is necessary.

(2) Those with rupture of a liver abscess. This is a life-threatening emergency requiring critical care (Fig. 6).

Rupture may occur into the following sites—

- Into the peritoneal cavity, producing features of acute peritonitis. In some patients, the florid features observed with bacterial peritonitis may be absent, so that there is a moderate delay in diagnosis. A laparotomy is mandatory. Large drains are kept in the peritoneal cavity; the liver abscess must also be drained. If diagnosis and exploratory laparotomy are delayed, multiple organ system failure occurs and death ensues. If diagnosis is quick and treatment is prompt, recovery is possible even if multiple organ dysfunction occurs in the postoperative phase.
- Along the right paracolic gutter with tenderness in the right flank and over the right iliac fossa. A wrong diagnosis of an acute appendicitis is often made. Surgical opinion should always be sought; an exploratory laparotomy may be necessary.
- The abscess may point through the intercostal spaces to the outside, either in the anterior or mid-axillary line.
- Into the lesser sac and subphrenic space, causing a subphrenic abscess. A CT-guided drainage, drainage through the use of a pig-tail catheter or drainage tube, or open surgical drainage is necessary.
- Into the stomach, duodenum or colon; this is very rare, and surgical advice should be sought.
- Into the right pleural space causing an empyema, or into the lower lobe of the right lung resulting in a lung abscess. A left lobe liver abscess may produce the same complication in the left pleural space and/or lower lobe of the left lung. The patient may cough up anchovy sauce pus. Management consists of repeated pleural taps to keep the pleura dry. The abscess within the liver should also be drained. A right lobe liver abscess can also produce a right lower lobe consolidation, or a bronchopneumonia involving the lower lobe of the right lung. A left lobe liver abscess could produce similar pleuropulmonary consolidations involving the left lung.
- Into the pericardium—this is one of the most dreaded of medical emergencies, and is rapidly fatal. Rupture into the pericardium invariably occurs from a left lobe liver abscess close to the diaphragm. Unexplained well marked tachycardia and/or a pericardial rub are often warning signs of the impending rupture. Pain over the left shoulder which worsens on deep breathing is another warning sign. Intrapericardial rupture leads to acute dyspnea, and quickly evolving cardiovascular collapse. Heroic measures can however save the patient. The pus in the pericardial space must be promptly aspirated percutaneously and the liver abscess must also be quickly drained. The help of a thoracic surgeon must be sought so that open drainage of the pericardium can be performed, if percutaneous aspiration is inadequate.

In addition to surgical attention and adequate drainage outlined above specific antiamebic treatment should also be given. It is to be noted that a huge liver abscess (for example, one occupying the greater part of the right lobe or one which fills repeatedly after tapping) may require drainage through a large drainage tube left in situ. The danger of introducing secondary infection is ever present in this situation. Indications for aspiration of a liver abscess are given in Box 5.

Prognosis

Though most patients with complicated amebic liver abscess recover if diagnosed quickly and adequately treated, deaths do occur. Bad prognostic features are deepening jaundice with bilirubin levels greater than 7 mg/dL, poor response to specific therapy, multiple abscesses or a single very large abscess occupying the greater part of the lobe of the liver, mental obtundation and encephalopathy and persistent hypoalbuminemia. There are reports of vegetative forms of *E. histolytica* which have developed a degree of resistance to metronidazole. Death is due to rupture into the peritoneal cavity (with delayed diagnosis), multiorgan failure, and rarely due to metastatic spread of amebic infection, particularly from amebic abscesses in the brain.

DENGUE HEMORRHAGIC FEVER

INTRODUCTION

Dengue hemorrhagic fever is a mosquito-borne (*Aedes aegypti* is the carrier), flavivirus infection which afflicts 500,000 patients per year throughout the tropical regions of the world.[1,2] Depending on epidemic activity, dengue and dengue hemorrhagic fever are observed with varying frequency in all parts of India. The average mortality is 5%; the fulminant forms carry a much higher mortality. The disease can be caused by any one of the four distinct dengue viruses—DEN-1, DEN-2, DEN-3, DEN-4. Infection caused by one virus does not necessarily confer immunity to any one of the other viruses.

PATHOGENESIS[3,4]

The pathogenesis underlying the features of dengue hemorrhagic fever is based on the presence of subneutralizing levels of dengue antibodies in the blood. This enhances the infectivity of a fresh dengue viral infection by increasing the binding and uptake of virus-antibody complexes through the Fc receptors on monocytes in the blood and on tissue macrophages. The immune response also involves cellular activation, with cytokine release and activation of complement. It is this primed immune response which is response for widespread capillary leakage, coagulopathy with extensive hemorrhagic manifestations and acute circulatory failure—the hallmarks of the illness.

CLINICAL FEATURES[3-5]

The clinical features are characterized by the sudden onset of fever, bodyache and headache. It is impossible to distinguish this presentation from other tropical infections at this stage. The suspicion of a viral infection is generally entertained by the presence of well-marked leucopenia (the WBC count may fall to less than 2,000/mm^3) and increasing thrombocytopenia. These early hematological features in a febrile patient should prompt the diagnosis of a possible dengue viral infection, more so in the presence of an outbreak of dengue in a particular area or district.

After 2–7 days, there is a defervescence in the fever and at this crucial time the classic features of this infection are observed with varying degree and intensity. These are: (1) hemorrhagic manifestations due to thrombocytopenia and coagulopathy; (2) widespread capillary leak and (3) acute circulatory failure—the dengue shock syndrome.

Hemorrhagic features are present in varying degree, the most common being purpuric lesions and ecchymosis. However, bleeding from thrombocytopenia, coagulopathy and capillary damage often takes the form of severe epistaxis, hematemesis and hematuria. We have observed bleeding into the pleural space, peritoneal cavity and into any organ system, including the brain. Fulminant dengue hemorrhagic fever is associated with disseminated intravascular coagulopathy with widespread bleeding tendency.

The capillary leak is manifested by edema of the feet and of the subcutaneous tissue, crackles over the lung bases which may at times progress to non-cardiogenic pulmonary edema, leading to acute lung injury and ARDS. Pleural effusions occur in severe cases and are a manifestation of the capillary leak syndrome. They are often an accompaniment of dengue shock. The pleural fluid does not contain inflammatory cells, is rich in albumin, the albumin content being over 60% of that in blood. Objective evidence of a capillary leak is provided by the presence of hemoconcentration (the hematocrit being elevated by 10–30%).

Acute circulatory failure is characterized by the clinical features of shock. Tachycardia, tachypnea, hypotension, oliguria, mental obtundation, lactic acid acidosis are all observed. Elevation of liver enzymes is invariably present; in fact liver enzymes are often raised well before the onset of hemorrhagic manifestations. Increasing serum bilirubin with progressive liver cell dysfunction may be observed. Evidence of multiple organ dysfunction is frequent and progressive in fulminant fatal cases.

The duration of shock lasts for 2–4 days, culminating in recovery or death. Death can also occur from a severe bleed into an organ system (e.g. brain) or from multiple organ failure. Myocardial involvement is evinced by poor systolic function on an ECHO study; stupor or coma due to encephalitis invariably points to a fatal end.

DIAGNOSIS

The diagnosis depends on the demonstration of IgM antibodies (by the ELISA technique) to the dengue virus. Unfortunately, not all patients develop IgM antibodies within the first week of the infection. In some patients a rise in IgM is observed after as long as 10 days. The Dengue antigen is positive within the first 3–4 days of the infection.

Differential diagnosis of acute hemorrhagic fevers in the tropics may pose problems. Important infections other than dengue hemorrhagic fever that merit consideration are meningococal sepsis and meningitis, fulminant Gram-negative infections causing a coagulopathy, fulminant falciparum infection, acute leptospiral infection, severe rickettsial infection, fulminant viral hepatitis, bacterial endocarditis and hemorrghagic exanthemas, as in hemorrhagic chicken pox and measles. Consideration of the clinical background, examination of peripheral blood smears, blood cultures, serological tests and other relevant laboratory investigations generally help in diagnosis.

Fortunately, hemorrhagic fevers caused by the Ebola and Hanta viruses are restricted to well-defined areas of

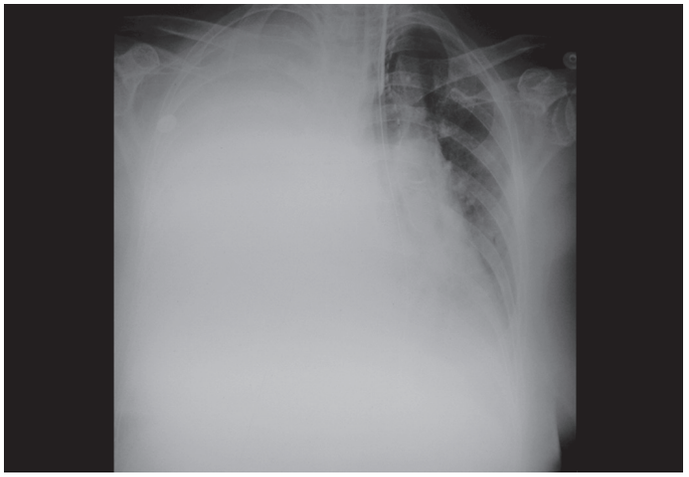

Fig. 7: Dengue—Complete opacification of the right lung likely as a result of large pleural fluid collection in a case of dengue

Africa. These highly infectious viral diseases cause fever with extensive hemorrhages, cellular death, multiple organ failure and have a mortality close to 80%.

Thrombotic thrombocytopenic purpura though rare is often mistaken for a fulminant infection causing widespread purpura (Fig. 7).

MANAGEMENT

Dengue hemorrhagic fever requires critical care; treatment is mainly supportive. No antimicrobial drug acts on the dengue virus. Hemorrhagic manifestations and coagulopathy are countered by replacement of deficient clotting factors and by platelet infusions. Anemia is corrected by infusion of packed cells. Hemorrhage into the pleural space or peritoneal cavity may require drainage.

Signs of impending shock should be detected early and treated by prompt infusion of colloids, plasma and, if necessary, by inotropic and vasopressor support. It is important to remember that shock can occur with dramatic and frightening suddenness. Oxygenation should be well maintained and the delivery of oxygen to the tissues should be adequate. It is important to insert a central venous catheter early in the natural history of the disease, as puncture sites can bleed profusely. Volume replacement is guided by clinical examination and by measuring central venous pressure. Over-infusion of fluids can precipitate or worsen ARDS. The difficulty arises when one is confronted with the capillary leak syndrome as manifested by edema and crackles over the lungs and progressive hypotension. An excessive fluid load with the purpose of reducing the hematocrit concentration to 40–45% can precipitate ARDS. One may need to temporize by using a judicious combination of IV fluids + inotropic and vasopressor support. Once shock has been effectively countered, a small titrated dose of IV frusemide reduces pulmonary congestion. If ARDS does occur in spite of all efforts, it is managed on conventional lines with intubation and appropriate ventilator support. Ventilation support is also necessary in patients who are in shock and acute circulatory failure. A combination of severe ARDS + severe hypotensive shock is of grim prognosis.

Metabolic acidosis is frequent and should be corrected. All organ systems must be given adequate support.

Secondary bacterial nosocomial infection is observed in some patients, requiring suitable antibiotic treatment. A combination of severe dengue with a superadded acute bacterial (generally Gram-negative) infection carries a very grave prognosis. Death occurs due to rapidly progressive multiorgan failure.

SEVERE LEPTOSPIROSIS

INTRODUCTION

Leptospirosis is a worldwide zoonosis afflicting many mammals; rodents form the most important animal reservoir. The disease is common in the tropics and is frequently observed in India, Southeast Asia, Africa, and South America. It is caused by a spirochete, the pathogenic species being the *Leptospira interrogans*. There are several serotypes of this genus; some of these preferentially infect select mammalian hosts. Thus, the serotype *L. icterohemorrhagica* is associated with the rat, *L. canicola* with dogs and *L. pomona* with swine and cattle. Leptospira are excreted through the urine of the infected mammalian hosts. Transmission of infection from animal to man generally occurs through contaminated water or moist soil. Leptospira enter through abrasions in the skin (generally on the feet and legs), or rarely through the mucosa of the mouth, pharynx or esophagus. The disease is therefore common in the monsoon, particularly at the time of floods, in areas where there is a large population of rats.

In most cases, human infection is asymptomatic or mild and cures itself. However, 5–15% of cases are severe or fatal.[1]

PATHOGENESIS[2]

The organisms, after gaining entry, generally through abraded skin, enter the bloodstream and are distributed to all organs of the body. The fulminant forms always severely affect liver function and often produce varying degrees of renal dysfunction. Leptospira can persist for months in the kidneys and ocular tissue.

The exact pathogenesis is unexplained as there are minor histopathological changes in the liver or kidney or other organ systems in the presence of severe functional derangement.

CLINICAL FEATURES[1,3-7]

The severe and fulminant forms of the disease are observed in icteric leptospirosis (Weils disease). The illness is ushered by fever, headache, severe muscle pains and marked conjunctival injection. Jaundice with impaired liver cell function appears by the fifth to seventh day and may persist for a month. However, death is very rarely related to liver cell failure.

All or many organ systems are affected. The most important organ involved is the kidney. Albuminuria, RBCs are invariably present. Oliguria with acute renal failure occurs in severe cases.

The lungs frequently show hemorrhagic bronchopneumonia. We have seen a few patients presenting with acute intra-alveolar hemorrhage that can cause death from overwhelming hypoxia, unless the patient is promptly intubated and ventilated with a high FiO_2. Intra-alveolar hemorrhage may be the presenting feature of severe disease.[3,4,7] ARDS is an important feature of severe leptospiral disease.

Meningitis (the CSF showing pleocytosis with raised protein) is frequently observed. It is likely that meningeal involvement may be related to an immunological mechanism than to actual invasion of the leptospira in the meninges. Organisms may be found in the CSF without meningeal or CNS symptoms. An obtunded mental state is either due to aseptic meningoencephalitis or due to uremic encephalopathy.

Fulminant leptospirosis is characterized by a hemorrhagic diathesis. Petechiae, epistaxis, subconjunctival hemorrhage, hemoptysis are common manifestations. Death can occur from subarachnoid hemorrhage or from exsanguinating GI bleeds. A coagulopathy with raised prothrombin time and thrombocytopenia is frequent. Bleeding is related both to the coagulopathy and to capillary damage. The overall clinical picture in its fully evolved form often resembles Gram-negative bacterial sepsis.

There is marked leucocytosis in the peripheral blood; WBC counts as high as 30,000/mm^3 or more may be observed.

DIAGNOSIS[8-11]

The diagnosis should be suspected on clinical grounds in endemic areas. The triad of fever, conjunctival injection with subconjunctival hemorrhage and jaundice should arouse immediate suspicion. A further association of abnormal urinary findings with varying degrees of renal insufficiency renders the diagnosis even more likely. Muscle pains associated with muscle tenderness are observed in close to 80% of patients. This is invariably associated with very high creatine phosphokinase (CPK) levels in blood. Patients presenting with fever and intra-alveolar hemorrhage invariably in our experience have very high CPK levels—a combination almost diagnostic of severe leptospiral disease. Leucocytosis is almost always present, but does not help in diagnosis.

The IgM for leptospiral infection (done by the ELISA technique) is generally positive by the fifth to seventh day.[8] Immunofluorescent assays are also being used for diagnosis. Serological tests for diagnosis are also available but these have poor sensitivity.[10] The PCR test for leptospirosis can help in diagnosis; we have no experience of its use. It is only done in special reference laboratories.[9,11]

The main differential diagnosis is sepsis caused by other organisms, fulminant viral hepatitis and fulminant *P. falciparum* infection. The latter does not generally cause deep jaundice. When meningitis is a presenting feature the disease has to be distinguished from other forms of aseptic meningitis and from tuberculous meningitis. Patients presenting with acute intra-alveolar hemorrhage need to be distinguished from acute Wegner's granulomatosis, systemic lupus erythematosus and other connective tissue disorders (Fig. 8).

Fig. 8: Leptospirosis—Chest X-ray shows multiple fluffy opacities in both lung fields as a result of fulminant leptospiral infection

TREATMENT[3,12]

Treatment in severe cases should be started on clinical suspicion. It should never await a laboratory diagnosis. Antibiotics should be used early in the course of the illness—by the 4th day. Penicillin G is the drug of choice; 2 million units 6 hourly are given IV for 8–10 days. Tetracycline (25–40 mg/kg per day) given every 6 hours and doxycycline 100 mg twice daily for 8–10 days are also effective. It should however be noted that a Cochrane systemic review failed to find sufficient evidence to provide clear guidelines for the use of antibiotics.[12]

Intra-alveolar hemorrhage requires intubation and ventilator support. There is a dramatic improvement in the clinical state, chest X-ray and arterial oxygenation following pulsed therapy with 1 g methylprednisolone IV daily for 3 days, followed by oral prednisolone (40 mg/day), tapered and stopped after 10 days. This dramatic improvement occurs within a few hours of the administration of the drug. Acute renal failure may warrant dialysis till recovery ensues.

Critical care is vital, with support to all organ systems. Fresh frozen plasma and platelet infusions are necessary to treat coagulopathy. Patients with severe leptospirosis need correction of hypovolemia, inotropes and vasopressors to counter hypotension. Fluid and electrolyte balance should be well maintained.

Acute respiratory distress syndrome requires intubation and appropriate ventilator support.

Patients with acute renal failure may require hemodialysis till such time as the kidney recovers.

If the patient recovers, kidney function and liver function return to normal. However, anterior uveitus may occur days or weeks after recovery or may persist if present during the course of the acute illness.

SCRUB TYPHUS

INTRODUCTION

Scrub typhus is a zoonotic disease of rural Asia caused by a Gram-negative intracellular bacterium orientia (formerly Rickettsia). This organism is transferred from rats to humans by the bite of a larval mite (chiggers) which has fed on an infected rat. It is believed that more than a billion people are at risk and a million cases are transmitted annually, making it the commonest Rickettesial disease.[1] Disease transmission occurs when infected mites burrow into the skin, feed on tissue fluid and inoculate the infective bacterium. The disease is uncommon in large metropolitan cities, but even so does occur, and is frequently misdiagnosed. It is endemic in all rural areas of India and is particularly observed in the North, Northeast and Eastern part of the country.

CLINICAL FEATURES[1]

More often than not the disease is mild, short lasting and easily missed. In its typical form it is characterized by fever, myalgia, conjunctival suffusion, generalized lymphadenopathy and the presence of an eschar (which is really an ulcer covered by a thick crust) at the site of the tick bite. The eschar is however present in not more than 50% of primary infections. There are other features which should suggest the diagnosis even in the absence of a typical eschar. These are a truncal macular or maculopapular rash which spreads peripherally, hearing loss concurrent with fever, persistent cough with bilateral reticular infiltrates at both bases on radiography of the chest.

Though most cases are mild, severe cases meriting critical care do occur. These patients develop or present with dyspnea, a progressive increase in the respiratory rate, tachycardia and a fall in O_2 saturation. They may develop a full blown ARDS.

High temperature, apathy, confusion may be observed and rarely these may progress to stupor, seizures and deep coma.

DIAGNOSIS[2]

The presence of an eschar is diagnostic but as mentioned earlier it is present only in 50% of cases. Also, an eschar even if present may be missed or misdiagnosed. It should be searched for carefully, particularly in moist areas of the skin, as in the axilla or the groin. Laboratory features which suggest the diagnosis, include a mild leucocytosis, atypical lymphocytes in the peripheral smear and a mild to moderate elevation of liver enzymes.

The differential diagnosis is from dengue, other viral infections and leptospirosis. The critically ill patients with scrub typhus may mimic severe typhoid. The latter does not cause conjunctival suffusion, a macular rash or generalized lymphadenopathy so often observed in scrub typhus. It is not uncommon for a patient to suffer a dual infection—in particular a dual infection of leptospirosis and scrub typhus.

The Weil-Felix test using the OXK antigen is widely used but insensitive. The indirect immunofluorescent assay and the immunoperoxidase tests are confirmatory tests but are performed only in a few reference laboratories. A rapid dot blot immunoassay not requiring a microscope has also been developed. Unfortunately there is no easily performed available test that can be used in rural areas where scrub typhus is endemic.

TREATMENT[3,4]

In pre-antibiotic days, the fatality rate was as high as 30%. Present antibiotic therapy offers a quick cure, lowers the risk of ARDS and has sharply reduced mortality. More often than not treatment is based on a clinical assumption of the diagnosis. Tetracycline 500 mg four times a day or doxycycline 100 mg twice daily for 7 days is recommended. In critically ill patients parenteral doxycycline or parenteral tetracycline or IV chloramphenicol (50–75 mg/kg per day) is administered. Critically ill patients may require ventilator support as also support to other organ systems.

Azithromycin is the drug of choice in pregnant women with scrub typhus or in children who contact the disease, as both tetracycline and doxycycline are contraindicated in the above situation. Azithromycin has also proved successful in patients with drug-resistant scrub typhus.

MELIOIDOSIS

INTRODUCTION

Melioidosis is an infection caused by the saprophytic bacterium *Burkholderia (B.) pseudomallei*. It is endemic in South and Southeast Asia, the incidence being particularly high in Northeast Thailand. The country with the highest number of recorded cases is Thailand where the average incidence is 4.4 per 100,000 people. The disease is also endemic in South China, Central and South America and parts of Africa. Human infection probably occurs through contaminated scratches and abrasions or occasionally following aspiration of contaminated fresh water. Agricultural workers and rice farmers in close contact with soil and water are at greater risk. It has been reported in India, particularly from Tamil Nadu and Karnataka. Cases have also been reported from Orissa, West Bengal, Assam, Andhra Pradesh and Maharashtra.[1-4]

CLINICAL FEATURES

Melioidosis can present acutely, subacutely or present in a chronic form. It is the acute form of the disease which merits critical care and which is described briefly below. The acute form of the disease is generally observed within 2 weeks of exposure. There are three modes of presentation—

1. The first is characterized by high fever and rapidly evolving features of overwhelming sepsis. ARDS, septic shock, multiorgan failure are observed in fatal cases. The clinical picture is indistinguishable from fulminant sepsis due to other causes.
2. The second mode of presentation is again with high fever, features of increasing sepsis and the presence of suppurative disease in one or more organ systems. The lung is perhaps the most frequently involved organ, a suppurative pneumonia involving one or more lobes being observed. If undiagnosed the condition progresses to increasingly severe sepsis with multiorgan failure.
3. The third mode of presentation is that of an acute pneumonia involving one or more lobes with the frequent occurrence of suppuration and cavitation. The lung may be the only organ involved. However, in a number of patients presenting with acute pneumonia, a careful search may reveal evidence of silent abscesses in the other organs—notably the liver and spleen.

DIAGNOSIS

A clinical suspicion of melioidosis can be confirmed by a blood culture positive for *B. pseudomallei*. When the lung is involved either in isolation or as part of other organ system involvement, sputum cultures are generally positive for the organism. It is important to inform the microbiologist if melioidosis is suspected, as identification of the organism in sputum samples which have polymicrobial flora is difficult and often missed.

At times, isolation of the organism is easier from the discharge of a metastatic cutaneous lesion or from the aspirate of a metastatic liver abscess.

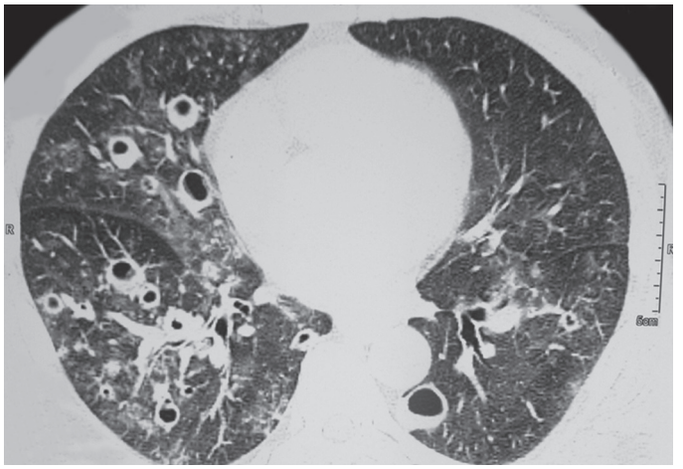

Fig. 9: Melioidosis. CT scan of the chest reveals multiple thick-walled cavitating lesions with air-fluid levels

IMAGING

Pneumonia is evident on an X-ray of the chest. A CT scan may reveal evidence of breakdown as also evidence of involvement of more than one lobe. Multiple small abscesses in different parts of the lung are missed on a radiographic examination and are visualized on a CT scan of the chest. Pleural effusions and empyema may complicate pulmonary involvement.

Imaging is helpful in revealing abscesses in other organ system—CT scan, magnetic resonance imaging (MRI) and in some instances positron emission tomography (PET) scans may be necessary to demonstrate other organ involvement (Fig. 9).

SEROLOGY

Indirect hemagglutination tests and complement fixation tests are believed to have a high diagnostic sensitivity, though we have no experience with these tests. People living in highly endemic areas, such as Thailand, have a high incidence of seropositivity for the disease. Therefore, in these areas the diagnostic titer needs to be high, preferably 1 in 640 or more to avoid false positive readings.

TREATMENT

The acute form of the disease or patients with multi-system involvement are best treated with ceftazidime in maximum

doses of 2 g IV 8-hourly together with one other antibiotic. This could be doxycycline (4 mg kg/day) or cotrimoxazole in maximal doses. The antibiotic course should be for 2–4 weeks. Following this, oral antibiotic maintenance thereby is advised for 6 months to a year. Antibiotic for maintenance therapy could either be doxycycline 4 mg/kg per day or cotrimoxazole (trimethoprin 10 mg/kg per day, sulfamethoxazole 50 mg/kg per day) or amoxycillin clavunate in high doses.

Prolonged courses are necessary because the disease is slow to respond and frequently relapses. Extrapulmonary abscesses may require surgical drainage.

CHAPTER 46

Antibiotic Therapy in the Intensive Care Unit

GENERAL CONSIDERATIONS

Patients are often admitted to the intensive care unit (ICU) with fulminant infections. Infection is also an important complication of patients admitted to the ICU for other unrelated life-threatening problems. In either case, treatment of infection needs to be prompt, comprehensive, but above all judicious.[1]

Till three decades ago, it was believed that the array of antibiotics available at that time would take care of infections in general and of infections in the ICU in particular. This expectedly has proved to be a mirage. There is an ecological balance between microorganisms and man in a particular environment. An attempt to eradicate one group of microorganisms by the injudicious use of antibiotics breeds resistant strains in increasing numbers and is often associated with an increasing number of different unrelated infections.

In fact, today we are faced with a world-wide epidemic of antibiotic resistance, and it appears that this epidemic is likely to spread and increase in its severity even more. There are two further disturbing facts. First, among the microorganisms showing increasing resistance to antibiotics are virulent Gram-negative pathogens, which can cause life-threatening infections. Second, we have exhausted our therapeutic antibiotic armamentarium against these Gram-negative organisms, and there do not appear to be any potent new drugs in the pipeline to counter these infections. We truly live in an era characterized by what the Infectious Diseases Society of America has termed—"Bad Bugs, No Drugs"![2] And how did we come to this sorry pass? It is due to our injudicious use of antibiotics that were previously effective; an antibiotic pressure (if one may term it so) on microorganisms that made them change and become resistant to their use. Darwin's hypothesis of survival of the fittest, which applies to the evolutionary process that led to *Homo sapiens,* also appears to apply to microorganisms. In order to survive the immense antibiotic pressure imposed by man, they had to change (alter their genetic structure) if they had to survive. And change they did, very effectively so, both to our dismay and danger.

Therefore, if we must save this situation or at least not let it get worse, every ICU and hospital should frame an antibiotic policy. Good antibiotic stewardship should aim at optimal clinical outcomes yet preserving the efficacy of antibiotics in use today. The importance of education to influence doctors to change their prescribing behavior with the above objective in mind is unquestioned.[3] Antibiotic policy and stewardship is perhaps most crucial in the ICU. An unwise or injudicious policy in the ICU characterized by overuse of potent antibiotics when this is not indicated, or the unnecessary use of a combination of antibiotics may eradicate infections in patients at that point in time but at the cost of breeding resistant microorganisms. This may have repercussions for patients admitted weeks or months later. This is because resistant organisms become part of the ICU ecology and can be transmitted to other patients admitted several weeks or months later, with devastating results.

The following section very briefly discusses principles of antibiotic therapy, which aim at both effectiveness and prevention of antibiotic resistance as far as possible.

PRINCIPLES GOVERNING ANTIBIOTIC POLICY IN CRITICALLY ILL PATIENTS[4]

- Antibiotics should be used in the presence of clinical and/or bacteriological suspicion of infection. It is important

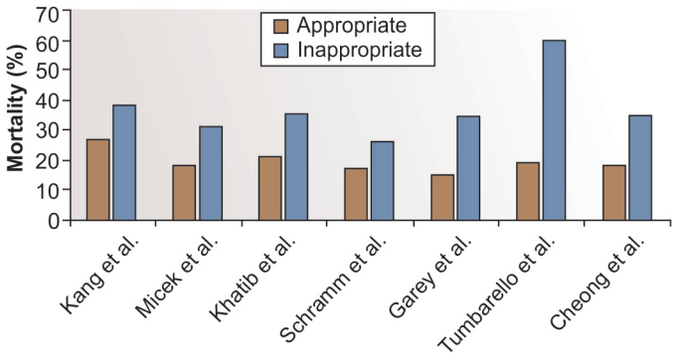

Fig. 1: The figure illustrates the increase in mortality when antibiotic therapy is inappropriate and delayed
Source: Morrell MR, Micek ST, Kollef MH. The management of severe sepsis and septic shock. Infect Dis Clin North Am. 2009;23(3):485-501.

to remember that the systemic inflammatory response (SIRS) which characterizes infection can also be caused by non-infectious causes. The use of antibiotics when the SIRS is due to a non-infectious cause does not help the patient and may even cause harm by exposing the patient to adverse effects of the antibiotic used and encouraging the growth of resistant microorganisms.

- Samples for appropriate staining and culture should be obtained from blood, body secretions and infected tissues before starting an antibiotic.
- The antibiotics chosen should be as per therapeutic protocols established for each individual ICU. Criteria for selection may vary with different ICUs, but once a selection is made, it should be followed and reviewed periodically. Criteria for selection of antibiotics in our ICU are discussed later.
- In severe life-threatening infections empiric antibiotics therapy should be started promptly after the above cultures have been taken without awaiting results. The antibiotics used should cover all likely microorganisms that could be implicated, depending upon the clinical scenario and the antibiogram of a particular ICU. The sooner treatment is started, the better—preferably within the first hour of admission. *Delay in treatment has clearly been shown to result in adverse outcomes.*[1]
- The dose of the antibiotic used should be optimized. Antibiotics, which act via time-dependent killing, are given at more frequent intervals. Antibiotics, which act through concentration-dependent killing, do so when the peak concentration is several times more than the minimum inhibitory concentration (MIC). Single dose therapy may be more advantageous.
- The choice of an antibiotic should depend not just on its efficacy against a particular organism, but its ability to reach and be concentrated at the site of infection.
- Combination therapy is used in the treatment of life-threatening infections. The reasons for combination therapy are—
  - Possible synergy against virulent particularly Gram-negative infection. Combination therapy is generally recommended in the treatment of multidrug-resistant *Pseudomonas aeruginosa*, *Acinetobacter*, *Klebsiella pneumoniae*.
  - Prevention of resistance. This again is with reference to severe Gram-negative infections—in particular *P. aeruginosa*, *Acinetobacter*. There is conflicting evidence if resistance can be prevented by using combination therapy. The general consensus is to use combination therapy when dealing with infections caused by *P. aeruginosa* or by *Acinetobacter*.[5]
  - Providing broader antibacterial coverage in life-threatening infections caused by multi-drug resistant microorganisms. This is perhaps the most important use of combination antimicrobial therapy. Empiric therapy against life-threatening infections should always be optimal and include two or even more agents in the hope that all possible organisms that could cause a particular infection are covered.
- Once the organism causing an acute infection has been identified through culture, antibiotic cover should be focused on eradicating that particular organism. In most instances, a single antibiotic of proven efficacy (as observed from the antibiogram of a particular ICU) will suffice.
- In critically ill patients, infection may be polymicrobial, e.g. in severe abdominal sepsis. All responsible organisms may be difficult to identify. Antibiotic coverage should cover against all likely aerobic and anaerobic causative organisms.
- It is important not to unnecessarily prolong antibiotic therapy. This however cannot be quantified. Though in many instances antibiotics can be stopped in 8–10 days; in other instances, they may need to be given for a much longer time.
- Clinical improvement should prompt de-escalation of antibiotic therapy.
- It is important to measure the efficacy of antimicrobial treatment. The first evaluation should be at 72 hours following empirical treatment. Worsening of the initial clinical manifestation, or evidence of new features of infection suggest that the empiric choice of the antibiotic/antibiotics is not appropriate. This should prompt fresh cultures of blood, infected secretions, or infected tissue and the use of rescue regimens with a broader spectrum of activity, so as to cover potentially multi-resistant organisms. If the early empiric therapy is deemed correct as per susceptibility testing, and the clinical course is still unfavorable, it is important to check whether the dose administered is correct, whether the antibiotic is administered at proper intervals so as to guarantee an adequate pharmacokinetic/pharmacodynamic (pK/pD) relationship,[6,7] and whether the antibiotic/antibiotics administered have good penetration into the infected tissue.
- One should be alert to the presence of adverse effects and emergence of resistant bacterial flora. Each class of antibiotics is associated with specific adverse effects.

Many adverse effects are however common to different classes of antibiotics. Also, the use of other drugs (with potential adverse effects) in critically ill individuals further complicates the problem as it may be difficult to attribute an adverse effect to one particular antibiotic.

It should be remembered that patients suffering from burns, heart failure or those who have had major surgery, frequently have an increase in body mass distribution, affecting plasma and tissue drug concentration. Drug elimination is also affected by renal insufficiency, hypotension and hemodynamic instability. All these factors influence the pharmacokinetic profile of antibiotics and may account for the large individual differences in antibiotic levels when the same dose is given to different individuals. It is therefore advisable to monitor antibiotic blood levels (whenever possible), particularly when the difference between optimal therapeutic and toxic level is small, as in the case for example with aminoglycosides and vancomycin. The introduction of pharmacokinetic model programs designed to monitor plasma drug concentrations allows adjustments in dosage to maximize clinical efficacy and yet reduces toxicity or adverse effects.[8]

The longer antimicrobials are used in a patient (particularly when more than one antibiotic is in use), the greater the chance for the development of multidrug resistant pathogens which may be the cause of treatment failure in an individual patient.

Surveillance studies with reference to culture of samples from infected foci and mucous membranes (nasopharynx, trachea and stools) are important to detect the emergence of multi-resistant bacterial pathogens.

ANTIBIOTIC RESISTANT GRAM-NEGATIVE ORGANISMS IN THE ICU[9]

It is important for the intensivist to be aware of the reasons for and the nature of increasing antibiotic resistance observed in the ICUs, if he or she is to make an informed calculated choice in the use of antibiotics—either for community acquired or nosocomial infection in the unit.

The evolution and spread of Gram-negative organisms producing extended spectrum β-lactamase (ESBL) has been responsible for an increasing number of antibiotic resistant Gram-negative infections. The extended spectrum β-lactamases are β-lactamases that confer bacterial resistance to the penicillins, first, second, third generation cephalosporins and aztreonam, by inducing hydrolysis of these antibiotics. The ESBLs are however not resistant to cephamycins or carbapenems and are inhibited by β-lactamase inhibitors such as clavulanic acid or tazobactam.

Extended spectrum β-lactamases represent an impressive example of the ability of Gram-negative organisms to develop new antibiotic resistance mechanisms, in the face of the introduction of new antimicrobial agents. Typically, ESBLs are derived from genes of *TEM-1, TEM-2* and *SHV-1* by mutations that alter the aminoacid configuration around the active site of these β-lactamases. A large and increasing number of ESBLs not of *TEM* or *SHV* lineage have also been described. Obviously, the increasing presence of ESBLs chiefly in ICUs and hospitals as also in the community is of great clinical significance, as antibiotic options in the treatment of ESBL producing organisms are markedly limited. The ESBLs are frequently plasmid encoded and plasmids responsible for ESBL production very often carry genes encoding resistance to other drug classes, e.g. aminoglycosides. Equally important is the fact that ESBL producing organisms are also often resistant to the quinolones—not just to ciprofloxacin but to other quinolones as well.

The ESBLs appeared on the medical scene in 1983. Reports came chiefly from Europe—Germany, France and the United Kingdom. By now, they have spread and have been reported from all over the world. It has been shown through genotyping that ESBLs can spread from one ICU to the hospital wards, from one hospital to another in the same city, from one city hospital to other hospitals in the country and also from country to country.

In India, there has been a tremendous increase in infections caused by ESBLs in ICUs all over the country. About 40–80% of organisms isolated in the ICUs are now ESBLs, pointing to the ever-increasing number of potentially antibiotic resistant infections.[10]

What is frightening is that ESBL producing gram negative organisms, as also Ps. aeruginosa, Kl. pneumoniae, Acinetobacter previously sensitive to the carbapenems are now showing increasing resistance to the latter because of their over-use. Also, the selection of intrinsically carbapenam-resistant organisms, such as Stenotrophomonas maltophilia and Enterococcus faecalis, is on the rise.

Risk Factors for Colonization and Infection with ESBL Producers[9]

Risk factors include—

- Seriously ill patients with prolonged hospital stay in whom invasive medical devices are present. Parenteral nutrition, recent surgery, hemodialysis, poor nutritional state, decubitus ulcers are other important risk factors.[9]
- Heavy antibiotic use is a major risk factor. Several studies have shown a relation between use of third generation cephalosporins in particular ceftazidime and the acquisition of ESBL producing organisms. Use of a variety of antibiotic classes have been found to be associated with subsequent infections due to ESBL producing organisms. These include aminoglycosides, quinolones, metronidazole and trimethoprim sulfamethoxazole. Conversely, prior use of penicillins, β-lactam-β-lactamase inhibitor combinations and carbapenems are not frequently associated with ESBL infection.

One is therefore left with the option of either using a β-lactam-β-lactamase inhibitor or the use of carbapenems in the treatment of ESBL infections.[9] It should be noted that

β-lactam-β-lactamase inhibitor combinations are effective against ESBLs producing a single β-lactamase. However, many Gram-negative ESBL organisms produce multiple ESBLs; this reduces effectiveness of β-lactam-β-lactamase inhibitor combinations.[9] Also the MIC against β-lactam-β-lactamase inhibitor at times depends on the inoculum, the MIC increasing markedly if the inoculum is increased.[9]

To worsen the nightmare of antibiotic resistant organisms, there has recently been slowly, but definitely increasing resistance of Gram-negative organisms to the carbapenems. Strains of *K. pneumoniae, P. aeruginosa*, *Acinetobacter* are now increasingly resistant to this class of antibiotics This can happen under the following circumstances[11-13]—

- When there is combinations of ESBL production and porin loss.
- When the organism produces carbapenemases—these are metalloenzymes, which render the carbapenems ineffective.
- When there is a change in the affinity of penicillin binding proteins to the carbapenems.

We are now left with colistin and polymyxin as our only weapons against Gram-negative organisms resistant to the other classes of antibiotics. There have been reports from an ICU in Delhi[14] of emerging colistin resistance as well. When colistin resistance indeed transpires on a large scale, the nightmare will become a grim reality.

Fortunately, the problem of methicillin-resistant *Staphylococcus aureus* (MRSA) infections is comparatively uncommon when compared to the West (except perhaps in a few units). Also, there are newer drugs available, which can as yet counter these infections. Intermediate resistance of MRSA to vancomycin and even complete resistance to vancomycin have now been observed. Vancomycin resistant enterococci, which however are responsive to the use of linezolid, should also be kept in mind.

REASONS FOR INCREASING MULTI-DRUG RESISTANT GRAM-NEGATIVE INFECTIONS

Why is there a continuing increase in multi-drug resistant Gram-negative infections in the ICU?

The basic reasons as already stated are overuse of antibiotics, inappropriate use of antibiotics, poor or absent antibiotic stewardship and inadequate infection control. If Gram-negative organisms, like the *P. aeruginosa*, *Acinetobacter baumannii*, *K. pneumoniae,* previously sensitive to carbapenems were repeatedly exposed to this class of antibiotics, resistance to the carbapenem group of drugs could perhaps arise from two mechanisms: (1) a genetic change in the organism which renders them resistant; (2) the antibiotic would destroy the sensitive strains but a small minority of inherently resistant strains would be left; these in time would multiply and spread, so that we would in time to come, be left with Gram-negative microorganisms resistant to the carbapenem group of antibiotics. Is there a way to remedy this situation? *An important way is for all hospitals to adopt a carbapenem-sparing antibiotic stewardship program. From the epidemiological point of view, restricting the indications and exposure of carbapenems will perhaps restore their efficacy*.

It is however also possible that the frequent use of a number of broad-spectrum antibiotics other than carbapenems, may ultimately lead to Gram-negative organisms becoming resistant to carbapenems. A clinical report described a group of infections due to *K. pneumoniae* in which 45% of *K. pneumoniae* strains produced ESBLs and 3.3% of *K. pneumoniae* strains carried *Klebsiella producing* carbapenemase-2 (KPC-2) carbapenem hydrolyzing enzymes.[15] The prior antibiotic exposure of patients in whom the KPC-2 enzymes were isolated was now investigated. It was observed that most of these patients had received a β-lactam or fluoroquinolone, but only 20% had received a carbapenem. The overall mortality in these bacteremic patients was 47%. Most isolates were from a single ribotype, suggesting that poor infection control was the mechanism for the spread of resistant pathogens selected by antibiotic pressure.

In a similar study in New York, a resistant *Acinetobacter* strain was related to the selection of this pathogen by the frequent use of cephalosporin.[16]

Similar studies relating to carbapenem resistant *P. aeruginosa* or carbapenem resistant *Stenotrophomonas* infection suggest that broad-spectrum agents more so than one specific agent may kill sensitive bacteria and allow pathogens as those stated above to clinically manifest themselves. Another relevant observation is that poor infection control contributes to the spread of resistant strains that have been selected through antibiotic pressure.[16]

CHOICE OF ANTIBIOTICS IN THE ICU

There are several factors that govern the choice of antibiotics to treat infection in the ICU. Many of these factors have already been discussed earlier. For the sake of completeness of this section, they bear brief repetition.

- Empiric antibiotic therapy in severe infections should adequately (in choice and dosage) cover all likely infecting microorganisms. Relevant cultures should be sent prior to empiric therapy. If the infecting microorganisms responsible for an infection is known, antibiotic therapy should be directed solely against that microorganism. A single appropriate antibiotic invariably suffices.
- The choice of antibiotic or antibiotics should not only consider efficacy but also the prevention of further antibiotic resistance.
- Community acquired infections generally need less powerful antibiotics compared to nosocomial infections, except when a community acquired infection is fulminant and life-threatening.
- It is crucial to know the microbiological flora in a particular ICU, the incidence of different organisms as gauged from cultures obtained from infected secretions and the

prevailing antibiotic sensitivity to each of these organisms. The organisms involved in each of the nosocomial infections should be noted as also their antibiotic sensitivity.

- The antibiotic or antibiotics chosen should not only be effective but be least toxic. For this the hepatic and renal function of the patient should be given due consideration.
- The pharmacokinetics of the antibiotic chosen should allow penetration and concentration of the antibiotic at the infected site.
- The cost of antibiotic therapy should also be taken into consideration, particularly in developing countries. It is positively obscene in a poor country to have a patient spend a fortune on very expensive drugs when a simple cheaper drug has the same or even better effect.
- Though it is best to use a single antibiotic, critically ill patients who require prompt empiric therapy, and infections which are invariably polymicrobial (as for example, severe abdominal sepsis), will require a combination of antibiotics. It must however be remembered that multi-drug antibiotic therapy is an important cause of increased antibiotic resistance.
- Finally, patient risk stratification helps in the choice of antibiotic therapy when the infecting microorganisms are unknown. The antibiotic policy may differ in different ICUs. The antibiotic policy or stewardship in our ICU depending both on the antibiogram observed and patient risk stratification is given below. We have stratified patient risks into Type I, Type II, Type III and Type IV.

13

Type I

Admitted to the ICU with a community acquired infection—

- No contact with health care system prior to admission.
- No prior antibiotic use in the previous 30 days.
- Patient young with no significant comorbidity.

Preferred Choice of Empirical Antibiotic Therapy

- IV Amoxicillin Clavulanate.
  or
- IV Ceftriaxone.

Note: Macrolides may be added when suspecting a respiratory tract infection.

Type II

- Contact with health care system (e.g. recent hospital admission or stay in nursing home or on dialysis program).
- Recent antibiotic therapy (within 90 days).
- Patients more than 65 years old with one or more significant comorbidities (involving lung, heart, kidney, liver).

Preferred Choice of Empirical Antibiotic Therapy

- Piperacillin tazobactam +/– macrolide (if respiratory tract infection suspected).
- If culture is positive for ESBL enterobacteriaceae, continue treatment as per sensitivity report (avoid broad spectrum antipseudomonal drugs).
- If cultures are negative for ESBL, de-escalate and treat as in Type I risk.
- If culture shows *P. aeruginosa*, *Acinetobacter*, MRSA escalate and treat as in Type III risk.

Type III (Nosocomial Infection or Fulminant Life-Threatening Community Acquired Infection)

- Severe infection or hospitalization in ICU for 5–7 days prior to infection.
- Infection following major invasive procedure.
- Recent, multiple antibiotic therapy.
- Patient more than 65 years, multiple comorbidities or immunocompromised.
- A community acquired infection which appears fulminant, life-threatening (irrespective of age or other associated factors).

Preferred Choice of Empirical Antibiotic Therapy

- Imipenem/Meropenem/Doripenem/Piperacillin tazobactam/cefoperazone sulbactam + aminoglycosides.
- Add linezolid or vancomycin only if MRSA infection is prevelant in the ICU or in community acquired infections.

Type IV

Type III patients with severe nosocomial infection or patients with fulminant community acquired infection, who run fever and remain very ill in spite of 3 days of adequate antibiotics as stated under type III + have one or more of the following risk factors for invasive fungal infections—

- Total parenteral nutrition (TPN), hemodialysis, immunosuppressed or immune-deficient, major abdominal surgery, diabetes, cirrhosis of the liver, multifocal fungal colonization, use of corticosteroids.

Empiric Antifungal Treatment is Advised

- If no prior exposure to azoles and hemodynamically stable, use fluconazole.
- If prior exposure to azoles and hemodynamically stable, use echinocandins/liposomal amphotericin B.
- Prior exposure to azoles and hemodynamically unstable, use echinocandins/liposomal amphotericin B.
- If *Aspergillus* suspected, start voriconazole.
- Continue as above, if culture shows no growth. If culture shows *Candida albican* sensitive to fluconazole, de-escalate to fluconazole (also see Chapter Invasive Fungal Infections in the ICU).
- If culture reports show susceptible *Pseudomonas*/*Acinetobacter,* continue piperacillin-tazobactam + aminoglycoside for 5 days and then continue piperacillin-tazobactam alone for the next 5–7 days.
- If culture shows non-ESBL enterobacteriaceae or methicillin-sensitive *Staphylococcus aureus* (MSSA) or *Streptococcus*—de-escalate and treat as Type I.

Table 1: Antibiotics of choice for commonly seen Gram-positive cocci and bacilli in the intensive care unit

Organisms	*Drug of first choice*	*Alternative drugs*
Gram-Positive Cocci		
• *Staphylococcus aureus* or coagulase-negative *staphylococci*		
– Penicillinase forming	Penicillinase-resistant, e.g. Cloxacillin, Nafcillin	1st or 2nd generation cephalosporin, vancomycin, ciprofloxacin, ampicillin-sulbactam, amoxicillin-clavulanic acid
– Methicillin-resistant	Vancomycin	Teicoplanin, linezolid, clindamycin, daptomycin, ceftaroline
• β-*hemolytic streptococci*		
– *Streptococcus pneumoniae* (penicillin sensitive)	Penicillin G, ampicillin	First, second, third generation cephalosporins, vancomycin, clindamycin, amoxicillin + clavulanic acid
– Penicillin resistant	Ceftriaxone	Levofloxacin, ertapenem, vancomycin, meropenem, cepefime, linezolid, clindamycin
Gram-Positive Bacilli		
• *Clostridium difficile*	Vancomycin (oral)	Metronidazole (oral), nitazoxanide
• *Clostridium tetani*	Penicillin G	Clindamycin, imipenem, meropenem

If culture shows—

- Multi-drug resistant *Acinetobacter,* start colistin—many prefer a combination of colistin + carbapenem (given as an extended infusion for 3 hours).
- Multi-drug resistant *P. aeruginosa*/*Klebsiella* – colistin + antipseudomonal β-lactam-β-lactamase inhibitor or carbapenems (extended 3 hours infusion).
- Vancomycin-resistant enterococcal (VRE), start linezolid/daptomycin.
- If for any reason a fungal infection is strongly suspected even though blood for fungal cultures are negative, treat for fungal infections as stated earlier under Type IV.

Risk stratification and use of appropriate antibiotics is undoubtedly not uniform for all ICUs. Each unit must decide on its own risk stratification and choice of antibiotics as per the prevalent microorganisms and the antibiogram in relation to these microorganisms.

A continuous surveillance of the possible changing 'flora' and changing susceptibility to various antibiotics is important to allow a modification of antibiotic choice in the ICU. This indeed is the essence of antibiotic stewardship.

TREATMENT OF PROVEN MULTI-DRUG RESISTANT *ACINETOBACTER BAUMANNII* INFECTION

The *Acinetobacter baumannii* is a dangerous Gram-negative organism often resistant to most available classes of antimicrobial agents. Once it gains entry into an ICU, it can wreak havoc among patients and is difficult to eradicate. The organism can persist within the environment of the ICU for weeks, being present on walls, tables, curtains, beds, respiratory and other equipment; it can contaminate water, disinfectants, monitors, thermometers, key pads of computers, laptops and the clothing of medical, paramedical and nursing personnel.[17]

This organism is often increasingly resistant to all classes of antibiotics, yet by and large so far has retained its sensitivity to colistin.

The optimal dose of colistin is unclear due to a lack of accurate pharmacokinetic and pharmacodynamic information. Studies have advocated the use of a loading dose of 9 million units IV and a maintenance dose of 4.5 million units IV 12 hourly or 3 million units IV 8 hourly in critically ill patients.[18]

In 2006, Li et al.[19] reported the phenomenon of hetero-resistance to colistin in multi-drug resistant *Acinetobacter* clinical isolates. Due to a resistant subpopulation, significant regrowth was observed within 24 hours following the initial killing (<2 hours) of the organisms by colistin. This suggests that the concentration of colistin in the blood achieved by the recommended dose of colistin may not be able to eradicate the more resistant subpopulation. The clinical application arising from the above microbiological findings is the recommendation not to use colistin alone against *Acinetobacter baumannii* infection but to combine it with another antimicrobial agent. The combination generally preferred is colistin + carbapenems, or colistin + piperacillin-tazobactam given as extended infusions.

Tigecycline can also act against *Acinetobacter baumannii* though its clinical efficacy remains controversial. The drug is bacteriostatic and resistance to the drug can occur during therapy. Tigecycline should not be used as monotherapy and is best used in combination with colistin. Tigecycline has low serum C_{max} values and should be avoided in bacteremia.[20]

Sulbactam In patients having sulbactam susceptible *Acinetobacter baumannii* infections, sulbactam should be the drug of choice, again combined with colistin.[5]

Rifamycin has an antibacterial activity against *Acinetobacter baumannii*. It is not used alone but in combination with another drug—preferably with colistin.[5]

Minocycline Minocycline also may have a role in minocycline susceptible *Acinetobacter baumannii* infections again in combination with another drug. There are very few clinical studies on this subject.[5]

A series of recently reportedly peptides have shown strong anti-bacterial activity against multi-drug resistant

Table 2: Antibiotics of choice for commonly seen Gram-negative cocci and bacilli in the intensive care unit

Organisms	*Drug of first choice*	*Alternative drugs*
Gram-Negative Cocci		
Neisseria meningitidis	Penicillin G, ampicillin, ceftriaxone, ceftazidime	Cefepime, meropenem
Gram-Negative Bacilli		
• Bacteroides fragilis	Piperacillin + tazobactam, any carbapenem, tigecycline	Clindamycin, metronidazole, ampicillin-sulbactam, amoxicillin-clavulanic acid
• *Enterobacter* sp.	Cefepime	Aztreonam, any carbapenem
• *Escherichia coli*	Third generation, cephalosporins	Piperacillin + tazobactam, Aminoglycosides, carbapenem
• *Pseudomonas aeruginosa*	Antipseudomonal, penicillins or ceftazidime	Ciprofloxacin or aztreonam, carbapenem + aminoglycosides, colistin + carbapenem
• *Klebsiella pneumoniae*	Ceftriaxone, cefoperazone, ceftazidime	Piperacillin, ampicillin-sulbactam, carbapenem
• Haemophilus influenzae	Cefuroxime, ceftriaxone, ceftazidime	Piperacillin + tazobactam, levofloxacin, azithromycin
• *Proteus* sp.	Cefotaxime, ceftriaxone, cefepime	Aminoglycosides, quinolones, aztreonam, meropenem
• Acinetobacter	Carbapenems	Colistin + Carbapenem/Sulbactum/Tigecycline

Acinetobacter baumannii. It may take some time for these new drugs to be carefully tried before use.

Table 1 lists the antimicrobial of choice for commonly encountered Gram-positive cocci and bacilli and Table 2 lists the antimicrobial of choice for commonly encountered Gram-negative cocci and bacilli.

MODE OF ACTION OF ANTIMICROBIAL AGENTS

Antimicrobial agents may be either bactericidal or bacteriostatic. Bactericidal agents kill microorganisms, whereas bacteriostatic agents prevent multiplication of the microorganisms, only when present within them. A critically ill patient in the ICU is often at a special disadvantage because of poor phagocytic function of the macrophages. There is also at times poor antibody function, as compared to less ill patients. Bactericidal agents should therefore be preferred; yet in many situations, bacteriostatic agents act just as well.

The mechanism of action of antimicrobial agents on microorganisms varies and may take the following forms—

- Interference with cell wall synthesis. This is the main mode of action of penicillins, cephalosporins, carbapenems, monobactams and vancomycin.
- Interference with cell membrane synthesis as with polymyxins and amphotericin B.
- Prevention of DNA replication, e.g. quinolones, rifampicin and metronidazole.
- Interference with protein synthesis as seen with chloramphenicol, tetracyclines, erythromycin, clindamycin, aminoglycosides and fusidic acid.
- Folic acid antagonists, e.g. sulfonamides, trimethoprim and their combinations.

The different modes of action of important antimicrobial agents have been illustrated in Figure 2.

The remaining part of this chapter deals very briefly with antibiotics used for serious infections in the ICU. Treatment for fungal infections has been discussed separately.

PENICILLINS

Penicillin G

In the ICU, this cheap and extremely effective antibiotic is used against acute pneumococcal infection, streptococcal infection, meningococcal infection and infections by Gram-positive bacilli—chiefly the clostridia. It is no longer used for treating *Staphylococcus* infections, as these strains are resistant to the drug. In fulminant infections in adults, the dose is 4,000,000 units intravenously (IV) 4 hourly.

Ampicillin

Ampicillin is a broad-spectrum penicillin with a significant spectrum of activity against Gram-negative bacilli. It is also nearly as effective as penicillin G against Gram-positive and Gram-negative cocci, and Gram-positive bacilli. It can therefore be used in place of penicillin G to treat fulminant infections mentioned under penicillin G. It is the drug of choice for infections due to *Enterococci*. Ampicillin and aminoglycosides form an extremely effective combination against *Enterococci*, as these drugs are synergistic against these organisms. The chief drawbacks of ampicillin are: (1) susceptibility to β-lactamase produced by *Staphylococci* and Gram-negative bacilli—most strains of *S. aureus* and more than 50% of *Escherichia coli* are ampicillin-resistant; (2) the occurrence of hypersensitivity reactions and (3) gastrointestinal side effects. These are similar to those observed with penicillin G and are briefly described below.

In fulminant streptococcal or in other fulminant infections as in pneumococcal or meningococcal meningitis, the dose of ampicillin is 2 g IV 4 hourly, i.e. 12 g/day. In less fulminant cases, 1 g IV 4 hourly suffices.

Anti-Staphylococcal Penicillins: Cloxacillin, Flucloxacillin and Methicillin

These are not destroyed by penicillinases, i.e. by β-lactamase enzymes. They are therefore most useful against *S. aureus*, most of which produce penicillinase. They are however

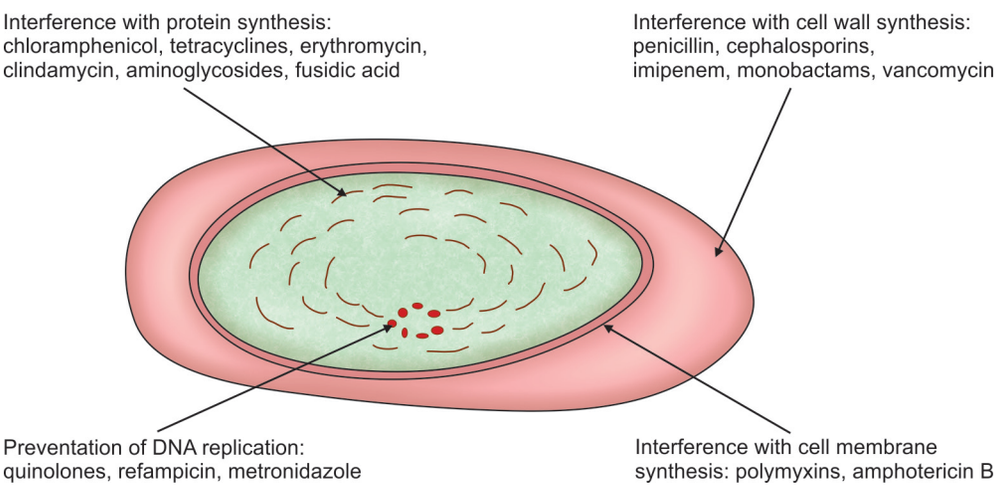

Fig. 2: Modes of action of important antimicrobials

less effective against other Gram-positive organisms, and inconsistently effective against *Staphylococcus epidermidis*. There is also an in vitro cross-resistance and cross-sensitivity between these three drugs, as also between these drugs and the cephalosporins.

Cloxacillin is only reserved for methicillin-sensitive staphylococcal infections in our unit; the dose in serious infections being 1 g IV 4 hourly. The incidence of MRSA is slowly increasing. In some other hospitals, notably those treating cancer patients, the incidence of MRSA is high.

Side Effects of Penicillins

The penicillins described above occasionally produce reactions. Antibody-mediated hypersensitivity reactions in rare instances may cause fatal anaphylaxis. Though a skin sensitivity test is mandatory before starting penicillin therapy, a negative skin test does not exclude the possibility of anaphylaxis. Other antibody-mediated hypersensitivity reactions include fever, urticaria, serum sickness and nephritis. Non-antibody-mediated reactions often occur in association with viral (notably Epstein-Barr virus) infections and take the form of fever with a measles-like rash.

Very large doses of penicillin, particularly in the presence of renal failure, may cause seizures, hemolytic anemia, neutropenia and thrombocytopenia.

Penicillins and β-Lactamase Inhibitors

The major mechanism of β-lactam resistance seen in both Gram-positive and Gram-negative infections is due to production of β-lactamase. The three currently available β-lactamase inhibitors are clavulanic acid, tazobactam and sulbactam.[1,2] The β-lactam-β-lactamase inhibitor, antibiotic combinations available are piperacillin-tazobactam, ticarcillin-clavulanate, ampicillin-sulbactam and amoxicillin-clavulanic acid. The last two combinations are effective against β-lactamase producing strains of *S. aureus*, *Haemophilus influenzae* and *Bacteroides fragilis*.[1,2]

Piperacillin tazobactam and ticarcillin-clavulanic acid are used against ESBL producing Gram-negative infections—in particular infections due to *P. aeruginosa* and *K. pneumoniae*.

Unfortunately, many Gram-negative organisms are now showing a steadily increasing resistance to piperacillin tazobactam and ticarcillin-clavulanic acid, particularly in ICU patients. In suspected Gram-negative infections, where the exact organisms causing infection are undetermined, empiric therapy with piperacillin-tazobactam + aminoglycoside or ticarcillin-clavulanic acid + an aminoglycoside is frequently used. The above combination is often prescribed in patients with intra-abdominal sepsis, pelvic suppuration, acute biliary infection as in cholangitis and cholangitic abscess. The dose of piperacillin-tazobactam is 4.5 g IV 8 hourly and of cefoperazone + sulbactam 3.1 g IV 8 hourly. Piperacillin-tazobactam should be used with caution in patients with renal and hepatic dysfunction.

AMINOGLYCOSIDES

These are extremely useful against Gram-negative bacilli including *Klebsiella* and *P. aeruginosa*. The aminoglycosides commonly used are gentamicin, tobramycin and amikacin. In severe fulminant Gram-negative infections, an aminoglycoside is always combined with another suitable antibiotic—either a third generation cephalosporin or piperacillin-tazobactam. Gram-negative infections in neutropenic patients should also preferably include an aminoglycoside in the therapeutic regime. The degree of resistance of Gram-negative organisms to aminoglycosides varies in different units. In our unit gentamicin-resistant organisms are frequently observed. We therefore prefer to use amikacin. Tobramycin offers no special advantage over gentamicin or amikacin.

It is important to bear in mind that ESBL producing Gram-negative organisms that are resistant to penicillins and first, second, third generation cephalosporins often also encode a gene which confers resistance to aminoglycosides as well.

Dosage

Aminoglycoside dosing is based on bodyweight. Only a small fraction of the aminoglycoside is distributed in adipose tissue, so that ideal bodyweight should be taken into consideration for estimating dosage in obese individuals as this could prevent overdosing. However, dosing based on ideal bodyweight may result in over dosage in patients who are underweight. It has been suggested that one can compare the ideal and actual bodyweight of each patient and use the lower of the two weights to determine the aminoglycoside dose.[3]

Once-Daily Dosing

The effect of aminoglycoside is concentration-dependent, higher concentration in the blood stream and tissues producing a greater bactericidal effect.[3] This is the rationale for using a single daily dose of the drug rather than divided dose regimes. There is no incontrovertible proof that once-daily dosing is more effective with regard to ultimate outcome than the divided dose regimen, though once-daily dosing continues to be preferred for being less time consuming and less costly. Efficacy and toxicity are probably the same as with divided dose regime.

In patients with renal dysfunction the dosage needs to be modified as per the creatinine clearance. This can be achieved by either decreasing the strength of the dose and/or an increase in the dosing interval. The dosing adjustment depending on creatinine clearance is given in the Table 3.

Toxic Effects

The major toxic effects of aminoglycosides are nephrotoxicity causing renal failure, and toxicity to the eighth cranial nerve causing deafness.[4-6]

The nephrotoxicity is due to the action of the aminoglycosides on the renal tubules. It is a very important primary cause or a contributory cause of renal failure in patients

Table 3: Aminoglycoside dosing by creatinine clearance

Cr/Cl (mL/min)	*Gentamicin/ Tobramycin (mg/kg)*	*Amikacin*	*Dosing interval*
>100	5.0	15.0	24 hours
70	4.0	12.0	↓
50	3.5	7.5	↓
40	2.5	7.5	48 hours
20	4.0	7.5	↓ 72 hours
10	3.0	4.0	↓
HD	2.0	5.0	96 hours

Abbreviations: Cr/Cl, creatinine clearance; HD, hemodialysis.
Source: Adapted from Turnidge J. Pharmacodynamic and dosing of aminoglycosides. Inf Dis Clin N Am. 2003.17:503-28.

in the ICU. Renal failure is generally (though not always) of the nonoliguric variety, the patient excreting more than 1,200 mL/day, yet showing a progressive rise in the serum creatinine. Both gentamicin and amikacin are equally nephrotoxic. Nephrotoxicity is related to drug levels in the blood. The likelihood of toxicity is thus related to the duration of time that the trough serum levels exceed 2 μg/mL for gentamicin, and 10 μg/mL for amikacin.[7] The rise in serum creatinine occurs after 5–7 days but can occur earlier in the presence of biliary obstruction,[6] or if there is some degree of renal insufficiency to start with. The use of furosemide and the presence of hypovolemia potentiate aminoglycoside nephrotoxicity.[8] Aminoglycosides are best omitted if renal toxicity is apparent from a rising serum creatinine level. Acute renal failure generally resolves within a week; rarely, it may take much longer to resolve, and the patient may then need to be supported by dialysis.

Early signs of renal toxicity include a fall in the urine output, proteinuria, and the presence of casts in the urine. These signs are however nonspecific and may be due to other causes operating in very ill patients in the ICU.

Ototoxicity from aminoglycosides results in nerve deafness and is dose-related. The nerve deafness is enhanced by the use of furosemide.[7,8] Rarely aminoglycosides potentiate neuromuscular blockade. In clinical practice, this is only observed in patients with myasthenia gravis, or in those being given muscle relaxants.

Prevention of toxic effects of aminoglycosides is helped by maintaining a normal intravascular volume and by the discriminate use of furosemide. Aminoglycosides should not generally be continued once the cultures are negative. In patients where renal failure is a likely hazard, one often prefers to use a safer antibiotic.

GLYCOPEPTIDES

Vancomycin[9]

Vancomycin is the drug of choice for MRSA and methicillin-resistant *Staphylococcus epidermidis* (MRSE) infections and for serious infections in patients allergic to penicillin. The drug is also used for penicillin resistant pneumococcal meningitis and pneumonia. It also forms a second-line therapy for most Gram-positive infections. When used against *Enterococci*, the drug should be given together with an aminoglycoside.

There are increasing numbers of reports related to MRSA strains showing reduced susceptibility to vancomycin. The emergence of MRSA strains with reduced vancomycin susceptibility has limited treatment options and increased the incidence of treatment failure. Also, the upward drift in the MIC for vancomycin in MRSA is associated with an increased risk of clinical treatment failure.

Vancomycin resistant *Enterococci* have been increasingly reported. The gene encoded within *Enterococci*, which confers resistance to vancomycin, can be transferred to the *S. aureus* so that problem of vancomycin resistant staphylococci in time to come may become formidable.

Dosage

The dose is 1 g 12 hourly IV. The drug is effective when used orally in a dose of 125–250 mg four times a day for *Clostridium difficile* infections.

Side Effects

The major side effects are on the kidneys and on the eighth nerve. Renal insufficiency and ototoxicity are thus to be watched out for. The dose should be appropriately reduced on the basis of the creatinine clearance test. Drug levels should be monitored in the presence of impaired renal function. If the drug is given as a bolus, or even otherwise, the drug can cause a severe erythematous rash, flushing and transient hypotension (Red Man Syndrome).

Teicoplanin

Teicoplanin is a new glycopeptide, which has a similar spectrum to vancomycin. Its main use is again MRSA and MRSE infections. It is believed to be less toxic than vancomycin.

Dosage

Adult Initially, 6 mg/kg on first day, followed by 3 mg/kg per day. Severe infection—6 mg/kg every 12 hour for the first 3 doses followed by 6 mg/kg per day. Doses may be given via intramuscular injection, IV bolus or IV infusion over 30 minutes.

Renal impairment Usual dose to be given for first 3 days, thereafter adjust dose according to creatinine clearance.

Creatinine clearance rate (mL/minute)	Dosage recommendation
40–60	1/2 initial dose given daily or initial dose every 2 days
Less than 40	1/3 initial dose given daily or initial dose every 3 days

Side Effects

It can cause both nephrotoxicity and ototoxicity.[10] The dose should be suitably reduced in patients with renal insufficiency. Thrombocytopenia can occur with higher doses.

β-LACTAM ANTIBIOTICS

A number of β-lactam antibiotics have been in use against resistant facultative Gram-negative bacilli. Of these, the commonly used ones are the third and fourth generation cephalosporins.

Third Generation Cephalosporins[11]

Cefotaxime, ceftazidime, ceftriaxone and cefoperazone are the third generation cephalosporins, which have been in frequent use against serious Gram-negative infections in the ICU for the last several years. They penetrate well into the CSF, and are therefore the drugs of choice in Gram-negative bacterial meningitis. Ceftazidime provides a wider cover (which includes *Pseudomonas*) and is to be preferred particularly for empiric therapy against Gram-negative bacterial meningitis. Gram-negative nosocomial infections in the ICU, as also infection of unknown origin in neutropenic patients, warrant the use of a third generation cephalosporin together with an aminoglycoside or ciprofloxacin. Cefotaxime is useful against Gram-negative organisms particularly *Klebsiella*, but lacks activity against *Pseudomonas*. Ceftazidime, on the other hand, has the greatest activity against *P. aeruginosa*, and some other *Pseudomonas* species. Cefoperazone sulbactam also has antipseudomonal activity and has significant activity against Gram-positive organisms including *Staphylococci*. Third generation cephalosporins are poorly active against *B. fragilis*, and display no activity against *Enterococci*, *Listeria*, and methicillin-resistant *Staphylococci*.

The above description of the use of third generation cephalosporins in relation to the treatment of Gram-negative infection unfortunately does not hold true since the growing presence of ESBL producing organisms. ESBLs renders Gram-negative organisms resistant to all penicillins, all first, second, third generation cephalosporins and to aztreonam.

The third generation cephalosporins offer two important advantages—

1. *Good tissue penetration* Penetration into the CSF has already been commented upon. Ceftriaxone and cefoperazone also reach high concentrations in the bile and may therefore be of special value in the treatment of severe cholangitis and cholangitic abscesses.
2. *Reduced nephrotoxicity* Cefotaxime, ceftriaxone and cefoperazone have little or no renal toxicity. Cefoperazone can thus be continued without any reduction in the dose in patients with renal failure. The dose of ceftazidime however needs to be reduced in patients with renal insufficiency; the degree of reduction is dependent on the serum creatinine levels and on creatinine clearance values.

Side Effects

The major side effect noticed in the ICU is the occurrence of reversible neutropenia in 10% of patients. This may cause confusion in the management of neutropenic patients. A slight rise in the liver enzymes is occasionally encountered. Prolonged prothrombin time and platelet dysfunction causing bleeding can sometimes occur, particularly with cefoperazone. Rarely, a positive Coombs test is related to cephalosporin therapy.

Dosage

Cefotaxime is administered in a dose of 1–2 g 6 hourly. The dose of ceftazidime is 1–2 g 12 hourly. Ceftriaxone and cefoperazone have much longer half-lives, and have the added advantage of a once a day dosing of 2 g IV. In fulminant infections the dose can be increased to 4 g daily.

Fourth Generation Cephalosporins[12]

Cefepime and Cefpirome are the fourth generation cephalosporins. They have good activity (similar to that of ceftazidime), against Gram-negative pathogens, including Enterobacteriaceae and *P. aeruginosa*. Some strains of enterobacter, citrobacter and serratia resistant to ceftazidime, aztreonam are susceptible to cefepime and cefpirome. They are also active against Gram-positive organisms (*Streptococcus pneumoniae*, *Streptococcus pyogenes* and MRSA)—activity similar to cefotaxime but better than ceftazidime. Like other cephalosporins they do not have activity against anaerobes. Compared to other second and third generation cephalosporins, they have lower affinity for β-lactamases and are not inducers of chromosomal β-lactamases.

Indications

They are used in Gram-negative infections, as in nosocomial pneumonia, urinary tract infections, febrile neutropenia, intra-abdominal infections (along with metronidazole).

Dosage

- Cefepime 1–2 g 12 hourly, 2 g 8 hourly, IV.
- Cefpirome 1–2 g 12 hourly, IV.

Both drugs require dosage adjustment in patients with renal dysfunction.

Side Effects

Side effects are similar to other cephalosporins. Cefpirome interferes with serum creatinine estimation by Jaffe's method. Hence falsely elevated serum creatinine levels will result, though blood urea nitrogen remains unaffected. Hence, cefpirome should be administered after blood sample collection or the high-performance liquid chromatography (HPLC)/enzymatic method should be used for estimating serum creatinine.

QUINOLONES

Ciprofloxacin

Ciprofloxacin has the following advantages—

- An excellent activity against Gram-negative organisms, particularly against *Bacillus typhosus*, Salmonella infection and *Pseudomonas*. It is therefore a useful alternative to aminoglycosides when combined with either piperacillin or ceftazidime or cefpirome in the treatment of *Pseudomonas* infections.
- Activity against MRSA and epidermidis. However, strains of MRSA are now becoming increasingly resistant to ciprofloxacin.
- Good tissue penetration, particularly in bones, lungs, bronchi, the hepatobiliary system, gut, prostate and the urinary tract. Penetration into the CSF is however poor. It is therefore useful against Gram-negative infections involving the above sites, particularly in severe osteomyelitis.

Ciprofloxacin lacks activity against *B. fragilis* and many non-aeruginosa species of *Pseudomonas*.

Again, it must be mentioned that ESBL producing Gram-negative organism are often found to be resistant to ciprofloxacin. There is also an increasing resistance particularly of *P. aeruginosa* and *K. pneumoniae* to ciprofloxacin though the degree of resistance will vary in different ICUs.

Dosage

In fulminant infections, it is administered intravenously in a dose of 200 mg 12 hourly. Once the infection is under good control, it is given orally in a dose of 500–750 mg twice a day.

Side Effects

Gastrointestinal disturbances are frequent. Skin rashes and transient gouty pains involving the fingers may be observed. A transient elevation in liver enzymes, and rarely in serum creatinine, may occur. The dose may need to be reduced in patients with renal insufficiency. Central nervous system excitation may take the form of headache, confusion and seizures. Serious but very rare side effects include anaphylactoid reactions that may cause death and possibly a hemorrhagic vasculitis.[13]

The drug is best avoided (unless absolutely necessary) in children, and pregnant and lactating women.

Newer Fluoroquinolones[14]

The newer fluoroquinolones include ofloxacin, levofloxacin (L-isomer of ofloxacin), gatifloxacin, moxifloxacin. These drugs are active against Gram-negative bacilli, including *Salmonella*, *B. typhosus*, *Shigella*, *H. influenzae* and *Pseudomonas* strain. However, among fluoroquinolones, ciprofloxacin has the highest activity against *Pseudomonas*. While ciprofloxacin and ofloxacin are also active against mycobacteria, the other fluoroquinolones are active against *mycoplasma*, *chlamydia* and *legionella*. For serious Gram-negative infections in the ICU, we have restricted the use of quinolones to ciprofloxacin and ofloxacin. They are invariably used in combination with a third generation or fourth generation cephalosporin or with piperacillin. Ciprofloxacin or ofloxacin is the drug of choice in fulminant *B. typhosus* infection. However, resistance of *B. typhosus* (Brucella) to these drugs has progressively increased so that the drug of choice against *Salmonella* infections today is ceftriaxone.

Dosage

The intravenous dose of ofloxacin is 200–400 mg 12 hourly. Gatifloxacin is given intravenously—400 mg once daily. The intravenous dose of levofloxacin and moxifloxacin is 500–750 mg once daily and 400 mg once daily respectively.

Side Effects

The side effects of the newer quinolones are by and large similar to those of ciprofloxacin.

MONOBACTAMS[15,16]

Aztreonam

This is a narrow spectrum antibiotic to be used exclusively against Gram-negative aerobic organisms. It does not have any activity against Gram-positive organisms and anaerobes. There is synergy reported between aztreonam and aminoglycosides against *P. aeruginosa*. Here again, Gram-negative organism producing ESBL are resistant to aztreonam.

Indications

Intra-abdominal sepsis, urinary tract infections and nosocomial pneumonia.

Dosage

The dose is 1–2 g IV every 6–8 hours. The dosage needs to be suitably adjusted in patients with renal failure.

Side Effects

Side effects are minor. Rarely, a rise in serum liver enzymes and in serum bilirubin have been reported.

LINEZOLID[17,18]

Linezolid is an oxazolidinone group antibiotic. It is bacteriostatic and acts by inhibiting the initiation of protein syntheses. It is predominantly effective against Gram-positive organisms, like MRSA, vancomycin-resistant enterococci, vancomycin-intermediate-resistance *Staphylococcus aureus* and penicillin-resistant pneumococci. It has 100% bioavailability when administered orally.

Linezolid may be associated with improved survival and better clinical cure rate compared to vancomycin in patients with nosocomial pneumonia caused by MRSA.[19] It is perhaps a more suitable alternative to vancomycin in nosocomial infections caused by MRSA particularly in pneumonia. There is however no definite proof of the superiority of linezolid over vancomycin or teicoplanin for other infections.

Dosage

The dose is 600 mg IV or orally every 12 hours.

Side Effects

The drug can cause vomiting, diarrhea and lead to candidal superinfection. Linezolid is a weak monoamine inhibitor and has a potential for interaction with adrenergic drugs. Resistance of organisms to the drug can occur on prolonged therapy; hence the routine use of this antibiotic should be discouraged.

CARBAPENEMS

Imipenem

Imipenem is a carbapenem with the widest antibacterial spectrum of any available antibiotic.[20,21] The drug is inactivated by enzymes in the renal tubule so that the drug cannot achieve high concentration in the urine. This is overcome by combining imipenem with an enzyme inhibitor cilastatin. Imipenem is one of the most expensive antimicrobials in use today. It is active against most clinically important bacteria. It has no activity against *Enterococcus faecium*, *Stenotrophomonas maltophilia*, many strains of *Burkholderia cepacia* and methicillin-resistant *Staphylococci*. Imipenem also inhibits endotoxin release from the Gram-negative bacterial cell wall.[22] It is therefore an extremely valuable drug to treat fulminant, unidentified infections in the ICU, or to treat fulminant infections due to multiple drug-resistant bacteria. It is particularly useful: (1) as empirical treatment of infection in severely immunocompromised patients; (2) in intra-abdominal or pelvic sepsis involving mixed infections with aerobes, anaerobes and enterococci; (3) infections with *Enterobacter* or *P. aeruginosa* resistant to other antibiotics.[13] It probably can be used as a single antibiotic in such patients. When the possibility of methicillin-resistant staphylococcal infection cannot be excluded, it should be combined with vancomycin.

The drug should be used with caution, restraint and circumspection as resistant bacteria are bound to emerge.[20,21] In fact, resistant bacteria have indeed emerged. Gram-negative organism producing carbapenases (metalloenzymes) are resistant to the action of carbapenems.

Dosage

Imipenem is given intravenously in a dose of 500 mg 6 hourly. The dose should be reduced by 50–75% in patients with renal failure.[23]

Side Effects

The main side effects are skin rashes, phlebitis, gastrointestinal symptoms and seizures, particularly in patients with renal insufficiency. Seizure disorders are reported in 1–3% of patients.[23] Patients with a previous history of seizure disorder are more prone to this complication.

Meropenem[15,16]

Meropenem is later carbapenem similar to imipenem. It has the same range of activity against Gram-negative organism and against anaerobes as imipenem.

Dose

The drug is given in a dose of 0.5–1 g 8 hourly in an intravenous infusion.

Side Effects

Incidence of seizures is reported to be less as compared to imipenem. The drug does not affect renal function.

Doripenem[24]

Doripenem is another Group 2 carbapenem with activity similar to meropenem and imipenem. It has the same spectrum of activity and potency against Gram-positive cocci as imipenem. Its Gram-negative activity is similar to that of meropenem except in *P. aeruginosa* where doripenem is twofold more potent than meropenem and imipenem.[25]

Dose

It is administered as 500 mg to 1 g 8 hourly IV. For drug resistant Gram-negative organisms, especially in patients with nosocomial pneumonias, it may be given as a 4-hour infusion.

Side Effects

Headache, nausea, diarrhea and phlebitis are the most commonly reported drug-related adverse events due to doripenem.

Ertapenem[26]

Ertapenem is a group 1 carbapenem that has similar spectrum of activity as imipenem and meropenem except that it does not act against *Pseudomonas* and *Acinetobacter*. It also acts against most Gram-positive bacteria excepting MRSA and *E. faecium*; it has excellent anaerobic activity.

Dose

It is administered as 1 g single dose either intravenously or intramuscularly. The once-daily regimen is attributed to its high protein binding capacity.

Side Effects

Nausea, vomiting and diarrhea may be seen in a small percentage of patients.

Tigecycline

It is the first of the glycyclines, which has an activity against aerobic Gram-negative bacteria and Gram-positive bacteria and anaerobes. The drug is particularly useful for the treatment of surgical wound infections, where both Gram-negative and MRSA are likely pathogens. It has an important role in the treatment of intra-abdominal infections, particularly due to multi-resistant organisms. These include Acinetobacter species, ESBL producing enterobacteriaceae, carbapenamase producing enterobacteriaceae, enterococci, Stenotrophomonas maltophilia. The drug has no action against Ps. aeruginosa and Proteus mirabilis.

Dosage

The dose is 100 mg loading dose followed by 50 mg IV twice daily. The major side effects appear to be dose related nausea and vomiting.

Polymyxin B and Colistin (Polymyxin E)[27]

Polymyxin B and colistin (polymyxin E) are cyclic cationic polypeptides, which act as membrane active agents on the Gram-negative cell wall. Colistin has recently emerged as a salvage drug for the treatment of severe multi-drug resistant Gram-negative infections. Colistin acts as a surface-active agent, and creates holes in the cell membrane of Gram-negative bacteria and disrupts them. It also binds to the lipopolysaccharide unit of the Gram-negative bacterial cell wall and blocks its endotoxic activity. Polymyxins selectively act on Gram-negative bacteria but are intrinsically resistant to *Providencia*, *Burkholderia*, *Morganella*, *Moraxella*, *Brucella*, *Edwardsiella*, *Vibrio*, *Aeromonas* and *Helicobacter* species. They also do not possess any activity against Gram-positive bacteria and anaerobes. In critically ill patients, it has been observed that after the initial rapid kill (<2 hours), there is substantial regrowth of organisms within 24 hours even when the dose of colistin is 64 times the minimum inhibitory concentration of *Acinetobacter*. This regrowth is due to resistant subpopulations and is termed as heteroresistance. Thus, polymyxins should never be used as monotherapy but always in combination with either imipenem, β-lactams, fluoroquinolones, tigecycline, minocycline or rifampicin. Complete cross-resistance is observed between the two polymyxins.

Dose

To start with, the prescribed dose is 1–2 million International units (IU) thrice daily. Recently, pK–pD studies conducted in critically ill patients have shown that colistin concentrations in vivo are below the MIC breakpoints (2 mg/L) even after the first few doses of the currently used dosing regimen. This amounts to a delay in starting appropriate treatment in the critically ill patients and is associated with increased mortality. Therefore, loading of up to 9 million IU and maintenance dosing (4.5 million IU twice daily) regimens have been recommended for colistin in combination with another antimicrobial agent. In patients with Gram-negative pulmonary infection, one to two million units of the daily dose can be given by nebulization.

Side Effects

- Nephrotoxicity and neurotoxicity.

NEWER ANTIBIOTICS

Daptomycin[28]

This drug is a lipopeptide active against Gram-positive cocci and MRSA. It is active against resistant and susceptible isolates of *S. aureus* and *enterococci*. The drug has been recently approved for the treatment for complicated skin and soft tissue infections. Daptomycin should not be used in the treatment of pneumonia as it is degraded by surfactant present in the lung. Its main use in limited to skin infections, bacteremia and endocarditis. It is given in a once-daily dosing of 4 mg/kg IV. The drug has a good safety profile except that it has been reported to cause rhabdomyolysis.

Quinupristin/Dalfopristin[29]

This drug is a streptogramin antibiotic. The drugs are present in a fixed 30:70 ratio and are synergistic. It is active against Gram-positive bacteria including VRE and MRSA. It is a bacteriostatic drug. It does not have activity against *Enterococcus faecalis*.

Dosage

The dose is 7.5 mg/kg IV 8 hourly for seriously ill patients to be administered preferably through a central vein, as local reactions may occur with use through peripheral veins.

Side Effects

The drug causes myalgias and arthralgias in up to 10% of patients.

Ceftobiprole and Ceftaroline[30]

They belong to the fifth generation of broad-spectrum cephalosporins with potent bactericidal activity against MRSA and penicillin resistant streptococcal pneumonia. The drug has a strong affinity for penicillin binding proteins of most Gram-negative and Gram-positive pathogens and is resistant to β-lactamase. It is being approved for use in patients with pneumonia and complicated skin and soft tissue infections (SSTIs).

Dalbavancin, Telavancin and Oritavancin[31]

These are bactericidal (inhibit cell wall synthesis) lipoglycopeptides with activity against Gram-positive bacteria. In addition to inhibiting cell wall synthesis, telavancin and oritavancin are also able to disrupt bacterial

membrane integrity and increase membrane permeability while oritavancin also inhibits RNA synthesis. The half-life of dalbavancin ranges from 147 hours to 258 hours, which allows for once-weekly dosing. The half-life of oritavancin of 393 hours may allow for one dose per treatment course, while telavancin requires daily administration. They are especially useful in the treatment of vancomycin resistant organisms. Clinical trials involving patients with complicated skin and skin structure infections (cSSSIs) have demonstrated that all three agents are equally efficacious. Telavancin was approved in 2009 for the treatment of complicated skin and skin structure tissue infections. Oritavancin and dalbavancin are still under clinical trials.

Dose

- Telavancin 600 mg 12 hourly daily.

Side Effects

The most common adverse effects reported are nausea, diarrhea, constipation, fever, taste disturbances and injection site reactions.

DRUG INTERACTIONS

Most ICU patients receive multiple drugs. The possibility and the potential for drug interactions are therefore very significant and should always be considered. Table 4 provides

Table 4: Modifications in dose and frequency of administration of important antimicrobial agents in patients with hepatic or renal dysfunction

Antibiotics	*Interval between doses with various creatinine clearances (renal failure)*			*Dose altered by dialysis*		*Dose in hepatic failure*
	Normal (50–80 mL/min)	*Moderate (10–50 mL/min)*	*Severe (<10 mL/min)*	*Hemodialysis*	*Peritoneal dialysis*

information on important interactions involving antimicrobial drugs used frequently in very ill patients in the ICU.

ADJUSTING DOSAGE SCHEDULES

Patients with hepatic or renal dysfunction often need modifications of drug dosage. Table 4 gives details regarding the use of antimicrobials against a background of renal or hepatic insufficiency in ICU patients.

Monitoring drug levels is particularly important in critically ill patients. Failure to attain therapeutic levels can have disastrous consequences, just as toxic levels add to the problems of a very ill patient. Monitoring drug levels, so as to avoid toxicity, is specially necessary in a patient population in whom the pharmacokinetics of a drug is difficult to predict. This is particularly so in patients whose hepatic or renal function is suspect, or in those who have clear evidence of hepatic or renal dysfunction. Unfortunately, in our set-up, monitoring drug levels is difficult, and till recently was non-existent. Fortunately, laboratories have now started to estimate serum levels of important drugs used in the ICU. This is of great help in adjusting the appropriate dose of these drugs (including antimicrobials), in very ill ICU patients.

CHAPTER 47

Invasive Fungal Infections in the ICU

INTRODUCTION

Fungal infections occur not only in immunocompromised patients (see Chapter The Immunocompromised Patients), but also in patients who are under critical care for various problems, e.g. acute infections, trauma or major surgery, and who have a normal immune defense mechanism to start with. Perhaps the most important cause of fungal overgrowth and any systemic or deep-seated fungal infection in these patients is the prolonged use of broad-spectrum antibiotics which alter the bacterial flora, and promote the growth of unusual resistant organisms and fungi. Acute or critical illnesses in the course of time also temporarily depress the immune mechanisms within the body to some extent. Thus patients with unresolved or persistent septic infections, or long-standing untreated foci of infection, e.g. undrained abscesses, show a decreased capacity to respond to immunological challenges. All major surgical procedures are also followed by a depressed immunological response; this is related to an increase in suppressor cells, a fall in T4 lymphocytes, and alterations in lymphokine production. These changes are however temporary, and are quickly reversed as recovery progresses. In the presence of complications, the postoperative changes noted above are protracted, and may well play a role in predisposing the patient to both bacterial and fungal infections. Finally, poor nutritional status further depresses the immune defense mechanisms. Thus a combination of various factors, varying in degree in each individual critically ill patient, form a background against which fungal infections can occasionally supervene. The environment too perhaps has some part to play, e.g. clear-cut nosocomial outbreaks of invasive aspergillosis have been described in critical care units, and these have been related to the marked increase in air-borne spores of *Aspergillus fumigatus* in these units.

The important invasive fungal infections encountered in a critical care setting are candidiasis and aspergillus infections. Occasionally, infections with the mucor species are observed, particularly in diabetics or other severely immunocompromised patients. Other fungal infections are being increasingly recognized in the West; in our country, however, we are as yet blissfully unaware of their possible occurrence.

CANDIDAL BLOODSTREAM INFECTIONS

Epidemiology

Candida represents the commonest form of invasive fungal disease[1] in most ICUs all over the world. It now accounts for 12% of all hospital-acquired bloodstream infections (BSIs). Though there was a major increase in candida BSI in the 1980s, the incidence of BSI has now stabilized or even declined in the West. The incidence of BSI with candida varies in different ICUs in our country. We have noted a definite increase in candidal BSI in our unit; perhaps this holds for many units in the large urban centers of India. An important epidemiological trend in many western centers is the shift in the distribution of candidal species responsible for BSI, *Candida albicans* being responsible for only half of all BSIs caused by yeast. Recent data from the Prospective Antifungal Therapy Alliance (PATH) database from 2004 to 2008 showed that the incidence of candidemia caused by the non-albicans candida species was higher (54.4%) than *C. albicans* (45.6%). The commonest non-albicans species that were isolated being *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. krusei.*[2] In our unit *C. albicans* is no longer the main isolate in BSI; there is a slow but definite increase in isolates of *C. tropicalis*, *C. glabrata*, *C. parapsilosis*, *C. krusei* and also an occasional presence of other rare candida species. *C. tropicalis* now is the main bloodstream isolate

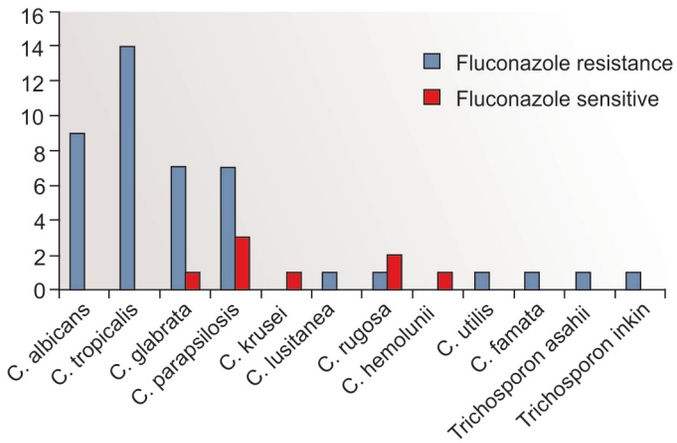

Fig. 1: Fluconazole resistance among yeast isolated from blood cultures (2010–2012)

constituting 14% of all bloodstream yeast isolates. It is possible that the increasing incidence of non-*C. albicans* species may be related to the extensive use of fluconazole not only as treatment but also as a prophylactic drug in patients in whom fungal infections are likely to occur. This epidemiological shift which is obvious in the West, but slowly making itself felt in our country as well, has important implications for therapy, because of intrinsic resistance of *C. glabrata* and *C. krusei* to fluconazole. Figure 1 illustrates the distribution of yeasts isolated from blood cultures and resistance to fluconazole.

A study on bloodstream fungal infection from the Sir Ganga Ram Hospital, New Delhi, India,[3] has also shown a significant increase in both candidemia and total antifungal use. There was increase in infections due to the non-albicans species and this was correlated to increasing use of fluconazole. The study also revealed the emergence and isolation of a novel species *C. haemolunii* with decreased susceptibility to both amphotericin B and azoles. The authors of this study have commented that decreased susceptibility to fluconazole, as well as the threat of emergence of cross-resistance to voriconazole against the background of high azole consumption, may limit the use of these agents as presumptive therapy for candida BSIs.

A study by Chakrabarti A et al (presented as a poster at the ID Week San Diego, 2012) included 25 ICUs across India and found that the incidence of candidemia was 7.0/1,000 ICU admissions over a 6-month period. This study highlighted the distribution of candidia species in these patients, the most common being *C. tropicalis* and the emergence of uncommon species like *C. haemulonii* and *C. rugosa*, *C. guilliermondii*, *C. pelliculosa* and also of azole resistant C. albicans and C. tropicalis. Figure 2 shows the distribution of various candida species in this study.

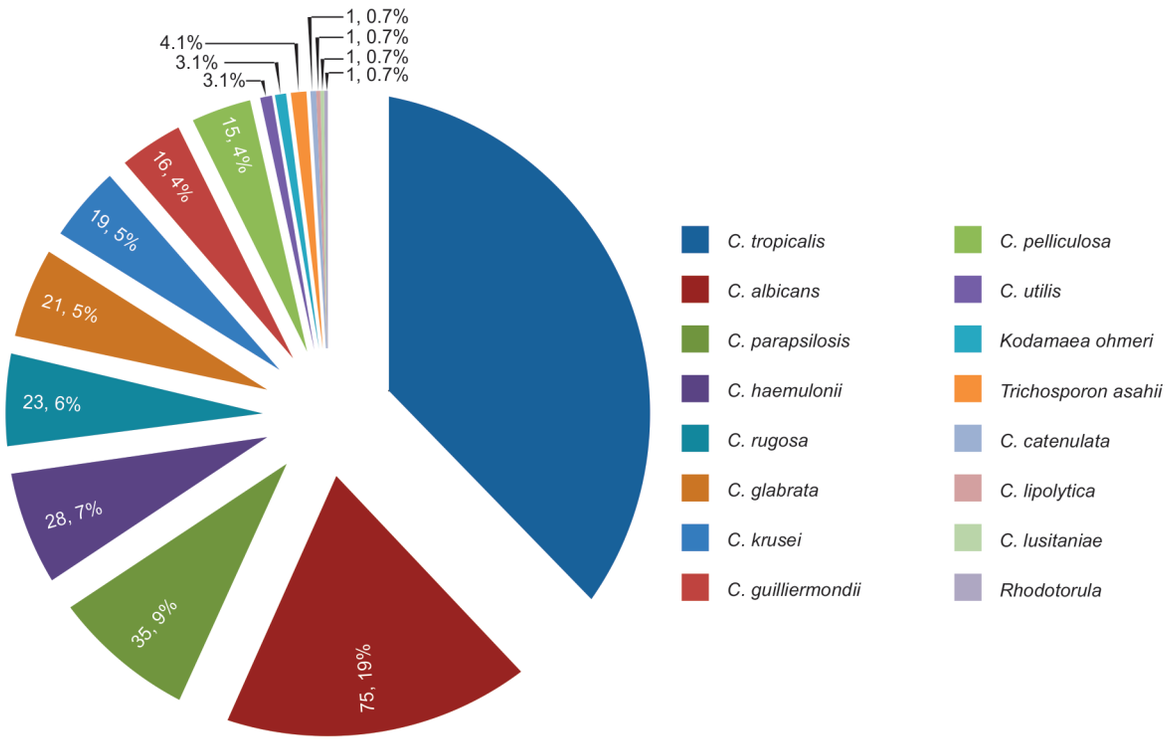

Fig 2 : Distribution of various candida species in candidemia patients

Box 1: Risk factors for invasive candidiasis

- Prolonged use of antibiotics
- Corticosteroids, immunosuppressive therapy
- Central venous catheterization
- Prolonged ICU stay
- Surgery
- TPN
- Diabetes, malignancy
- Organ transplant
- Dialysis
- Pancreatitis
- Multifocal colonization

Risk Factors for Invasive Candidiasis

Specific to the ICU, several risk stratification schemes exist to identify patients at high risk for candidemia. A multicenter cohort study from Spain[4] involving 1,699 adult ICU patients identified surgery, multifocal colonization, TPN and severe sepsis to be strong predictors of candidal infection. Another large cohort study from American and Brazilian ICUs identified the following features to predict invasive candidiasis. These factors were antibiotics, central venous catheter (CVC), TPN, dialysis, major surgery, pancreatitis, use of steroids and other immunosuppressive agents.[5]

Both these studies in our opinion have omitted one major risk factor for invasive candidiasis—*duration of ICU* stay. The longer the stay in the ICU, the greater the chance of the patient developing a fungal infection. What combination of risk factors stated above are more likely to cause invasive candidiasis is undetermined. The risk factors for invasive candidiasis are listed in Box 1.

According to the Indian study by Chakrabarti et al. quoted earlier, central venous catheterization, urethral catheterization and mechanical ventilation were seen as significant risk factors associated with candidemia in the ICU. Table 1 shows the various risk factors linked with candidemia as found in this study.

Proof of invasive candidiasis rests in a positive blood culture for candida. Unfortunately blood cultures are positive only in 50–70% of patients with invasive candidiasis. It is important to note that a positive blood culture for candida should never be ignored as a possible contaminant and should prompt search for the source of infection. Biopsy of specific lesions from a normally sterile site (e.g. lung, liver) demonstrating the histopathology of invasive candidiasis can give a definite diagnosis, but this is often not feasible in critically ill patients. Because of these difficulties in diagnosis, a non-culture based diagnosis test has been researched upon and recently approved by the Food and Drug Administration. This test is the 1-3-β-D-glucan test. 1-3-β-D-glucan is an important major component of the fungal cell wall and it can be detected from the blood and assayed in patients with invasive candidiasis. It has a sensitivity of 75–100% and a specificity of 88–100%. However, this is a broad spectrum assay that detects not just candida but also *Aspergillus*, *Fusarium*, *Acremonium*, *Saccharomyces* species.[6] The test therefore requires careful interpretation. In fact none of the currently available tests allow of a reliable diagnosis. Hence, in a febrile critically ill patient who is unresponsive to antibiotics and who has risk factors for invasive candidiasis, empiric treatment against candidal infection is justified.

Table 1: Risk factors associated with candidemia in the ICU

Risk factors	*No. of cases*
CVL catheterization	218
Urethral catheterization	201
Invasive mechanical ventilation	169
Drainage catheter	88
Antibiotic therapy	63
Dialysis	55
Total parenteral nutrition	55
Steroid therapy	61

Source: Chakrabarti A et al. Candidemia in Intensive Care Units of India: a Six Months Interim Report on Active Surveillance. ID week 2012, San Diego. Poster Abstract Session: Clinical Mycology and Fungal Virulence October 18, 2012.

Clinical Features

Pyrexia of unknown origin not responding to antibiotics therapy is the key presentation in most cases. Candidal infection can involve any organ system in invasive candidiasis. Liver and spleen involvement lead to hepatosplenomegaly. The kidney, lungs, brain may also be involved. Endophthalmitis is a rare but noteworthy feature in some patients.

Treatment[7]

Treatment should not await a confirmed culture. High risk cases presenting with fever and showing a sharp clinical deterioration should be promptly started on antifungal therapy. The CVC should as far as possible be removed. If absolutely necessary a new central line on the opposite side should be inserted.

For non-neutropenic hemodynamically stable patients, fluconazole is the drug of choice unless there is a suspicion of a fluconazole resistant species—e.g. history of a recent azole exposure or a history of previous colonization by *C. glabrata*, *C. krusei*. If used empirically the drug is given IV in a dose of 800 mg/day, the dose being adjusted with reference to renal function. The drug is continued till the offending candida species has been identified.

In neutropenic patients, or in hemodynamically unstable patients, or in ICUs where there is significant infection rate with fluconazole resistant species, an echinocandin is the drug of choice till species identification of the fungal isolate is made. The echinocandin generally used is caspofungin. Two other commercially available echinocandins are also available. These are micafungin and anidulafungin. Experience with

the last two echinocandins is however limited. Lyophylized amphotericin can also be used if there is intolerance to or unavailability of an echinocandins. Voriconazole is an acceptable alternative but offers no advantage over fluconazole. It is to be recommended as step-drown oral therapy for selected cases of candidiasis due to *C. krusei* or voriconazole susceptible *C. glabrata*. If infection has been caused by *C. parapsilosis*, fluconazole is preferred as these fungi are less susceptible to echinocandins.

The duration of therapy recommended is 14 days from the last positive cultures. If cultures remain negative treatment should continue for 7–10 days after the patient is afebrile. Treatment at times needs to be longer depending on the degree of infection and the site involved.

INVASIVE ASPERGILLOSIS

Invasive aspergillosis is less commonly encountered than invasive candidiasis. Sinopulmonary infection is most often observed, though many organ systems can be involved. *A. fumigatus*, *A. flavus* and *A. niger* account for nearly all human disease. Though the disease may rarely be encountered in immunocompetent individuals, it is most frequently seen in immunocompromised or immunosuppressant patients in the ICU.

The risk factors are—

- Prolonged neutropenia.
- Corticosteroids and immunosuppressive therapy.
- Solid organ transplant patients.
- Hemopoietic stem cell transplant patients.
- Advanced HIV with CD counts often below 200 cells/μL.
- Chronic granulomatous disease.

The clinical features have been discussed in the Chapter The Immunocompromised Patients.

Demonstration of the aspergillus in biopsy samples is the gold standard for diagnosis. A positive aspergillus culture from the blood though uncommon is also confirmatory. A bronchoalveolar lavage (BAL) culture positive for aspergillus should lend strong suspicion for invasive pulmonary aspergillosis, if clinical features are compatible with the diagnosis.

Computed tomography (CT) findings of the chest may suggest the diagnosis—cavitations, nodules, wedge shaped pleural based shadows suggesting pulmonary infarcts, the halo sign, the crescent sign may be observed. The clinical and imaging features as also the value of the galactomannan test and the β glucan test have been commented upon in the Chapter The Immunocompromised Patients.

Treatment[8]

According to a multicenter randomized open label trial comparing amphotericin B to voriconazole as initial therapy for invasive aspergillosis, voriconazole was associated with increased survival (76% vs 58%). Voriconazole is therefore generally recommended as first line therapy. Before voriconazole, itraconazole was used intravenously against invasive aspergillosis with reasonable success. Voriconazole has now replaced itraconazole in treatment. Posaconazole is an additional extended triazole for treating refractory disease.

The echinocandins (caspofungin) can be used as alternative therapy to voriconazole particularly in patients who cannot tolerate voriconazole or who are refractory to standard therapy. Many units use a combination of amphotericin B or amphotericin B lipid formulation and voriconazole in the treatment of severe invasive aspergillosis. There is however very little evidence for the increased efficacy and safety of this combination therapy.

The final drugs recommended as salvage therapy for invasive aspergillosis are micafungin and anidulafungin, two new echinocandins.[8] The experience with micafungin or anidulafungin is limited. The drugs are best kept in reserve for salvage therapy.

MUCORMYCOSIS

Mucormycosis is a life threatening mould infection caused by fungi belonging to the older Mucorales. The organisms causing this mould infection include Rhizopus, Rhizomucor, Absidia and Mucor. These organisms almost always have a predilection for immunocompromised patients and present with a rapid onset angioinvasive disease. Risk factors include diabetes, acidosis, solid organ and bone marrow transplant recipients, use of immunosuppressant drugs, iron overload, deferoxamine treatment.

Diabetes and in particular diabetic acidosis are major risk factors. Patients present with rhinocerebral disease that causes destruction of the nasal septum and paranasal sinuses; the disease then extends into and destroys the orbit and penetrates upward into the brain.

Pulmonary mucormycosis is the typical presentation in post-transplant patients. Invasion of vessels with ischemic necrosis of the tissue is a typical feature of this fungal disease.

Treatment[9] is with high dose amphotericin B 1–1.5 mg/kg per day or amphotericin B lipid preparation in doses of 5–7.5 mg/kg per day. Azoles and echinocandins are ineffective in mucormycosis.

Urgent surgical treatment is always necessary to excise and debride involved tissue in rhinocerebral disease. Surgery may also be necessary in pulmonary mucormycosis.

Early diagnosis is critical for survival. Diagnosis is made on clinical grounds and the presence of the fungus in scrapings of involved tissue, and of the fungus in the discharge from infected tissue. Delay in initiating treatment increases mortality. Posaconazole has been recently used as prophylaxis in severely immunocompromised patients. This drug has also occasionally been used as salvage therapy but is not a standard treatment for the disease.

The efficacies of antifungal agents are listed in Table 2. Doses and dosing adjustment of commonly used antifungal agents are listed in Table 3.

This is followed by a brief description on the role of amphotericin B in fungal infections.

Table 2: Efficacy of antifungal agents in fungal infections

	Amphotericin B or Amphotericin B lipid formulation	*Fluconazole*	*Voriconazole*	*Echinocandin*
C. Albicans	+	+	+	+
C. Tropicales	+	+	+	+
C. Glabrata	+	-	-	+
C. Krusei	+	-	+	+
C. Parapsilosis	+	+	+	+/-
Aspergillus	+	-	+	+
Cryptococcus	+	+	+	-
Mucorales	+	-	-	-
Fusarium	-	-	+	+/-

Note: Aspergillus terreus is intrinsically resistant to amphotericin B. *Aspergillus lentulus* is intrinsically resistant to azoles.

Table 3: Doses of commonly used antifungal agents

Drug	*Dose*	*Dose adjustment*
Invasive Candidiasis		
Amphotericin B	0.6–1 mg/kg/day, IV	None, careful monitoring of renal and liver function
Amphotericin B lipid formulation	3–5 mg/kg/day, IV	None, careful monitoring of renal and liver function
Fluconazole	400–800 mg/day, IV or PO	Renal insufficiency
Voriconazole	IV, 6 mg/kg every 12 hr for 2 doses followed by 3–4 mg/kg every 12 hour PO, <40 kg –100 mg every 12 hr; >40 kg –200 mg every 12 hour	Hepatic dysfunction
Echinocandins		
Caspofungin	70 mg loading dose followed by 50 mg/day, IV	Hepatic dysfunction
Micafungin	100 mg/kg	
Anidulafungin	200 mg loading dose followed by 100 mg/day, IV	None
Invasive Aspergillus		
Amphotericin B	1–1.5 mg/kg/day, IV	As listed above
Amphotericin B lipid formulation	5 mg/kg/day, IV	As listed above
Voriconazole	As listed above	As listed above
Echinocandins	As listed above	As listed above
Itraconazole	IV, 200 mg every 12 hr for 4 doses followed by 200 mg/day PO, 200–400 mg/day	Multiple drug interaction, IV not recommended for CrCl <30 mL/min
Mucormycosis		
Amphotericin B	1–1.5 mg/kg/day, IV	As listed above
Amphotericin B lipid formulation	≥5 mg/kg/day, IV	As listed above

Abbreviations: PO, by mouth; IV, intravenous; CrCl, creatinine clearance.

Amphotericin B

For poor developing countries, the cheapest of all antifungal agents against invasive fungal infection is amphotericin B deoxycholate and it is therefore appropriate to add a few additional remarks on this drug. The drug has important side effects and in critically ill patients it is best to start with a test dose of 1 mg in adults (0.5 mg in children <30 kg) given over 1 hour. This is followed after 4 hours by a dose of 0.5 mg/kg administered over 3–4 hours. Even if the test dose produces a reaction, 10 mg is administered after 4 hours. The dose is

increased by 15–20 mg daily so that the dose of 0.5–1 mg/kg is reached within 3–7 days. The drug is then continued daily till a total dose of at least 1–1.5 g is administered. In granulocytopenic patients empirically given amphotericin B should be continued till recovery from granulocytopenia ensues. Deep visceral infections may require a total dose of 2–3 g or even more.

Amphotericin B should be given in a 5% dextrose solution. Electrolyte solutions should be avoided, as they cause precipitation of the amphotericin B suspension. Side effects are common; pyrexia with chills is the most frequent side effect observed. Intravenous hydrocortisone in a dose of 50 mg given at the time of infusion often controls a severe pyrexial reaction. Other important side effects include hypotension, nausea, thrombophlebitis, hypokalemia and renal dysfunction with a rise in the serum creatinine level. A significant rise in the latter warrants a temporary stoppage of the drug; it is restarted when the creatinine level drops. Permanent renal tubular damage may occur when large doses (3–4 g) of amphotericin B are used.

Amphotericin B does not achieve significant concentration in the urine, CSF or peritoneal fluid. In cases of fungal meningitis, intrathecal administration of amphotericin B may be combined with intravenous therapy. The intrathecal dose is 0.5–1 mg dissolved in the CSF. The total dose should not exceed 15 mg. Arachnoiditis and motor or sensory disturbances may occur as complications. An Omaha reservoir is sometimes used for instillation of amphotericin B into the cerebral ventricles in patients with CNS fungal infection. The danger of introducing secondary bacterial infection is ever present with this mode of administration.

Clinical Resistance to Amphotericin B

Clinical resistance to amphotericin B is observed in severely immunocompromised patients, in patients with infected prosthetic valves or other foreign bodies, and in advanced visceral fungal infections involving the liver, spleen or kidneys.

Hepatosplenic candidiasis is a clinically resistant infection which may prove resistant to even high doses of amphotericin B. The development of fever, abdominal pain, or liver cell dysfunction occurring in a patient recovering from granulocytopenia should raise suspicion of candidal infection within the abdomen. Investigations should include ultrasound, CT and, if necessary, MRI imaging of the abdominal organs. A combination of amphotericin B and flucytosine or fluconazole should be promptly started. Therapy may need to be continued for several months, and may yet be unsuccessful.

Microbiological resistance to amphotericin B has been reported in *C. albicans*, *C. tropicales*, other candida species, as also against other fungi—*Trichosporon beigeli*, Fusarium species, and *Pseudallescheria boydii* species.[10] In the West, *Trichosporon beigelii*, Fusarium species, and *P. boydii* species are increasingly recognized causes of systemic fungal infections.[10] A combination therapy of high doses of amphotericin B with flucytosine or fluconazole is recommended as initial treatment. If unsuccessful, fluconazole plus flucytosine is advised for systemic fungal infections due to polyene resistant fungi.[10]

Systemic fungal infections originating from an infected foreign body, viz. an infected prosthetic valve, can never be controlled unless the foreign body is first removed. Fungal valvular endocarditis invariably necessitates removal of the valve. Further examples where removal of infected foreign bodies is mandatory include—

- Removal of central venous lines.
- Removal of infected ventriculoperitoneal shunts in patients with fungal infections of the CNS.
- Removal of urinary catheters in patients with candidiasis involving the urinary tract.
- Removal of a dialysis catheter in fungal peritonitis associated with peritoneal dialysis.

It is not enough to use antifungal drugs in the treatment of systemic fungal infections in critically ill patients. As always, overall critical care is of vital importance. An assiduous search to determine why systemic fungal infection occurred, and whether the source of infection can be controlled or eradicated is of great importance.

Flucytosine

Flucytosine is an antifungal drug that has not been discussed earlier. It is effective both orally and on intravenous use and is active against candida species and cryptcoccus. It enters cerebrospinal fluid as also urine and peritoneal fluid and is particularly useful in fungal (especially cryptococcal) infections involving the meninges and/or the neuroaxis. Its excretion is reduced in renal failure; the daily dose should therefore be adjusted in these patients. Its main disadvantage is the development of either primary or secondary drug resistance to a significant number of fungal isolates. There is also the danger of bone marrow suppression, particularly with use of toxic doses. The dose of flucytosine is 100 mg/kg of bodyweight orally, divided in four equal doses every 6 hours. The dose for intravenous infusions is 50 mg/kg infused over 20–40 minutes every 6 hours. If possible blood levels of the drug should be estimated and not allowed to go beyond 100–120 µg/dL.

As has already been mentioned, combination therapy with amphotericin B and flucytosine is often used in relatively resistant fungal infection. The drugs when used together are synergistic, so that the dose of amphotericin may be reduced in patients who do not tolerate its full dose. In cryptococcal meningitis, a combination therapy of 0.3–0.6 mg/kg of amphotericin B and the usual dose of flucytosine is more effective in sterilizing the CSF and prevents relapse. Alternatively, IV amphotericin B (0.7 mg/kg per day) can be used for the first 2 weeks, followed by fluconazole or flucytosine orally.

Surgical Infections in the Intensive Care Unit

- Postoperative Wound Infections
- Necrotizing Soft Tissue Infections
- Intra-Abdominal Sepsis
- Abdominal Compartment Syndrome

CHAPTER 48

Postoperative Wound Infections

INTRODUCTION

Surgical infections in the intensive care unit fall into the following two groups.

Infections Which Require Prompt Surgery

These include serious soft tissue infections like necrotizing fasciitis, acute inflammatory intra-abdominal disease, acute suppurative disease tucked away (and therefore not easily evident) in other parts of the human anatomy, e.g. the thorax, within the head and neck, or in the skeleton.

Acute inflammatory or acute suppurative disease within the abdomen accounts for most infections requiring definitive surgery. Important surgical problems within the abdomen include acute suppurative appendicitis, empyema of the gall-bladder, pancreatic suppuration, and peritonitis following a leak from the bowel. Peritonitis may be generalized or may be localized, and may ultimately result in an intra-abdominal abscess. A localized intra-abdominal abscess may go unrecognized, and is responsible for a hidden, or rather undiscovered source of systemic sepsis, septic shock and multiple organ failure. Pelvic suppuration is also an important and at times unrecognized source of systemic sepsis. Pelvic suppuration may present as pelvic peritonitis, pelvic abscess or suppuration involving the organs within the pelvis—chiefly tubo-ovarian suppuration.

Wound Infections Which Occur as a Complication of Surgery

Infected post-surgical wounds pose serious problems for critically ill patients in the ICU.[1] Major surgery performed for problems totally unrelated to infection can thus be complicated by wound infection. The rather hostile microbiological environment in the ICU, almost certainly encourages such wound infections. Besides nosocomial wound infections, the postoperative surgical patient is also exposed to other nosocomial infections prevalent in the ICU. These chiefly include nosocomial pneumonias, urinary infections and catheter (central line) related sepsis. These nosocomial complications can drastically influence the morbidity and mortality of surgical patients in the ICU, and call for prompt diagnosis and treatment.

POSTOPERATIVE WOUND INFECTIONS[1-4]

General Considerations

Wound infections account for about a quarter to a sixth of all nosocomial infections. Despite the most meticulous attention to surgical technique, a surgical incision exposes sterile tissue to some degree of contamination.[2] The rate of infection of a surgical wound mainly depends on the nature of the wound. Operative wounds are classified as (i) clean; (ii) clean-contaminated; (iii) contaminated; (iv) dirty and infected, based on the degree of contamination at the time of surgery. The incidence of postoperative wound infections in clean wounds may be less than 2%. On the other hand, in dirty and infected wounds, the incidence may be as high as 40%.[3] Table 1 gives the classification of surgical wounds and the incidence of wound infection.[3]

The propensity to infection in surgical wounds depends on a number of other factors—

- The degree of attention paid to preoperative, intraoperative and postoperative asepsis; ensuring adequate tissue perfusion and eliminating tissue dead space, reduces the incidence of postoperative infections.

Table 1: Classification of surgical wounds and incidence of wound infection

Type of wound	*Characteristics*	*Incidence of infection (%)*
Clean	Non-traumatic, inflammation absent, respiratory, genitourinary or GI tracts not breached	<2
Clean contaminated	GI, respiratory, biliary or genitourinary tracts entered without significant spillage	2–8
Contaminated	Gross spillage from GI tract	8–15
Dirty and infected	Acute bacterial inflammation present, traumatic wound with devitalized tissue, foreign body, fecal contamination, or delayed treatment	12–40

Source: Adopted from Cruse PJ. Wound infections: epidemiology and clinical characteristics. In: Howard RJ, Simmons RL (Eds). Surgical Infectious Disease. New York: McGraw Hill Companies; 1988. p. 320.

- The stage of disease when surgery is performed. Surgery performed late in the natural history of a disease is often prolonged, complicated and more likely to result in postoperative infections.
- The duration of preoperative hospitalization influences the incidence of wound infections. The infection rate almost doubles with each week of hospitalization prior to surgery. Colonization with nosocomial and often resistant bacteria is common, particularly if the patient has been in the ICU prior to surgery.
- The risk of wound infection increases with prolonged surgery, the liberal use of cautery, and the placement of drains.
- A concurrent but remote infection (e.g. pulmonary infection, urinary tract infection or skin infection) increases the likelihood of wound infection. It is always wise to postpone elective surgery till such infections are eradicated.
- Infections are more likely in the old, feeble, diabetic, malnourished, anemic patients and those with chronic hepatitis or renal or cardiac dysfunction.
- Immunosuppression because of disease or drugs (antimitotic drugs, corticosteroids) is associated with a far greater risk of wound infection.
- A history of shock or prolonged hypotension during or soon after surgery is a risk factor—probably related to poor tissue perfusion.
- An important factor which decides the nature and severity of wound infection is the nature of organisms likely to contaminate the wound. Possible contamination with *Staphylococcus aureus*, Gram-negative organisms, or anaerobes, like clostridia, can give rise to violent tissue infections in spite of all the care in the world.[1]

Factors predisposing to postoperative wound infections are listed in Box 1.

Box 1: Predisposing factors for postoperative wound infections

- Poor preoperative, intraoperative or postoperative asepsis
- Prolonged or complicated surgery, or surgery performed late in the natural history of the disease
- Prolonged hypotension during or soon after surgery
- Prolonged period of hospitalization particularly in the ICU
- Presence of coexisting infection elsewhere in the body (lungs, skin, urinary tract)
- Adverse host factors, e.g. old, feeble, malnourished, anemic patients and those with hepatic or renal dysfunction
- Immunocompromised patients
- Pathogenicity of infecting organism

Clinical Features

The diagnosis of wound infection is based on a history, physical examination and the results of Gram stain and culture report of a discharge from the wound.[1-3,5,6] Wound pain due to infection may be difficult to distinguish from postoperative incisional discomfort. Most wound infections occur between the fourth to seventh day of surgery. Fever occurring 2–4 days after surgery should prompt examination of the wound, which may show erythema, edema, tenderness, warmth and often purulent discharge. Rarely a crepitus may be palpated. Deeper soft tissue infections may show no physical signs initially—particularly so in obese patients.

The microbiological spectrum responsible for wound infections is vast. Staphylococcal infections generally occur 4–6 days after surgery. The infection is well localized, painful and purulent.[6]

Gram-negative wound infections usually present with fewer local inflammatory signs, but with systemic features of fever, tachycardia and leucocytosis. Systemic sepsis may follow depending on the virulence of the organisms, and the resistance of the host. Gram-negative infections are usually due to contamination by enteric bacilli as well as by anaerobic streptococci and by *Bacteroides fragilis*. The incubation period for most of these infections is 7–14 days.[6] The potential gastrointestinal sources for such infections should be carefully looked for.

Fever, and severe pain in a surgical or traumatic wound accompanied by a progressively toxic state should lead to a suspicion of a wound infected by Group A streptococci or clostridia.[5] Early diagnosis, use of appropriate antibiotics and prompt surgical treatment are lifesaving.

Treatment

Surgical Drainage and Debridement

This should be left to the surgeon's expertise. The principle in management is drainage of infections and debridement of necrotic tissue. Drainage requires removal of skin sutures or staples, and laying the wound open. Dressings should be done daily or as often as instructed by the surgeon. The wound is

allowed to granulate and heal by secondary intention. If the wound is clean and clear of infection, secondary suturing may be done.

Antibiotics

Antibiotics are invariably used except for the very mild and superficial infections. The empiric choice of antibiotics in severe wound infections depends on the clinical picture and the nature of the surgery performed. Antibiotic therapy may be suitably modified after culture sensitivity reports of the discharge from an infected wound are available.

Hyperbaric Oxygen

The use of hyperbaric oxygen in certain infections will be commented upon in the section on Clostridial Myonecrosis in Chapter Necrotizing Soft Tissue Infections.

Antibiotic Prophylaxis[7,8]

Prophylactic antibiotics decrease the incidence of wound infections. The selection of the antibiotic depends on the possible pathogens in a given situation, and should be left to the discretion of the surgeon. The commonly used antibiotics for prophylaxis include either a third generation cephalosporin like ceftazidime 1 g intravenously, or a second generation cephalosporin like cefazolin 1 g intravenously, or an aminoglycoside like gentamicin 60–80 mg intravenously. It is important to stress that the unnecessary, indiscriminate and prolonged use of powerful antibiotics for prophylaxis can cause untoward side effects. These include hypersensitivity reactions, possible toxic effects (as on the kidneys with the use of aminoglycosides), and above all the emergence of drug-resistant superinfections. A single agent generally suffices for prophylactic therapy. This should be given immediately prior to the skin incision and should be repeated during surgery if this exceeds 3 hours, or twice the half-life of the drug. Most surgeons in the West do not continue antibiotics beyond the first day, as they believe that continuing the drug does not confer any additional benefit. In our country many surgeons prefer to continue the antibiotic for 5–7 days. In contaminated wounds or dirty and infected wounds, the extended use of antibiotics for a number of days after surgery, as best judged by the surgeon, is accepted practice.

In clean surgical wounds involving open heart surgery or intracranial surgery, the use of antibiotics for more days, is also justified. It is however doubtful if extended use in these patients confers any special benefit.

Mechanical cleansing of the bowel plus administration of a non-absorbable oral antibiotic is generally done to reduce the bacterial load in the colon and the distal small bowel before colorectal surgery. Oral amoxicillin is the antibiotic most often used. Metronidazole 400 mg thrice daily is also given for 4 days prior to surgery to reduce the load of anaerobic organisms within the large bowel. Most surgeons also use a systemic antibiotic for prophylactic purposes just before the skin incision. This combined approach of oral and systemic antibiotic prophylaxis reduces the bacterial flora within the gut, and helps to reduce the incidence of septic complications.

CHAPTER 49

Necrotizing Soft Tissue Infections

INTRODUCTION

Necrotizing soft tissue infections (NSTIs) cover a wide range of infections in the soft tissue compartment. They spread very rapidly causing extensive necrosis and gangrene of the dermis, subcutaneous tissue, fascia and often extend into the underlying muscle (myonecrosis) and the tissue beneath the muscle. NSTIs include a spectrum of diseases which range from necrotizing fasciitis to Fournier's disease and gas gangrene. Though many different terms have been used to describe these infections, the term NSTI encompasses all necrotizing infections involving the soft tissue compartment. They have common clinical, pathophysiological, microbial, treatment and outcome characteristics.[1]

Necrotizing soft tissue infections are generally community-acquired. It can involve any part of the body but usually affects the upper and lower extremity and occasionally involves the groin and perineal areas. The infection can however occur after surgery, presenting as a wound infection even after minor surgical procedures.

RISK FACTORS

More than 80–90% of infections occur in patients who have pre-existing comorbidities.[2,3] The two perhaps most important risk factors are diabetes, present in 56–70% of cases[3] and the presence of a portal of entry. Portals of entry include surgery, needle punctures as after injections (particularly with contaminated needles used by drug addicts), minor abrasions and trauma. Blunt trauma or muscle strain with hematoma formation is also implicated as a risk factor. Other risk factors postulated are advanced age, peripheral vascular disease, chronic alcoholism, cirrhosis, chronic liver disease, cancer, use of immunosuppressant drugs and intravenous drug abuse.[2,3] Pre-existing comorbid states that contribute to mortality include cardiopulmonary disease, cancer and malnutrition.[4] Although pre-existing conditions increase both the risk for NSTI and mortality from NSTI, the main risk factor for mortality is the time to surgical debridement. The greater the time lag between the early symptoms of an NSTI and surgical debridement, the greater the risk of death (mortality 38%). The lesser the time lag, the better the outcome (mortality 4%).[4]

PATHOPHYSIOLOGY

The pathophysiology of all NSTIs is similar. Organisms gain entry through a break in the skin barrier causing a soft tissue infection in the dermis, superficial fascia of the subcutaneous tissue, initially sparing the overlying skin and underlying muscle. The rapidly spreading infection causes thrombosis of penetrating vessels with resulting necrosis of tissue supplied by these vessels. There is therefore a necrosis of dermis, fascia, subcutaneous tissue ultimately also involving the underlying muscle and overlying skin. Microorganisms multiply in this necrotic tissue. Systemic spread of infection can cause overwhelming severe sepsis with septic shock. Toxic shock syndrome results if the toxin is associated with infection by the group A *Streptococcus*. Muscle involvement generally occurs late, except with clostridial infection when muscle involvement can be early.

MICROBIOLOGY[5]

Though NSTIs can be caused by a single microbe (monomicrobial), more often than not the cause is polymicrobial. Organisms in polymicrobial infections include Gram-positive, Gram-negative organisms, anaerobes and aerobes. Polymicrobial infections are virulent and lead to a synergism between facultative aerobes and anaerobes. Monomicrobial infections occur in 15–30% of cases, the most common organism responsible for this infection being the group A *Streptococcus*. Necrotizing fasciitis is classically caused by *Streptococcus pyogenes* infection. Occasionally, monomicrobial infections are caused by *Clostridium* or *Staphylococcus aureus*. The most frequent Gram-negative organisms found in polymicrobial infection are *E. coli, Klebsiella*, *Pseudomonas*, *Enterobacter* and *Acinetobacter*. Though the management of all NSTIs is basically similar, identification of the infecting organism on culture may guide a more appropriate choice of antibiotics.

CLINICAL FEATURES[2,3,6,7]

The infection begins with fever and the appearance of a localized, red, indurated painful swelling at the site of minor trauma or at the site of a surgical wound. At times no evidence of even minor trauma is available both on history and physical examination. Pain is often a predominant feature and the significance of this is often ignored as the wound or infected area appears reasonably clean to start with. The infection spreads very rapidly with increasing pain, fever and toxemia. Characteristic local features include edema, violaceous discoloration, pain beyond the zone of the inflamed area, and the appearance of vesicles and hemorrhagic bullae. A palpable crepitus may be present and is a diagnostic feature. When the presence of crepitus is in doubt, an X-ray of the soft tissues, or better still a magnetic resonance imaging (MRI), may demonstrate gas in tissue planes. Within a few days extensive necrosis and sloughing of skin, subcutaneous tissue, fascia and at times even of the muscle occurs. Fever, tachycardia, tachypnea and overwhelming sepsis are often present. The mortality is as high as 30–70%; death being due to sepsis, septic shock and multiple organ failure.

DIAGNOSIS

The diagnosis is easy when there is clear evidence of tissue necrosis. Initially NSTIs are often misdiagnosed as cellulitis or abscess since both necrotizing and non-necrotizing soft tissue infections cause pain, erythema, induration and swelling. The presence of necrotic bullae immediately point to an NSTI; but this occurs late in the natural history. Points which should arouse suspicion of a possible NSTI are pain out of proportion to physical findings,[2] tenderness to palpation beyond the area of skin involvement, lack of a definite margin to the inflammation and a dusky erythema. The presence of bullae and/or crepitus on palpation though late in the evolution of the illness confirms the diagnosis.

INVESTIGATIONS

Blood culture in severe cases reveals bacteremia. There is marked leukocytosis. Severe anemia is due to both hemolysis and infection. Sepsis can lead to disseminated intravascular coagulopathy with a deranged coagulation profile. With extensive involvement of muscle (myonecrosis), rhabdomyolysis occurs and contributes to renal failure. Investigations assessing function of different organ systems are necessary.

When the clinical diagnosis is in doubt a fine needle aspiration or an incisional biopsy should be performed. These procedures may demonstrate the organisms on Gram stain. The material obtained should also be cultured on both aerobic and anaerobic media, and an antibiotic sensitivity of the organisms grown should be asked for.

Imaging Studies[8]

Soft tissue radiographs may demonstrate subcutaneous emphysema. An MRI study of the affected area picks up air in the soft tissues that can be missed by soft tissue radiography. This finding is not necessary for diagnosis and in any case may occur late in the disease.

MANAGEMENT

The principles of management are early diagnosis, prompt excision and debridement of all involved necrotic tissue, use of immediate empiric broad spectrum antibiotic therapy and critical care with support to all organ systems. Nutritional supplementation is invariably needed to meet the increased metabolic needs of the patients. In all patients, particularly in diabetics (who are at great risk for NSTIs), strict glycemic control should prevail.

Excision and Debridement

Necrotizing soft tissue infections (these include necrotizing fasciitis, Fournier's disease and gas gangrene) are life-threatening infections in which extensive surgical excision and debridement are necessary for survival. Delay in surgery significantly increases mortality. Debridement needs to be extensive, as infection is present well beyond the margins of the involved skin area. Incomplete debridement leads to further spread of necrosis. The margins of the excised area after surgery must appear perfectly healthy. The wound should be lightly packed and dressed; planned surgery may be required every 24–48 hours to ensure that ongoing necrosis is not present. Further excision and debridement is performed, if necessary. Repeated dressing change should be done in the

early days after debridement to ensure that the wound is clean and there is no evidence of recurrence or of ongoing infection. Wounds that cannot be closed by primary suture require split thickness skin graft.[3] The use of hyperbaric oxygen has been advocated following surgery. Its use in the management of NSTIs to reduce morbidity and mortality has however not been established. Hyperbaric oxygen therapy should be given a try following surgical excision and debridement in patients with clostridial myonecrosis.[9]

Antibiotic Therapy

Streptococcus pyogenes infection causing necrotizing fasciitis responds best to penicillin G, two mega units intravenously every 4 hours. Clindamycin is a suitable alternative. However, since necrotizing fasciitis can be caused by other organisms and since infection is much more often polymicrobial than monomicrobial, prompt broad spectrum antibiotic therapy should be started the moment a diagnosis is made or strongly suspected. Antibiotics should cover Gram-positive, Gram-negative organisms and anaerobes. Gram-positive coverage should be given by using penicillin or an extended spectrum penicillin derivative (like piperacillin tazobactum) or by vancomycin in penicillin allergic patients. Gram-negative coverage should be given with either a third generation cephalosporin or carbapenem and anaerobic cover with clindamycin or metronidazole.[9] Clindamycin has been particularly useful in children as it blocks exotoxin and M protein production leading to decreased inflammation and sepsis.[10] If a staphylococcal infection is suspected vancomycin 500 mg 6 hours or 1 g twice daily should be added to the antibiotic regime.

Antibiotics should be continued till the debridged wound is clean and infection has been controlled.

Critical Care

Critical care is vital for survival. These patients require fluid and electrolyte replacement as also cardiovascular and renal support. Ventilator support is often necessary. Critical care is as for severe sepsis and septic shock.

Nutritional Support

As mentioned earlier nutritional supplementation is important for overall care.

CLOSTRIDIAL MYONECROSIS[5,7,9]

Clostridial myonecrosis requires special mention for two reasons—

1. Infection by clostridia often produces early muscle necrosis.
2. This fulminant infection though rare is still encountered in poor developing countries.

Clostridial myonecrosis is a quick spreading fulminant infection, also known as gas gangrene; it is fortunately rare. It follows gross contamination of traumatic wounds by manure and is more likely to occur in the presence of devitalized tissue and poor perfusion. It can also occur when surgery is performed in a nonsterile environment where there is little regard for asepsis. In poor developing countries, there are operation theaters in smaller towns where conditions for surgery leave a lot to be desired. Clostridial myonecrosis in our country is a rare but important cause of wound infection in septic abortions. Operations on the gallbladder or large bowel can also rarely produce clostridial infection. The wound in clostridial myonecrosis is pale, painful with a watery, serous, or a serosanguinous discharge; above all it has a putrid smell. Crepitus is frequent; however, it may be absent in the early stages of infection. It is to be noted that crepitus in a wound infection can be produced by gas-forming organisms other than clostridia. Clostridial infection spreads rapidly and can lead to gangrene, overwhelming sepsis, shock and death. A Gram stain of the discharge from the wound shows Gram-positive cocci and a few neutrophils. A quick diagnosis, the use of appropriate antibiotics, and rapid surgical excision and debridement are necessary as in necrotizing fasciitis.

Investigations

The white blood cells (WBC) count is usually raised with an increase in the mature and immature neutrophils. Gram stain and culture from the wound discharge help to identify the pathogens causing the wound infection. A sensitivity test to various drugs helps in the choice of an appropriate antibiotic. Most experienced surgeons can predict with a fair degree of accuracy, the nature of the infection from the history, the surgery performed and the appearance of the wound.

Management

Crystalline penicillin alone in massive doses of 2–4 million units intravenously 4 hourly can control clostridial myonecrosis and monomicrobial cellulitis. Critical care of the patient involves cardiorespiratory support and attention to the functions of other organ systems as outlined in the Chapter Sepsis and Septic Shock. Critical care is vital for survival.

Use of Hyperbaric Oxygen[10]

Hyperbaric oxygen as a mode of treatment has been recommended as an adjunct to surgery and to antibiotic therapy for clostridial myonecrosis and for other soft tissue necrotizing infections. Hyperbaric oxygen is bactericidal for *Clostridium perfringens* and bacteriostatic for other anaerobic bacteria. Hyperbaric oxygen has however no effect on the toxin already produced; it can only reduce further production of exotoxin. It leads to an arrest of further necrosis, and often produces a visible improvement in the wound. As many as 14–15 sessions in the hyperbaric chamber may be necessary. The difficulty often lies in transporting very ill patients to a distant center.

CHAPTER 50

Intra-Abdominal Sepsis

GENERAL CONSIDERATIONS

One of the most important surgical problems requiring intensive care is intra-abdominal sepsis. Intra-abdominal infections (IAIs) are currently classified into uncomplicated or complicated. In uncomplicated IAIs, the infection involves a single organ and does not involve the peritoneum. In complicated IAIs, the infection spreads beyond the organ causing either a localized peritonitis (an intra-abdominal abscess) or a generalized peritonitis. The merit of this classification is dubious as what appears clinically as uncomplicated, not uncommonly is termed complicated at surgery.

Intra-abdominal infections can also be classified into community acquired or nosocomial. Nosocomial infections carry an increased mortality as these patients are more seriously ill, and have an increased propensity to infections caused by multi-drug resistant organisms. The classification of IAIs should also take into consideration the clinical severity—i.e. whether the patient has merely sepsis, severe sepsis or septic shock. Patients with septic shock have the highest mortality.

The most frequent site of intra-abdominal sepsis is the peritoneal cavity. If generalized, it results in generalized peritonitis; if localized, it forms an intraperitoneal abscess. Perhaps the commonest site of an intraperitoneal abscess is in the right lower quadrant in association with acute appendicitis or a perforated duodenal ulcer. Localized intraperitoneal abscesses also occur in the left lower quadrant, and the pelvic, subhepatic and subphrenic spaces. Less frequently they may be found in the lesser sac or between the loops of the intestine.

Retroperitoneal abscesses occur in the space between the transversalis fascia and the retroperitoneum. They may occur posteriorly or anteriorly. Posterior retroperitoneal abscesses are usually related to suppuration within the kidneys, pancreas or the spine. Rarely they can be due to an infected blood clot. Anterior retroperitoneal abscesses occur following surgery performed for an intra-abdominal infection.

Visceral abscesses occur most often within the liver and the pancreas. An empyema of the gallbladder is also best considered an abscess. A tubo-ovarian abscess is an important focus of suppuration within the pelvis. Occasionally, visceral abscesses can form in other organs like the kidney or the spleen.

The grave danger of any form of intra-abdominal suppuration is progressive sepsis leading to septic shock and to multiple organ failure. Critically ill patients who develop intra-abdominal sepsis fall into two groups. The first consists of patients with less severe infections and good immune responses, so that the infection is contained and an intra-abdominal abscess results. These patients are less likely to progress to multiple organ failure. The second group comprises of those whose defense mechanisms are either very poor or suppressed, or those whose defenses are overwhelmed by virulent pathogens. These patients often develop generalized peritonitis without the formation of a localized abscess, and progress rapidly to septic shock and multiple organ failure. Death often results in spite of good critical care, surgery, antibiotics and nutritional support.

ETIOLOGY[1]

The most common causes preceding intra-abdominal suppuration are perforated peptic ulcer, acute appendicitis and acute diverticulitis. Perforation of any portion of the gut within the abdominal cavity, whatever the etiology, leads to peritonitis and intra-abdominal sepsis. Besides a perforated peptic ulcer, other important perforations

include appendicular perforation, diverticular perforation, perforation of the small bowel in enteric fever and perforation of a tuberculous ulcer. Corticosteroids can cause a peptic ulcer which may perforate, and nonsteroidal anti-inflammatory drugs can induce perforation in any portion of the gastrointestinal tract, including the large bowel. Occasionally, perforation with localized or generalized peritonitis can occur in inflammatory bowel disease.

Gangrene of the bowel from strangulation and obstruction, or from mesenteric vascular ischemia or occlusion are important causes of peritonitis.

Rupture of an empyema of the gallbladder or a gangrenous cholecystitis also causes generalized peritonitis. Acute inflammatory disease within the pelvis initially causes pelvic peritonitis, which may progress to a generalized peritonitis. Acute salpingitis, tubo-ovarian abscess are the classic examples of inflammatory pelvic pathologies. Acalculous cholecystitis and acute pancreatitis can complicate the course of a critical illness and are believed to be related to poor perfusion states in critically ill patients. In our country, septic abortion and puerperal sepsis are important causes of peritonitis.

In a critical care setting, low perfusion states, as observed in cardiogenic shock, congestive heart failure or shock due to any cause, can cause ischemia to the gut with a breach in its anatomic integrity.

Trauma to the abdomen either blunt or penetrating is also an important cause of intra-abdominal sepsis.

Postoperative peritonitis may be the direct result of abdominal surgery. It is more lethal than the other forms of peritonitis. Peritonitis following surgery is most commonly due to anastomotic dehiscence. Ischemia, infection, hemorrhage can all singly or in combination promote dehiscence. Excessive spillage and soiling of the peritoneum during handling of viscera during surgery can also lead to postoperative intra-abdominal sepsis. In gynecological operations on the pelvic viscera, an uncommon but important cause of postoperative peritonitis is an ileal perforation a few inches above the ileocecal junction. In my opinion, this is related to undue pressure on the ileocecal area exerted by a retractor during surgery. A small area of the ileum is devitalized or suffers pressure necrosis, and this perforates on the third or fourth postoperative day. Diagnosis may be difficult and delayed, leading to disastrous consequences.

Primary peritonitis is due to a generalized peritoneal infection unrelated to any intra-abdominal perforation or septic pathology. The most important background against which primary bacterial peritonitis occurs is in patients with cirrhosis of the liver with ascites. Infection is generally due to gram-negative organisms; it is probably hematogenous in origin. Primary bacterial peritonitis is also observed in patients with nephrotic syndrome, systemic lupus erythematosus and very rarely in immunocompromised individuals. A primary pneumococcal peritonitis is a dangerous entity in children, and is often mistaken for peritonitis following an appendicular perforation. Box 1 lists the common causes of intra-abdominal sepsis.

Box 1: Common causes of intra-abdominal sepsis

- Gastrointestinal—
  - Perforations—
    - Perforated gastric or duodenal ulcer
    - Perforation of hollow viscus or any part of the gut
    - Enteric or tuberculous ulcer
    - Inflammatory bowel disease
    - Diverticulitis
    - Iatrogenic [corticosteroid and nonsteroidal anti-inflammatory drugs (NSAID) use]
  - Infection—
    - Acute appendicitis
    - Diverticulitis
    - Gangrene from strangulation
    - Obstruction
    - Ischemia to the bowel
- Acute necrotizing pancreatitis
- Cholecystitis (acute, acalculous, gangrenous)
- Liver abscess (pyogenic, amebic), splenic abscess
- Pelvic pathologies—
  - Acute salpingitis
  - Tubo-ovarian abscess
  - Septic abortions/puerperal sepsis
- Perinephric/Retroperitoneal abscesses
- Trauma to the abdomen
- Following abdominal surgery
- Low-perfusion states (congestive cardiac failure, shock of any etiology)
- Primary bacterial peritonitis—
  - Cirrhosis of liver with ascites
  - Nephrotic syndrome
  - Systemic lupus erythematosus (SLE), other immunocompromised states
  - Pneumococcal peritonitis in children

PATHOPHYSIOLOGY[2]

The term peritonitis used without qualification, refers to acute bacterial suppurative peritonitis. Presence of sterile bile, blood or gastric acid in peritoneal cavity can also cause intense peritoneal irritation, and a chemical inflammation which is clinically indistinguishable from surgical peritonitis. The notable difference in these situations is the absence of bacterial infection, which when present plays a crucial role in the evolution of the natural history and the fatal outcome.

Bacterial contamination of the peritoneum is countered by local peritoneal defenses, and by a general immune response. The following pathophysiological changes are observed in suppurative peritonitis—

1. Local inflammation of the peritoneum.
2. Adynamic ileus.
3. Hypovolemia, chiefly related to (1) and (2) above.
4. Changes in other organ systems secondary to (1) and (2) above.
5. Hormonal and metabolic changes related chiefly to the immediate and acute stress of infection.
6. The evolution of the sepsis syndrome.

The sepsis syndrome is a systemic response of the body to bacteria, their toxins and to other bacterial products. Sepsis and the semantics of clinical states closely associated with sepsis have been discussed in the Chapter Sepsis and Septic Shock. It is worth stressing that intra-abdominal sepsis can be fulminant, and can quickly graduate to septic shock, multiple organ dysfunction and death. In earlier years, before intensive care came into being, most patients with generalized suppurative peritonitis died before sepsis with multiple organ system failure could fully evolve. Sepsis is due to endotoxins and other toxins of bacteria and their products, having far-reaching effects on all organ systems of the body. The syndrome however is not just the direct result of infection; it is also partly due to the unorchestrated response of the defense mechanisms of the body to infection. This is dealt with at length in the Chapters Sepsis and Septic Shock and Multiple Organ Dysfunction Syndrome. Localized undrained intra-abdominal abscesses (peritoneal, retroperitoneal or visceral) can also lead to the syndrome of sepsis and multiple organ failure. The tempo of the evolution of the syndrome with a localized abscess is generally slower than with generalized suppurative peritonitis.

The section below briefly deals with the pathophysiological changes listed under points (1) to (5). It then proceeds to mention the pathogenic factors which determine the severity of intra-abdominal sepsis.

Local Peritoneal Inflammation

The local response to a peritoneal insult is characterized by hyperemia of the peritoneum with vascular congestion, edema and transudation of fluid from the extracellular interstitial compartment into the abdominal cavity. This transudation is accompanied by the diapedesis of polymorphonuclear leukocytes. It is followed by exudation of a protein-rich exudate containing large quantities of fibrin and other plasma proteins. Clotting of this protein-rich exudate results in sticking together of the bowel loops to other viscera and the parietes in the areas of inflammation. This helps to localize the area of peritoneal contamination, to some extent.

Adynamic Ileus

Initially there is a short period of bowel hypermotility; motility is then depressed, and is followed by a complete adynamic ileus. The gut distends and is filled with fluid and air, most of the latter being swallowed air. Fluid secretion into the gut is markedly enhanced, whilst absorption of fluid from the gut is markedly impaired. There is therefore sequestration of a large volume of fluid within the lumen of the gut.

Hypovolemia

The loss and sequestration of fluid in the gut and in the peritoneal cavity may be marked and results in a fall in the volume of the interstitial tissue compartment and in the circulating volume within the vascular compartment. Fluid is also trapped as edema beneath the mesothelium of visceral peritoneal linings, adding thereby to the volume of water, electrolytes and proteins translocated into the third space. The degree of loss of extracellular fluid into this nonfunctional third space is proportional to the surface area of the peritoneum involved. The volume of sequestrated fluid may be as large as 4–6 liters in 24 hours.

Secondary Changes in Other Organ Systems

Cardiac Response

Cardiac response is conditioned by hypovolemia and progressive metabolic acidosis. Diminished venous return due to a fall in circulating volume leads to a fall in cardiac output, hypotension, a decrease in oxygen transport and to poor oxygenation of tissues. This promotes metabolic acidosis, which in turn further depresses cardiac function. The clinical importance of this should never be forgotten. Expanding the extracellular and intravascular compartments by intravenous infusions can reverse the above trends. In fact, if the patient is made normovolemic and survives the initial crisis, the circulatory state often graduates to that typically seen in sepsis. The hemodynamic changes are then characterized by a high cardiac output, hypotension and a low systemic peripheral vascular resistance (see Chapter Sepsis and Septic Shock). Even so, the tissue demand for oxygen is often inadequately met, so that tissue hypoxia results.

Renal Changes

These are secondary to hypovolemia, fall in cardiac output, and the effects of increased secretion of the antidiuretic hormone and aldosterone (see below). Renal perfusion suffers and there is a fall in the glomerular filtration rate due to the prerenal factors stated above. Renal insufficiency develops to a varying extent and enhances metabolic acidosis.

Respiratory Changes

Abdominal distension due to ileus, together with restriction of diaphragmatic and intercostal movements due to pain, results in a fall in the tidal volume. This predisposes to atelectasis, which in turn results in a ventilation-perfusion mismatch, and a fall in the PaO_2.

Hormonal and Metabolic Changes

Peritonitis causes an almost immediate response from the adrenal medulla. There is an outpouring of epinephrine and norepinephrine into the blood, resulting in vasoconstriction, tachycardia and sweating. There is also an increased secretion of adrenocortical hormones for the first 2–3 days following a peritoneal insult. Secretion of antidiuretic hormone and aldosterone is also increased, causing a reduction in urine output with conservation of sodium and water. Water retention may exceed sodium retention, leading to hyponatremia.

The metabolic rate is generally increased with a corresponding increase in oxygen demand by the tissues. For reasons stated above, the cardiopulmonary system is unable

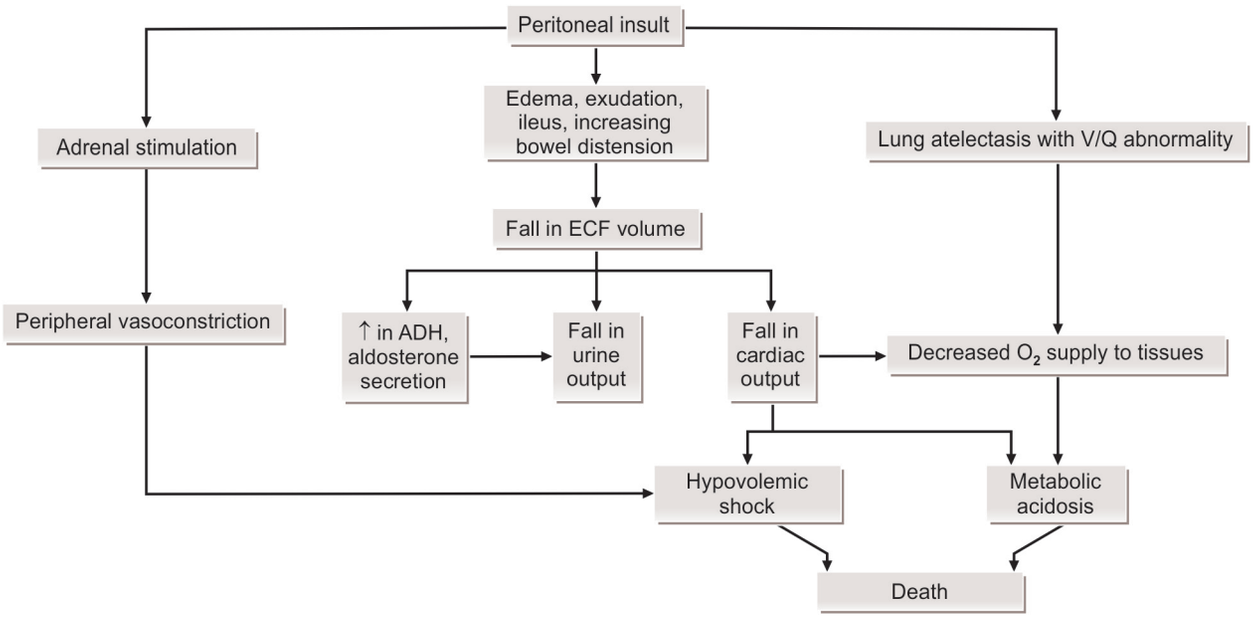
to achieve delivery of oxygen commensurate with the demand for oxygen by the tissues, resulting in tissue hypoxemia and lactic acid acidosis.

Protein catabolism is also increased from the very start, and progressively becomes more severe. Weight loss of 25–30% of lean body mass is observed if peritonitis persists. Though albumin synthesis is increased, serum albumin levels progressively fall, as albumin accumulates in the peritoneal cavity, and is lost to the general circulation.

If the above described general responses to suppurative peritonitis go unchecked, and if the hypovolemic circulatory state is uncorrected, there is increasing tissue hypoxia and increasing metabolic acidosis causing increasing dysfunction of all organ systems. Death results from irreversible hypovolemic shock. The classical clinical description of peritonitis by Hippocrates corresponds to this terminal hopeless state.

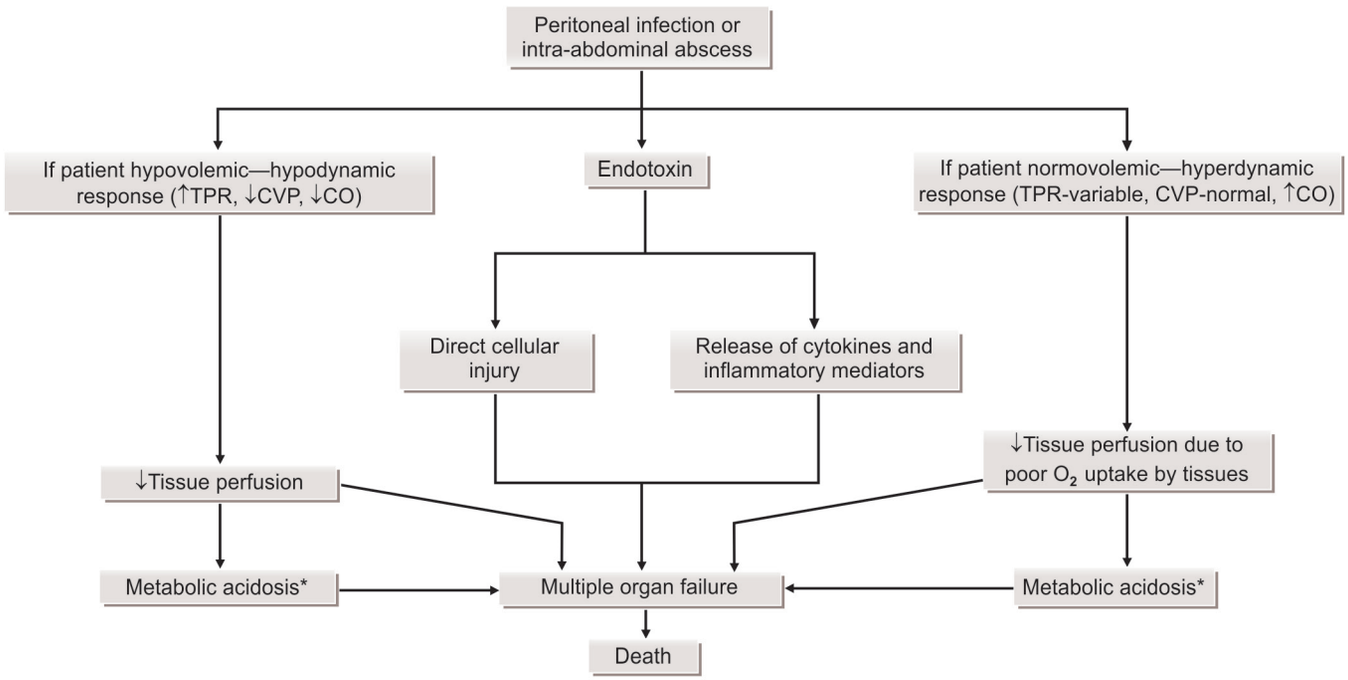
The general and specific responses to peritonitis are illustrated in Flowcharts 1 and 2.

Flowchart 1: General responses to peritonitis



Abbreviations: ECF, extracellular fluid; ADH, antidiuretic hormone; V/Q, ventilation/perfusion.

Flowchart 2: Specific responses to peritonitis



Peritoneal infection or intra-abdominal abscess
If patient hypovolemic—hypodynamic response (↑TPR, ↓CVP, ↓CO)
Endotoxin
If patient normovolemic—hyperdynamic response (TPR-variable, CVP-normal, ↑CO)
Direct cellular injury
Release of cytokines and inflammatory mediators
↓Tissue perfusion due to poor O_2 uptake by tissues
↓Tissue perfusion
Metabolic acidosis*
Multiple organ failure
Metabolic acidosis*
Death

*If early treatment successful, recovery possible.

Abbreviations: TPR, temperature, pulse, respiration; CVP, central venous pressure; CO, cardiac output.

Box 2: Factors determining severity of intra-abdominal sepsis

- Virulence and microbiology of pathogens
- Extent of contamination—
  - Maximal spillage in ileal and cecal perforation
- Presence of foreign bodies and blood
- Errors in management—
  - Unrecognized, unsutured perforations and leaks
  - Inadequate surgical drainage and debridement
  - Administration of laxatives in abdominal sepsis
- An immunocompromised patient
- Comorbid conditions—diabetes, chronic renal disease, cirrhosis of the liver, chronic alcoholism
- Elderly patients >70–75 years

Factors Determining Severity of Intra-Abdominal Sepsis (Box 2)

Virulence and Microbiology of Pathogens

The larger the dose of pathogens and greater their virulence, the more severe the infection. The microbiology of intra-abdominal sepsis is polymicrobial. This is always so when the peritoneal cavity is invaded from the GI tract. The most common bacteria are coliform organisms (mainly *Escherichia coli*), other *enterococci*, *Bacteroides fragilis*, anaerobic cocci and *Clostridia*. Other Gram-negative bacilli such as *Klebsiella* and *Proteus* species are often present, but form a small part of the total flora. There are an increasing number of fungal isolates in patients with prolonged sepsis and in immunocompromised hosts. Anaerobes always play an important role in contributing to the virulence of intra-abdominal and intraperitoneal sepsis. It is important to note that a patient in whom peritonitis or an intra-abdominal abscess develops in the hospital whilst on antibiotics may have a different aerobic flora. *Klebsiella*, *Proteus* and *Pseudomonas* often predominate, and may be resistant to antibiotics.

Extent of Contamination

The severity of peritonitis and intra-abdominal sepsis following spontaneous or traumatic perforation of the GI tract depends on the size and location of the perforation. Ileal or cecal perforations with spillage are associated with a greater contamination and greater morbidity than perforations of the very proximal or very distal parts of the GI tract. Proximally the gut has fewer bacteria, and distally the fecal contents are more solid, and the inflammation is more easily localized. On the other hand, ileal and cecal contents are liquid and have a high concentration of bacteria and of residual enzymes, which prevent localization of the infection.

Presence of Foreign Bodies and Blood

The presence of a foreign body or blood clots (which invariably get infected) increases the morbidity and mortality in peritoneal inflammation.

Errors in Management

The following errors need to be stressed, and should be avoided—

- Draining the peritoneal cavity at surgery, without also ensuring that all leaks from the GI tract or a ruptured viscus have been surgically sealed. A continuing source of peritoneal contamination always spells death.
- Attempting to control infection and sepsis by the use of antibiotics without adequate surgical drainage and debridement.
- An important error of commission is the administration of laxatives or enemas in abdominal sepsis. This increases the risk of rupture of an inflamed bowel segment.

Immunosuppressed Patients

Cancer, the prior use of antimitotic drugs, radiation therapy, myeloproliferative disease and human immunodeficiency virus (HIV) infection lead to a poor immune response to acute infection. The extent, gravity and prognosis of intra-abdominal sepsis are worse compared to immunocompetent patients.

Comorbid Conditions

The prognosis is comparatively poor when intra-abdominal sepsis occurs in uncontrolled diabetics, in cirrhotics, in alcoholics, in patients with chronic renal or heart failure and in the elderly.

CLINICAL FEATURES AND DIAGNOSIS[1,3]

The clinical features of intra-abdominal sepsis depend on the age of the patient, the background disease against which intra-abdominal infection develops, and whether the patient is immunocompetent or immunosuppressed.

Peritonitis presents as an acute abdomen, but localized suppuration (intraperitoneal abscess) may present with subtle manifestations.

Abdominal pain is the most important symptom of generalized peritonitis. It is severe and constant, the patient preferring to lie absolutely still in bed without any movement. Even turning in bed from one side to the other sharply increases the pain. To start with, the pain is maximal over the initial site of inflammation; it then spreads to involve the whole abdomen as generalized inflammation supervenes. Pain is often accompanied by nausea and vomiting.

The abdomen may show distension because of ileus. Abdominal movements on respiration are poor; the patient is tachypneic with shallow intercostal breathing. Tenderness on palpation, with guarding and rigidity, are accompaniments of peritoneal irritation and inflammation. Rebound tenderness is present; percussion of the abdomen is painful, and is merely a gentler method of eliciting rebound tenderness. Free fluid in the abdomen is difficult to detect on clinical examination, but is often present. Auscultation typically reveals a silent abdomen; the heart sounds are clearly heard on abdominal auscultation.

Table 1: Localized pain in the abdomen particularly if associated with a palpable tender "lump" helps to determine the intra-abdominal pathology

Right upper and middle quadrant	*Epigastric*	*Left upper and middle quadrant*
Acute cholecystitis Acalculous cholecystitis Hepatic abscess Hepatitis Cholangitis Pancreatitis Appendicitis (in pregnant women) Empyema of the gallbladder with obstruction to the cystic or common bile duct Pyelonephritis	Pancreatitis Pancreatic abscess Perforated peptic ulcer Mallory-Weiss syndrome Left lobe liver abscess Subphrenic abscess	Perforated peptic ulcer Pancreatitis Pancreatic abscess Splenic abscess Subdiaphragmatic abscess Pyelonephritis
Right lower quadrant	*Periumbilical*	*Left lower quadrant*
Acute appendicitis Acute salpingits Perforation of the cecum Pyelonephritis	Early acute intra-abdominal abscess Anastomotic leaks Abdominal compartment syndrome	Diverticular abscess Colonic perforation

Rectal examination and pelvic examination may reveal tenderness or a painful inflammatory mass. The hernial orifices and the genitals must always be inspected and examined.

Systemic features include fever, tachycardia, tachypnea and leukocytosis. None of these however may be present. Leukocytosis is generally observed but not always so. Leukopenia, if present, is of ominous significance.

Hypovolemic Shock

Clinical features of hypovolemia and hypovolemic shock are often present in the first few days of acute generalized suppurative peritonitis. This is, as explained earlier, due to sequestration of fluid from the interstitial tissue compartment into the peritoneal cavity and the lumen of the gut. Hypotension, tachycardia and oliguria with a rise in the nonprotein nitrogen and creatinine levels are observed. If the circulatory state is uncorrected and if prompt surgery for the peritonitis is delayed, the patient rapidly deteriorates and dies. The Hippocratic facies—"hollow eyes, collapsed temples, the color of the face brown, black, livid or lead colored"—is the description of a patient about to die with generalized peritonitis.

If on the other hand hypovolemia is corrected, the circulatory hemodynamics restored and critical care offered, the patient may proceed to develop all the features of prolonged sepsis. Sepsis may or may not respond to surgery and antibiotics. Sepsis will never respond if the cause or the source that seeds the peritoneum is undetected, or is not eradicated totally by surgical procedures. In patients with multiple bowel perforations, or in whom surgery has been delayed, or is inadequate, radical eradication of the sources of peritonitis is impossibly difficult. The very friable bowel loops with total obliteration of tissue planes render the approach to the sites of perforation impossible. Death from multiple organ failure is inevitable in these patients. The better the critical care offered, the slower and more agonizing the death, particularly so in young patients. It is pathetic to helplessly watch the slow decline, and the final inevitable disintegration of all organ system functions in these patients.

Localized Peritoneal and Retroperitoneal Inflammation

In the form of an intra-abdominal abscess, localized peritoneal and retroperitoneal inflammation may show few or no clinical signs. A tender localized mass is not always palpable. A subphrenic abscess may present with dyspnea, hiccups, referred shoulder pain, basal atelectasis or pleural effusion. A pelvic abscess may present with diarrhea or urgency of micturition. A rectal and vaginal examination may elicit tenderness, by causing direct pressure over the inflamed mass or peritoneum. A psoas abscess may manifest as spasm and pain in the hip, when the psoas is stretched on extension of the hip (the psoas sign). Retroperitoneal perinephric abscesses are difficult to diagnose clinically till the abscess surfaces and produces warmth and tenderness over the loin posteriorly.

Systemic features include fever, often spiky in nature and leukocytosis. If the abscess is undrained, sepsis is protracted, and leads to progressive multiple organ dysfunction, failure and death (see Chapters Multiple Organ Dysfunction Syndrome and Sepsis and Septic Shock).

Localized pain, tenderness, guarding over different quadrants of the abdomen (particularly when associated with a lump) often point to the site of the abdominal pathology. Table 1 is not all-inclusive in this regard but illustrates the above point.

The diagnosis of intra-abdominal sepsis is particularly difficult in the following groups of patients—

1. *In the immunosuppressed patient*, inflammatory reactions and all immune responses are suppressed or muted. The usual abdominal signs may be barely elicitable.

This is particularly so in severely neutropenic patients. The presence of fever of undetermined origin in these patients should prompt a meticulous search for possible abdominal sepsis. Imaging studies are of great help in arriving at a correct diagnosis.

2. *In patients who are critically ill in the ICU*[3-5] for unrelated problems, but who develop intra-abdominal sepsis as a complication, intra-abdominal sepsis may be fortuitous or iatrogenic (as for example, peptic perforation in a patient on corticosteroids). It may also occur as a complication of a poor perfusion state or a low output syndrome. This can cause bowel ischemia, a small leak from the bowel and intra-abdominal suppuration. Acalculous cholecystitis or acute pancreatitis can also occur as a complication of a low output syndrome or due to poor perfusion of the abdominal viscera. Intra-abdominal suppuration could also result from an anastomotic leak in an operated patient receiving postoperative surgical care, or from a fortuitously occurring abdominal pathology unrelated to the primary illness.

   Recognition of intra-abdominal suppuration is difficult because of the paucity of symptoms and physical signs, the preoccupation of the intensivist with the primary critical illness for which the patient is admitted, and because of the frequent presence of a blunted sensorium in a very ill patient. The use of analgesics, in particular opioid analgesics, antibiotics, and of mechanical ventilator support in a critically ill individual, renders the diagnosis of a life-threatening abdominal pathology doubly difficult. The history is not likely to be contributory in an obtunded patient. It retains its importance if the patient is alert and can describe the nature and site of pain, and can help the examining physician to localize the site of pain or confirm its generalized nature on abdominal palpation. Abdominal examination in suspected intra-abdominal suppuration in a critically ill individual should be performed serially. A digital rectal examination should always be done; a vaginal examination for suspected pelvic sepsis is also important. Since abdominal pain for various reasons may be difficult to evaluate in a critically ill patient, an overall concern with other clinical features may point to possible intra-abdominal sepsis. The occurrence of a new fever, increasing tachycardia, tachypnea should arouse suspicion for an occult abdominal pathology. Patient-ventilator asynchrony, an increased respiratory rate, a rise in peak inspiratory pressure may be features of a metabolic acidosis consequent to abdominal sepsis. Abdominal distension, absent bowel sounds, an increase in the nasogastric aspirate, inability to tolerate nasogastric feeds are tell-tale features of possible mischief in the abdomen. Increase in bowel movements may signal infection with *Clostridium difficile*. Change in quantity or character of the drainage fluid from an intra-abdominal drain after surgery should arouse suspicion of a possible anastomotic leak. Increased discharge from the operated wound should suggest wound dehiscene from infection. A delay in diagnosis of an acute abdomen or intra-abdominal sepsis in a critically ill patient is associated with an increased mortality.
3. *In the immediate postoperative patient*, intra-abdominal sepsis including peritonitis is difficult to diagnose if it occurs as a complication in a patient who has been operated upon very recently. This complication again may be fortuitous or iatrogenic (chiefly as a result of perforation of the bowel during surgery). The pain of the surgical wound is not immediately distinguishable from the pain of peritonitis. The persistence of paralytic ileus after surgery should always suggest an underlying perforation with peritonitis or a localized abscess within the abdominal cavity. Physical signs of tenderness, guarding and rigidity are often difficult to evaluate in these patients in the immediate postoperative period. When perforation of the gut with peritonitis occurs soon after a cesarean section for a full-term delivery, the diagnosis is doubly difficult. The stretched abdominal muscles (as a result of pregnancy) show minimal guarding and little or no rigidity. A history of sudden pain in the abdomen a few days after surgery, the presence of ileus, rebound tenderness and the demonstration of free fluid within the abdomen should point to the correct diagnosis.

DIFFERENTIAL DIAGNOSIS[3,4]

The differential diagnosis of intra-abdominal sepsis is extensive and includes all other causes of acute abdomen—in particular acute bowel obstruction, acute bowel ischemia, pancreatitis and a ruptured ectopic pregnancy in a female patient. An intra-abdominal abscess may masquerade as systemic sepsis, the source of which is undetermined. In patients with cirrhosis of the liver, primary peritonitis needs to be distinguished from peritonitis secondary to perforation or inflammation of the abdominal viscera.

Acute medical problems may present with acute abdominal pain and tenderness in the abdomen, and mimic intra-abdominal inflammation due to surgical pathologies. The most important of these problems are acute pneumonia which produces referred pain in the upper abdomen and at times even in the right iliac fossa, and acute viral hepatitis which can produce generalized abdominal pain, pain in the right iliac fossa and pain in the right upper abdomen. This is particularly observed in children and in young adults. Acute myocardial infarction may mimic a surgical abdomen if it presents with severe epigastric pain, vomiting or shock. Acute falciparum malaria can also present with severe abdominal pain. The latter is also a classic feature of severe diabetic ketoacidosis. The importance of a routine urine examination cannot be overemphasized. Acute glomerulonephritis in children often present with abdominal pain or severe loin pain. Acute exanthemas in children often present with fever and generalized or even localized abdominal pain. The diagnosis is apparent with the appearance of a characteristic skin rash. Finally, other rare but important causes of severe abdominal pain (not generally associated with rigidity or

Box 3: Important medical conditions that can mimic an acute abdomen

- Pneumonia (referred pain in abdomen)
- Acute hepatitis
- Acute myocardial infarction—presenting with severe abdominal pain and vomiting
- Dengue (intra-abdominal bleed)
- Acute exanthemas in children
- Diabetic ketoacidosis
- Acute glomerulonephritis—particularly in children
- Uremia
- Acute adrenal insufficiency
- Acute falciparum malaria
- Acute sickle cell crisis
- Acute porphyria
- Acute enterocolitis

rebound tenderness) are acute porphyria and acute adrenal crisis. Box 3 gives a list of important medical conditions that can mimic an acute abdomen.

Laboratory Findings

Blood examination should include a complete blood count, platelet count, erythrocyte sedimentation rate (ESR), serum electrolytes, liver function tests, blood sugar, blood urea and serum creatinine. Systemic features of sepsis should warrant investigations for the coagulation profile, arterial blood gas analysis, blood lactate, procalcitonin level and tests to evaluate functions of different organ systems. A routine urine examination together with cultures of blood, urine and peritoneal fluid are important investigations before starting empiric antibiotic therapy.

Marked leukocytosis spells acute infection and/or suppuration. Severe leukopenia can also be a feature of sepsis. It is important to obtain a differential cell count to see if there is shift to the left. In a critically ill individual, a sharp sudden rise in bilirubin might signify an acute acalculous cholecystitis. A rise in amylase and lipase points to pancreatitis. An isolated rise in amylase can also occur in a perforated viscus, bowel obstruction or ischemic bowel. A sharp rise in bilirubin, transaminases, alkaline phosphate may point to a pathology in the liver and biliary tree. Increased blood lactate generally occurs with sepsis and tissue hypoxia. Abdominal compartment syndrome should be suspected when acidosis, hypoxemia, distended abdomen and oliguria are present. A bladder pressure greater than 30 mm Hg may warrant urgent surgical decompression.

Imaging Studies[6,7]

These are of crucial importance in the diagnosis of intra-abdominal inflammation, as also in the differential diagnosis of other causes of acute abdomen.

An X-Ray of the Chest (If Possible in the Upright Posture)

This can exclude pneumonia as a cause of acute abdominal pain and fever. Gas under the diaphragm is indicative of a perforated viscus. Intra-abdominal suppuration often causes elevation of one or both domes of the diaphragm and basal atelectasis.

Pleural effusion is an important finding in a subphrenic abscess or in acute pancreatitis.

An X-Ray of the Abdomen (AP) in the Erect Posture[6,7]

Gas under the diaphragm is indicative of perforation of a hollow viscus. Fluid levels, often in a step-ladder fashion, point to an intestinal obstruction. Small bowel or large bowel obstructions can be diagnosed from the pattern of the bowel proximal to the obstruction. Three or more fluid levels in the abdomen should be considered significant, and point to some degree of obstruction within the gut. A follow-up X-ray needs to be done in such patients after some hours. Paralytic ileus, whether due to medical or surgical problems, is characterized by marked distension of the small gut. This may involve the colon as well. Acute dilatation of the stomach is demonstrated by the outline of a hugely distended stomach, with an air-fluid level.

If perforation of a viscus is suspected, and the patient is too ill for an X-ray in the erect posture, then a left lateral decubitus X-ray of the abdomen (with the left side down) is of help. It may show the presence of free air between the liver margin and the abdominal wall. An X-ray of the chest or abdomen with the patient in the supine posture may not yield this crucial information, and may therefore be misleading.

Presence of free fluid and gas in the peritoneal cavity after perforation of the gut is visible as a fluid collection (generally gravitating into the pelvis), with a clear horizontal air-fluid level.

Rarer findings in intra-abdominal suppuration on a plain X-ray include: (1) air in the wall of the gut—pneumatosis intestinalis is observed in some patients with gangrene of the gut; (2) air in the gallbladder lumen in patients with empyema caused by gas forming organisms; (3) thumb-printing of the colonic wall in ischemic colitis; (4) marked distension of the colon in megacolon and in Ogilvie's syndrome. The latter occurs after surgery, and is characterized by severe ileus involving the large bowel. Cecal distension may lead to perforation and peritonitis in some patients.

Ultrasonography of the Abdomen[6,7]

This is a portable, noninvasive useful diagnostic tool. It is of special value in diagnosing acute cholecystitis, cholangitis or stones in the gallbladder. Ultrasonography is useful in the diagnosis of acute pancreatitis, pancreatic fluid collections, intraperitoneal and retroperitoneal abscesses, pelvic abscesses, pelvic tumors and ruptured ectopic pregnancy.

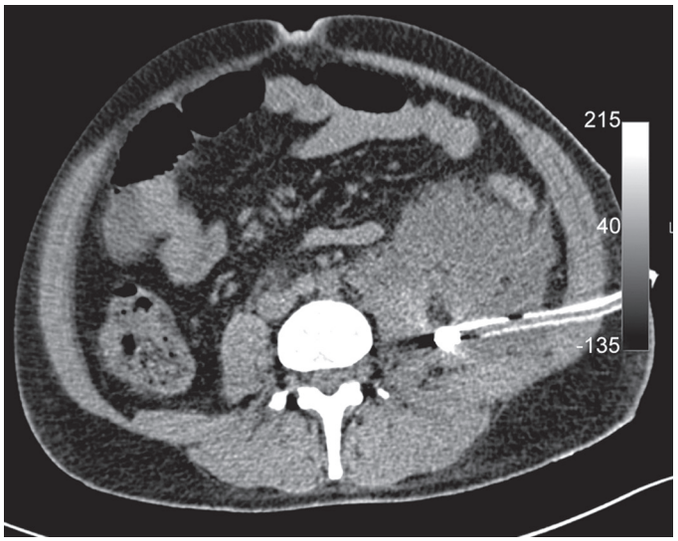


Fig. 1: CT abdomen shows a drainage tube in situ in the left lumbar region within a fluid collection as a result of pancreatic sepsis

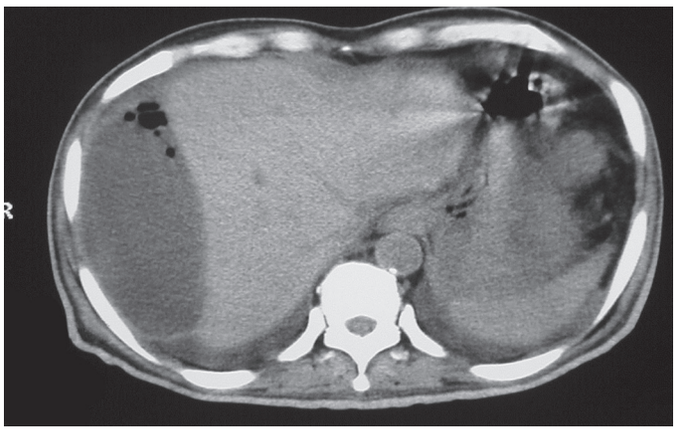

Fig. 2: Abdominal sepsis—CT of the abdomen reveals a large sub-phrenic fluid collection with specs of air within

Unfortunately, the sensitivity of an ultrasound examination is lost or vitiated to an extent, by the presence of overlying gas in the bowel, by skin incisions and bulky dressings over surgical wounds. The presence of an ileostomy, colostomy or open wounds limits the use of this otherwise extremely valuable diagnostic investigation.

Computed Tomography Scan[6]

A computed tomography (CT) scan (Figs 1 to 3) is more sensitive and specific than an ultrasound for identification of abscesses within the abdomen (intraperitoneal, retroperitoneal or within a viscus). It is particularly useful for the correct diagnosis of pancreatic necrosis or pancreatic and peripancreatic suppuration. The sensitivity of a good CT scan of the abdomen approaches 95–100%.

Gastrografin Studies

Oral gastrografin is sometimes used in patients with intestinal obstruction to determine the site of a small bowel obstruction

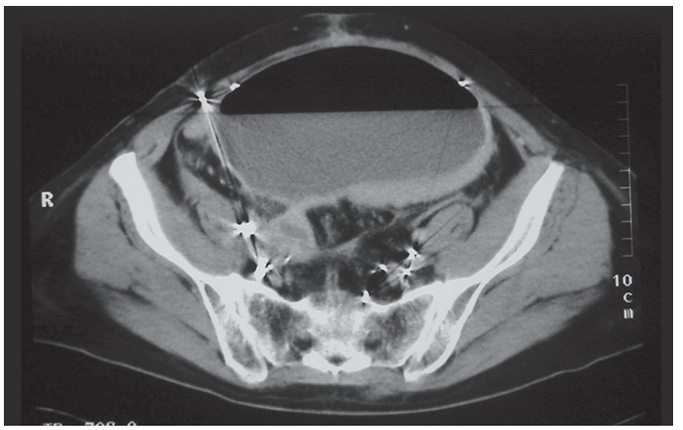

Fig. 3: Abdominal sepsis—CT scan of the abdomen reveals a large fluid collection in the mid-abdomen with an air fluid level

just before surgery. If a patient operated upon for a perforation of the gut fails to improve and shows continuing sepsis, it probably indicates the presence of one or more other perforations or the formation of a new intra-abdominal abscess. Oral gastrografin can demonstrate a perforation with a leak of the dye in the peritoneal cavity, or can outline the anatomic site of an enteric fistula.

Gastrografin given rectally helps to distinguish between a terminal ileal obstruction and a proximal colonic obstruction.

Angiographic Studies

Acute intra-abdominal suppuration is sometimes associated or complicated by massive bleeds. This is particularly observed with suppurative pancreatitis which can cause bleeds within the gut or outside it. Most patients are generally too ill for open exploratory surgery to stop such bleeds. The distortion of tissue planes also often makes this task impossibly difficult. Angiographic studies with the catheter placed in the appropriate vessels can demonstrate the bleeding vessels, which can then be suitably embolized with gelfoam coil or other agents. CT angiographic studies are invaluable in the diagnosis of occlusion of the mesenteric vessels causing bowel ischemia and gangrene.

MANAGEMENT[3-5,8,9]

Management consists of the following important features—

- Quick restoration of the circulatory hemodynamics.
- Source control—surgical intervention is invariably necessary.
- Prompt use of antibiotic therapy.
- Critical care and support of different organ systems.
- Maintenance of nutrition.

Management Prior to Surgery

Restoration of Circulatory Hemodynamics

Most patients are hypovolemic from the massive sequestration of fluid into the peritoneum and into the lumen of the gut.

Intravenous infusions of normal saline, dextrose saline and Ringer lactate solutions should be given to raise the central venous pressure (CVP), the filling pressures of the ventricles and the cardiac output. Vasopressor and inotropic support may be necessary (see Chapter Sepsis and Septic Shock). Intake/output charts are carefully maintained. All vital signs, the arterial blood pressure in particular, are also carefully monitored. Abnormalities in electrolyte balance and acid-base equilibrium should be corrected. The hemoglobin should be raised by packed cell infusions and kept close to 10 g/dL. Deranged clotting mechanisms should be corrected by infusions of fresh frozen plasma.

Too rapid infusions in patients with overt cardiac dysfunction can cause pulmonary edema. *Over-resuscitation of shock can cause hypervolemia, and should be avoided as this can precipitate the subsequent development of acute respiratory distress syndrome (ARDS).*

Antibiotic Therapy[10]

(See Chapter Antibiotic Therapy in the Intensive Care Unit)

Empiric therapy should be promptly started, especially in critically ill patients (within 1 hour) after relevant cultures have been sent. One should never await culture results before starting therapy. Cultures of infected material should also be sent during surgery; the empiric antibiotic regime may need modification depending on these results.

The empiric regime that is chosen for IAIs depends chiefly on—

- Presumed/Identified source of infection.
- Presumed pathogens involved, the risk factors for likely major resistant patterns and the prevailing antibiotic sensitivity in the unit.
- The severity of the patient's illness.

Risk factors include high severity of the illness, age more than 70 years, co-morbidities, high level of antibiotic exposure, poor nutritional state, underlying cancer.

IAIs are invariably polymicrobial. Major pathogens in community acquired IAIs are Enterobacteriaceae, Streptococcus spp. and anerobes (chiefly B. fragilis). The spectrum is broader in nosocomial infections and further includes enterococcus, Kl. pneumoniae, Ps. pyocyaneus and Acinetobacter baumannii.

Multidrug resistant infections are invariably present in critically ill patients with nosocomial infection. Unfortunately the level of resistance due to increased prevalence of ESBLs in community acquired infections is also on the rise.

The antibiotic regimes are best considered under the following three heads—

I. Extrabiliary Community Acquired IAIs.
II. Biliary Community Acquired IAIs.
III. Nosocomial IAIs.

The regimes we use as per our antibiotic sensitivity results are given below.

I. Extrabiliary Community Acquired IAIs:
   A. Patients not critically ill; no risk factors for ESBL.
      Amoxicillin clavulanate or Ceftriaxone
   B. Patient not critically ill; risk factors for ESBL present.
      Amoxicillin clavulanate + Tigecycline
   C. Patient critically ill (i.e. severe sepsis or septic shock) but no risk factors for ESBLs.
      Piperacillin tazobactam
   D. Patient critically ill + risk factors for ESBLs.
      Meropenem/Imipenem + Tigecycline + Fluconazole

II. Biliary Community Acquired IAIs:
   A. Patients not critically ill; no risk factors for ESBLs.
      Amoxicillin clavulanate or cefoperazone sulbactam
   B. Patient not critically ill; risk factors for ESBLs present.
      Tigecycline
   C. Patient critically ill (i.e. severe sepsis or septic shock) but no risk factors for ESBLs.
      Piperacillin tazobactam
   D. Patient critically ill + risk factors for ESBLs present.
      Piperacillin tazobactam + Tigecycline + Fluconazole

III. Antibiotic therapy for hospital acquired infections.
   Piperacillin tazobactam + Tigecycline + Echinocandins or Meropenem/Imipenem + Tigecycline + Echinocandins

Fungal infections should always be suspected and covered in critically ill patients with IAIs. Echinocandins are preferred to fluconazole in severe nosocomial IAIs.

Definitive Surgical Treatment[11,12]

Surgery

The definitive treatment of IAIs lies in the surgical eradication of the septic focus and debridement of necrotic tissue. Surgery should not be unnecessarily delayed. In some patients a single operation may not be sufficient to achieve source control. A re-laparotomy may be needed. Three methods of surgical management of severe IAIs following initial laparotomy are currently debated—(1) open abdomen, (2) planned laparotomy and (3) on-demand laparotomy. Currently on-demand (i.e. only when felt necessary) laparotomy is the preferred method as it results in a reduction of laparotomies and in medical cost.

Percutaneous Drainage of Abscesses[13]

Well-localized peritoneal or retroperitoneal abscesses that are easily accessible by percutaneous needle aspiration, can be drained in this fashion. Repeated aspirations can be done under ultrasound or CT guidance, or preferably, a large bore pigtail drain or a sump catheter is placed in the abscess cavity, again under ultrasound or CT guidance. The abscess cavity can than be intermittently irrigated with normal saline and appropriate antibiotics. The drain is removed when the drainage ceases and when the abscess cavity appears obliterated on a CT scan or a sinogram. Percutaneous drainage is obviously not to be used if the abscess cavity contains thick pus or a significant quantity of necrotic material. Drainage through a pigtail or sump catheter is likely to be unsuccessful if there are multiple pockets of pus. If the response to percutaneous drainage is inadequate, open surgical drainage with debridement of necrotic tissue should be performed.

Critical Care[8,9]

This is vital both during the preoperative and postoperative stages. Attention to *fluid, electrolyte and acid-base balance, and to nutrition* are vital. *Cardiorespiratory support* and, in particular, *ventilator support* are invariably necessary in critically ill patients. Hemodynamic monitoring which includes an arterial line and in complicated problems the insertion of a Swan-Ganz catheter may be necessary. Antibiotics may need to be continued for 2 weeks or even longer in some patients.

Persistent sepsis after abdominal surgery indicates one or more of the following—

1. An undetected perforation of the gut or a new perforation.
2. A postoperative intra-abdominal abscess.
3. The presence of devitalized gut due to ischemia involving a segment of the bowel.
   A rising bilirubin with a rise in liver enzymes following abdominal surgery for a perforation suggests that factors (1) and (2), or both in combination, are possibly present as postoperative complications.
4. An ongoing peritoneal infection often due to resistant organisms.
5. *Fungal infection* The occurrence of a superadded fungal infection should always be considered in unresolved intra-abdominal sepsis, particularly in immunocompromised patients or in those who have received prolonged broad-spectrum antibiotic therapy. The discharge from wounds, fistulae, should always be sent for fungal culture. Blood cultures for fungal infection may be positive even when discharge from the area of suppuration is negative. Appropriate antifungal treatment is life-saving in fungal infections.
6. *Nosocomial infection* (wound infection by resistant bacteria, pneumonia, catheter-related sepsis, urinary tract infections).

CHAPTER 51

Abdominal Compartment Syndrome

INTRODUCTION

The abdominal cavity is a space defined partly by rigid structures such as the spine, pelvic bones, costal arches, and partly by flexible structures, such as the abdominal muscle wall and the diaphragm. The intra-abdominal contents are limited by these anatomical boundaries. If there is a discrepancy between the total volume of the intra-abdominal contents (sum total of viscera, fluid, vessels) and the anatomical space limited by the boundaries described above, intra-abdominal pressure (IAP) rises. This predicament could occur if there is a marked increase in the total volume of intra-abdominal structures (swelling of viscera or accumulation of fluid) or decreased space within the abdominal cavity. In clinical medicine, it is the increase in volume of the total intra-abdominal contents within a confined space that leads to increased IAP.[1] To start with the stretch of the flexible boundaries of the abdominal compartment accommodates the increased volume of the intra-abdominal contents. Once the limits of accommodation are reached, even a small rise in the volume of intra-abdominal contents will produce a sharp rise in pressure. There is considerable work to show that increasing IAP can have a deleterious effect on organ function and can contribute significantly to multiorgan failure.

DEFINITIONS WITH REGARDS TO VARIOUS DEGREES OF RISE IN INTRA-ABDOMINAL PRESSURE

- *Normal intra-abdominal pressure* The normal IAP is measured in the supine position and is less than 10 mm Hg.[2]
- *Elevated intra-abdominal pressure* Intra-abdominal hypertension (IAH) is defined as a peak pressure more than or equal to 12 mm Hg on taking two measurements 1–6 hours apart.[2]
- *Abdominal compartment syndrome* Abdominal compartment syndrome (ACS) is diagnosed when (1) the peak IAP is more than or equal to 20 mm Hg on two successive measurements 1–2 hours apart, and (2) there is one or more organ failure not previously present, as defined by a sequential organ failure assessment (SOFA) score of more than or equal to 3.[2]

The ACS is of three types: (1) primary, (2) secondary and (3) tertiary. The consensus definitions of these three types are given below—

1. *Primary ACS* is that caused by intra-abdominal or pelvic pathology usually requiring abdominal surgery and/or angioradiologic intervention. The pathology may be traumatic and/or inflammatory in nature.[2]
2. *Secondary ACS* is ACS that is due to increased volume of intra-abdominal contents—fluid, swelling of viscera, and not due to an intra-abdominal pathology requiring surgery or angioradiologic intervention. Secondary ACS is observed during massive fluid resuscitation for major nonabdominal/pelvic injury, burns, acute pancreatitis and septic shock arising from nonabdominal and nonpelvic infections.
3. *Tertiary ACS* refers to ACS that develops or persists despite attempts to prevent or treat primary or secondary ACS.

Hyperacute ACS is a term used for very early secondary ACS that develops when surgery or angioradiological control of an injury is carried out simultaneously with massive resuscitation for the shock caused by the same injury.[3]

MEASUREMENT OF INTRA-ABDOMINAL PRESSURE

The IAP is measured indirectly by measuring the intravesical pressure. The recommended technique is to clamp the urinary catheter and instill 25 mL of sterile room temperature saline into the bladder, with the patient lying supine. After zeroing the transducer and allowing 30–60 seconds for stabilization the mean IAP can be read on a bedside monitor or as the height of the column in the urinary drainage tubing.

PATIENTS AT RISK FOR DEVELOPING ABDOMINAL COMPARTMENT SYNDROME[1]

These chiefly include—

- Patients with severe sepsis, particularly those with severe abdominal sepsis.
- Patients undergoing massive fluid resuscitation, whatever the cause—chiefly sepsis, trauma.
- Patients with acute pancreatitis, bowel gangrene.
- Patients with severe burns needing resuscitation with large volumes of fluid.

It is recommended that all patients falling in the above categories should be closely monitored for the development of ACS.

CLINICAL FEATURES[4,5]

- Increased pressure in the intra-abdominal cavity high enough to cause the ACS progressively impairs organ function.
- The first organ to be affected is the kidney, and the first clinical feature is a progressively falling urine output with a rising creatinine. This is due to a fall in renal perfusion, and reduced glomerular filtration. There is also an increase in renal venous pressure.
- The cardiovascular system is quick to suffer. The increased IAP leads to compression of the inferior vena cava, reduced venous blood flow to the heart with a reduced cardiac output. The fall in cardiac output affects the oxygen supply to all body tissues and probably plays an important role in evolving multiple organ dysfunctions. The filling pressure as measured from the central venous line may be falsely elevated because of both increased intra-abdominal and intrathoracic pressure.
- The respiratory system changes are characterized by increasing intrathoracic pressures, decreased lung volumes, decreased compliance and decreased alveolar ventilation. Respiratory failure with hypoxia and hypercapnia results.
- The gastrointestinal system is also markedly affected. The increased IAP leads to a fall in splanchnic perfusion, a fall in mucosal perfusion with the formation of mucosal erosions and ulcers. There is bacterial translocation which worsens organ dysfunction and failure.
- Liver functions are adversely affected because of the high IAP reducing both portal vein flow and hepatic flow. Glucose metabolism, mitochondrial function and cytochrome p50 function are all impaired.
- The central nervous system is also indirectly affected by the high IAP. The intracranial pressure is increased (largely due to an increased intrathoracic pressure) and the cerebral perfusion pressure is reduced.
- Multiorgan failure results from (1) the primary pathology and the treatment that causes the ACS; (2) tissue hypoperfusion and hypoxia caused by the cardiovascular and respiratory effects of the ACS; (3) a hypothesis has been postulated that the ACS itself acts as a proinflammatory stimulus in patients already primed by the primary pathology that resulted in ACS.[8]
- Studies have illustrated the association between ACS and multiple organ dysfunction syndrome (MODS).[6] Some workers believe that the increased bacterial translocation caused by ACS induced ischemia to the gut may play an important role in an evolving MODS.

TREATMENT[1,4,6]

The optimal treatment is abdominal decompression by surgery in all patients where the high IAP is associated with evidence of organ dysfunction. Following abdominal decompression there is a quick improvement in hemodynamic and respiratory parameters with improvement in tissue perfusion and oxygenation. After decompression, intravascular volume should be maintained. It is advisable to use vasoconstrictor agents to avoid fluctuations in blood pressure and to prevent reperfusion injury from the washout of the by-products of anaerobic metabolism. Following decompression the abdomen is left open, using one of the methods to later allow temporary abdominal closure.

CHAPTER 52

Multiple Organ Dysfunction Syndrome

INTRODUCTION

The multiple organ dysfunction syndrome (MODS) (also called multiple organ failure) has gained increasing importance over the last 30 years. It remains even today one of the major therapeutic challenges faced by physicians treating patients with critical illnesses due to widely differing etiologies. Single organ failure was long recognized as an important cause of morbidity and mortality in surgical patients. In the late 1960s, extended organ failure sequentially involving the lungs, liver and kidneys, and finally resulting in death, was observed in patients suffering from severe trauma. In 1973, Tilney and colleagues reported on a case of failure of multiple organ systems causing death, following the repair of a ruptured aortic aneurysm.[1] The syndrome of multiple organ failure as a distinct nosologic entity was increasingly recognized in the 1980s,[2] and today it is rightly considered as an unsolved problem carrying a forbidding mortality in ICUs all over the world.

What is the reason for the increasing incidence of this frightening entity over the last three decades? Ironically enough, the recognition and increasing incidence of this syndrome is to an extent related to better critical care in the early phase of a severe illness—critical care which enables the patient to weather the initial storm, and not succumb to it. It is only against such a background, where very ill patients are expertly cared for and supported over a period of time (this being virtually impossible 40 years ago), that the syndrome of multiple organ dysfunction or failure unfolds. In other words, this syndrome is a product of "progress" in critical care, and "progress" in life-saving technology.

The syndrome of multiple organ failure illustrates perfectly the interdependence of different organs of the body—an idea that was intuitively grasped by the ancient Ayurvedic physicians in India. The syndrome also illustrates the fact that no organ functions in isolation, that each organ influences the other, and that deranged function in one has far-reaching effects on the other organs. It is this harmony of the whole, rather than the function of individual parts, which spells the difference between health and disease, as also between survival and death.

DEFINITION AND CONCEPT

There is as yet no precise definition of multiple organ failure. Clinically, it can be considered as the sequential or concomitant occurrence of severe derangement of function in multiple organ systems of the body, against a background of a critical illness. Various serious illnesses can induce multiple organ failure, the commonest and most frequent being sepsis, trauma and shock from any cause. The syndrome semantically has been given various name—sequential organ failure,[3] multiple organ failure[4] and multiple system organ failure (MSOF).[5] For reasons stated below, and in agreement with the recommendations of an ACCP/SCCM Consensus Conference on the subject,[6] the term multiple organ dysfunction syndrome is to be preferred.

The difficulty in precise definition is directly related to defining what failure of function exactly means or signifies in various organ systems of the body. Parameters of one or more organ system failure vary with different investigators. The variability of indices constituting organ failure in different studies prevents a correct interpretation and comparison between mortality figures and the effects of treatment. There is yet no universally acceptable classification system which defines parameters of organ specific failure. Knaus and colleagues[7-9] developed an Acute Physiologic and

Chronic Health Evaluation Score II (APACHE II) system, which is considered by many to be a significant advance in this direction. The APACHE II scoring system gives precise measurements of organ-specific failure in five systems: (1) the cardiovascular, (2) pulmonary, (3) renal, (4) neurologic and (5) hematologic systems.

Since the initial description of the APACHE II system, there has been an increasing awareness of the role of the liver in multiple organ dysfunction and failure. Precise measurements defining severe liver cell dysfunctions have therefore also been incorporated recently in the APACHE II score.[9]

A modified APACHE II criteria for organ system failure, which purports to define failure of each specific organ system, is given in Box 1.

In our opinion, the usefulness of the above system lies only in predicting ICU outcome. It merely forecasts a very high mortality when three or more organ systems have failed for more than 3 days. Even in this prognostication, there are, as will be discussed later, certain important exceptions that need to be carefully considered.

The APACHE III scoring system is a refinement of the APACHE II. Analysis of the APACHE III database of 17,440 patients indicates that a consideration of the features of the acute disease together with detailed physiological mapping perhaps provides better estimates of ICU mortality than the number of organs termed "dysfunctional". Also, different combinations of organ dysfunction could result in differing mortality. Thus, mortality was 20% in patients with cardiovascular and hematological dysfunction vis-à-vis 76% in those with cardiovascular and neurological dysfunction.

There are important lacunae in our present-day concept of the MODS and these lacunae are briefly discussed below—

1. The major criticism is that the parameters defined above take into consideration failure of an organ system at only one point in time, when the disease process is perhaps too advanced to respond to treatment. The syndrome of multiple organ failure is in reality a dynamic ongoing process, so that consideration of disturbed function, without reference to the tempo and natural course of the disease, is unsatisfactory.

   Each organ system in this syndrome has to tread a path of increasing dysfunction that can end in terminal failure, from which there is no return. Organ dysfunction may be mild, moderate or severe. Multiple organs may show varying dysfunction. The recognition and significance of early organ dysfunction is not just of academic interest; it may help to initiate treatment at an early stage in the natural history of the syndrome. It is important to test specific variables of function (both singly and in groups or combinations) of different organ systems against outcome. This concept should perhaps be mirrored semantically by using the term multiple organ dysfunction, rather than multiple organ failure. An ACCP or SCCM Consensus Conference, which was held in 1991, defined MODS as the *presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention*.[6] We strongly concur with this definition.
2. A summative conceptual model of organ system dysfunction which merely stresses the number of organs that have critically failed at one given point in time (as in the APACHE II system) is only of statistical prognostic value. It is relevant to consider varying degrees of dysfunction (from the mild to the hopelessly irreversible) in each organ system, at different points in time in the natural history of a critical illness, as also to consider, if possible, the inter-relation between these failing organ systems. The Sequential Organ Failure Assessment System (SOFA score) offers a more clear insight and a more practical and realistic concept for predicting mortality in MODS[10] (Table 1).
3. The definition of organ failure is problematic in certain organ systems. Thus, one could accept varying degrees

Box 1: Modified APACHE II criteria for organ system failure*

Cardiovascular failure (presence of one or more of the following)—
- Heart rate ≤54/min
- Mean arterial blood pressure ≤49 mm Hg (systolic blood pressure ≤60 mm Hg)
- Occurrence of ventricular tachycardia and/or ventricular fibrillation
- Serum pH ≤7.24 with a $PaCO_2$ of ≤40 mm Hg

Respiratory failure (presence of one or more of the following)—
- Respiratory rate ≤5/min or >49/min
- $PaCO_2$ ≥50 mm Hg
- $(A\text{-}a)O_2$ ≥350 mm Hg
- Dependent on ventilator or CPAP on the 2nd day of OSF (i.e. not applicable for the initial 24 hr of OSF)

Renal failure (presence of one or more of the following)†—
- Urine output ≤479 mL/24 hour or ≤159 mL/8 hour
- Serum BUN ≥100 mg/100 mL
- Serum creatinine ≥3.5 mg/100 mL

Hematologic failure (presence of one or more of the following)—
- WBC ≤1000/mm^3
- Platelets ≤20,000/mm^3
- Hematocrit ≤20%

Neurologic failure—
- Glasgow Coma Score ≤6 (in absence of sedation)
- Glasgow Coma Score: sum of best eye opening, best verbal, and best motor responses (for Glasgow Coma Scale, refer to Table 1 of Chapter Critical Care Scoring)

Hepatic failure (presence of both of the following)—
- Serum bilirubin >6 mg%
- Prothrombin time >4 sec over control (in absence of systemic anticoagulation)

*If the patient had one or more of the following during a 24-hr period (regardless of other values), organ system failure (OSF) existed on that day.
†Excluding patients on chronic dialysis prior to hospital admission.

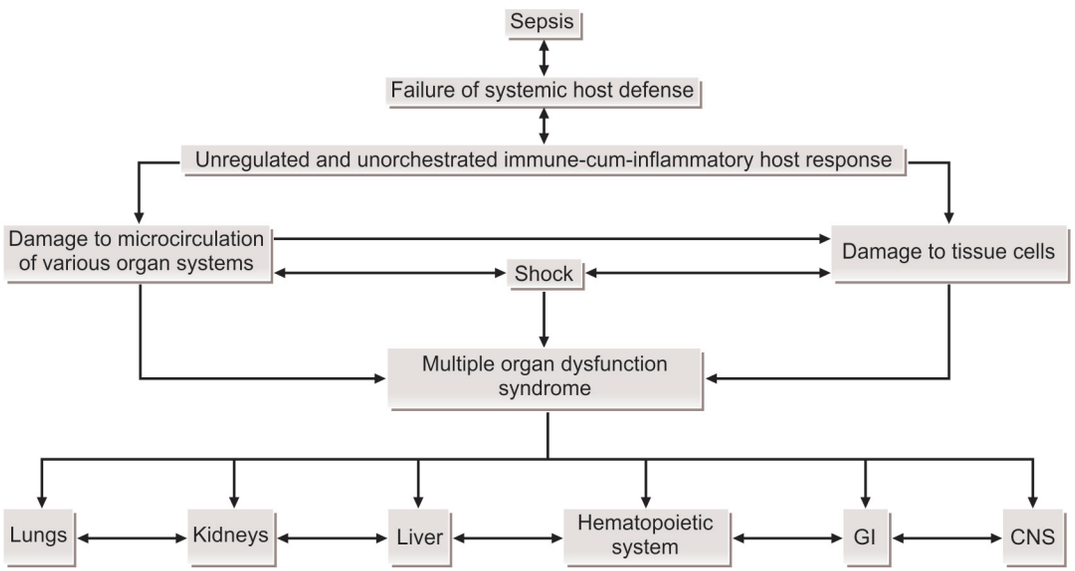
Table 1: Sequential Organ Failure Assessment (SOFA) Score

	0	*1*	*2*	*3*	*4*
Respiration— - PaO_2/FiO_2	>400	≤400	≤300	≤200 with ventilatory support	≤100 with ventilatory support
Coagulation— - Platelets (x $10^3/mm^3$)	>150	≤150	≤100	≤50	≤20
Liver—Bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Cardiovascular— - Hypotension	No hypotension	MAP <70 mm Hg	Dopamine ≤5 or dobutamine (any dose)*	Dopamine >5 or epi ≤0.1 or norepi ≤0.1*	Dopamine >15 or epi >0.1 or norepi >0.1*
Central nervous system— - Glasgow coma score	15	13–14	10–12	6–9	<6
Renal— - Creatinine (mg/dL) - Urine output	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or <500 mL/day	>5 or <200 mL/day

*Adrenergic agents administered for at least 1 hour (doses given are in µg/kg per minute).
Abbreviations: epi, epinephrine; norepi, norepinephrine.

Flowchart 1: Inter-relationships between organ systems in the evolution of the multiple organ dysfunction syndrome (MODS)



of oliguria and azotemia to reflect renal dysfunction and failure, just as one would accept a Glasgow coma score of less than 6 to denote severe dysfunction involving the neurological system. But what constitutes dysfunction of the gastrointestinal system? How does one quantitate degree of dysfunction in this system? There is no measurement today that reflects a breakdown of the mucosal barrier of the gut, permitting intraluminal bacteria and their products access to the portal and systemic circulations. Similarly, hepatobiliary dysfunction and poor protein synthesis by the liver may not reflect and may well be dissociated from the phagocytic function of Kupffer cells, or production by the liver cells of inflammatory peptide and lipid mediators that produce far-ranging effects in distant organ systems. We are thus abysmally ignorant of measurement of functions that may well play a crucial role in amplifying disturbed function in various organ systems.

4. Disturbed function in each organ system may not have equal pathogenetic significance in the evolution of the syndrome. If this be so, the view that the clinical expression of multiple organ dysfunction and its outcome merely depend on the numerical sum of specific organ failures, is simplistic and may not be true. The interdependency and interrelationship of organ systems, and the special importance of factors (related to organ dysfunction) which worsen host defense failure and further impair regulation of immune and inflammatory responses by the host, are crucial to the concept and evolution of the syndrome (Flowchart 1).

ETIOLOGY

Numerous reports and our own experience over many years confirm that sepsis is the main predisposing cause of multiple organ dysfunction.[11,12] However, many causes other than sepsis and septic shock can also result in this syndrome. Trauma and shock from causes other than sepsis are classic examples in which the clinical features of multiple organ dysfunction may exist without any evidence of infection.

The ACCP or SCCM Consensus Conference in our opinion has given a valuable semantic classification of the terminology related to sepsis. The reader is referred to their description which is detailed in the Chapter Sepsis and Septic Shock.

In a tropical setting, the etiology of multiple organ dysfunction is best classified thus.

Sepsis

Sepsis by definition is an expression of the systemic inflammatory response syndrome (SIRS) (see Chapter Sepsis and Septic Shock) due to infection. The commonest infection producing sepsis is a bacterial one, and the commonest sites of bacterial infection producing sepsis and related multiple organ dysfunction in our ICU are bloodstream infections, intra-abdominal sepsis, pulmonary infections and urosepsis. However, localized infection in the form of an abscess anywhere in the body, as also nosocomial infections, if undetected and untreated, result in sepsis which may evolve into multiple organ failure. Gram-positive and Gram-negative aerobic or anaerobic organisms can produce localized or generalized sepsis, and culminate in multiple organ dysfunction.

Tropical Infections[13]

For tropical infections, see Chapter Community-Acquired Pneumonias Requiring Critical Care. These are of special importance in our part of the world—

- The most important tropical problem responsible for multiple organ dysfunction and failure is severe infection due to *Plasmodium falciparum*.[14]
- Extensive miliary tuberculosis and disseminated hematogenous tuberculosis, particularly in immunocompromised individuals (as those on corticosteroids or other immunosuppressant drugs), can lead to a rapidly evolving multiple organ failure. The diagnosis may be missed if not suspected. The patient is generally too ill to provide sputum for examination.
- Tetanus is another important cause. Multiple organ failure is most often due to iatrogenic sepsis, but it could also result directly from the disease *per se*.
- Fulminant typhoid and salmonella infections can occur anywhere in the world, but are commoner in poor developing countries. They can result in a picture of sepsis and multiple organ dysfunction.

  A peculiar though uncommon form of Gram-negative infection following the ingestion of contaminated food is also occasionally observed in the tropics. This results after a very brief period of gastrointestinal symptoms, to features of sepsis, culminating in acute lung injury. Liver cell dysfunction and renal dysfunction also often occur. Blood cultures if done early may grow *E. coli* or *Klebsiella*. Early treatment and good critical care generally lead to recovery.
- Fulminant amebic infections characterized by an amebic abscess of the liver rupturing into the peritoneum and/or the lung or the pleural space, or necrotizing amebic colitis can also cause multiple organ dysfunction.

Fungal, Viral, Leptospiral and Rickettsial Infections

These infections can produce the picture of sepsis with multiple organ failure. Fungal infections are assuming increasing importance. They should be particularly kept in mind in immunocompromised patients, neutropenic patients, in patients who have received antibiotic therapy and in those on intravenous hyperalimentation.

Fulminant dengue can lead to multiple organ dysfunction through hemorrhagic shock or through transudation of fluid in various organ systems, or through bleeding into various organ systems. Hemorrhagic viral fevers, like the Ebola virus or the Hanta virus fevers, are fortunately confined to specific areas in Africa. They are fulminant and frequently fatal. MODS and death result from bleeding and widespread cell necrosis in various organ systems of the body.

Multiple organ dysfunction syndrome in rabies is of academic interest, as patients die within 24–72 hours. One patient, who was offered intensive care in our unit, survived for 26 days and then succumbed. MODS was observed in this patient.[15]

Severe leptospiral infections can cause hepatic, renal and CNS dysfunctions. Respiratory failure may be due to ARDS or to alveolar hemorrhage.

Severe Hemorrhage Causing Shock or Shock from Any Cause

Each of the above entities can lead to multiple organ dysfunction.

Trauma

Trauma is an extremely important cause of multiple organ dysfunction, perhaps second only to sepsis. In hospitals with trauma units, it constitutes the most important cause of MODS. Trauma can cause multiple organ dysfunction and failure, even in the absence of any evidence of infection. When infection does complicate trauma, it adds to the risk of multiple organ dysfunction.

Other Conditions Not Initiated by or Due to Infection

a. Important conditions—
   - Burns.
   - Acute pancreatitis.
   - Multiple blood transfusions.

Table 2: Incidence and mortality of multiple systems organ failure

				Mortality rate per No. of organ system failed		
Study	*Patients*	*ICU population*	*Incidence (%)*	*1*	*2*	*3*
Knaus et al.[6]	5,815	M, S[2]	819 (15)	40	60	100
ECMO[a]	490	M, S[3]	74 (15.1)	40[1]	55	80–100
Fry et al.[5]	553	S[4]	38 (6.9)	30[1]	60	85–100
Montgomery et al.[b]	207	M, S[3]	22 (10.6)	NE	NE	NE
Pine et al.[c]	106	S[5]	21 (19.8)	10	50	100
Bell et al.[d]	84	M, S[3]	40 (47.6)	40	54	80–100

[1] Multiple systems organ failure (MSOF) defined as severe acquired dysfunction in ≥2 organ systems during critical illness or after trauma or major operation.
[2] Random ICU admissions prospectively followed.
[3] Patients at risk for ARDS or with established ARDS prospectively identified.
[4] Emergency surgical patients retrospectively reviewed.
[5] Patients with trauma or intra-abdominal sepsis retrospectively reviewed.
[6] Patients with pre-existing intra-abdominal sepsis prospectively followed.

- Poisonings, in particular organophosphorus poisoning.
- Following complications during cardiopulmonary bypass surgery.
- Eclampsia.
- Severe vasculitides.
- Acute connective tissue disease.

b. Less common conditions—
- Thrombotic thrombocytopenic purpura.
- Atrial myxoma.
- Cholesterol emboli syndrome.
- Steven-Johnson syndrome, toxic epidermal necrolysis.
- Hemophagocytic syndrome.

It is extremely important to rule out noninfectious causes of MODS, particularly in patients diagnosed as sepsis, whose blood cultures are negative and whose source of sepsis is undetermined. In our experience, MODS caused by unusual poisonings, acute vasculitides (particularly acute Wegner's granulomatosis), acute connective tissue disease, atrial myxoma, thrombotic thrombocytopenic purpura, though rare, can be easily missed and wrongly diagnosed as sepsis with MODS.

Severe Derangement in the Function of Any One Major Organ System

Severe dysfunction of one organ system can over a period of time lead to dysfunction of multiple organ systems. A classic example is acute liver cell failure, irrespective of its etiology (e.g. drugs, poisons, viral causes). In a short span of time, multiple organ dysfunction is observed. Similarly, persistent or prolonged severe cardiac dysfunction, or acute renal failure can result in MODS. Again, trauma to the lungs with massive contusions produces a primary respiratory failure. Over a period of time, other organ systems can be secondarily involved.

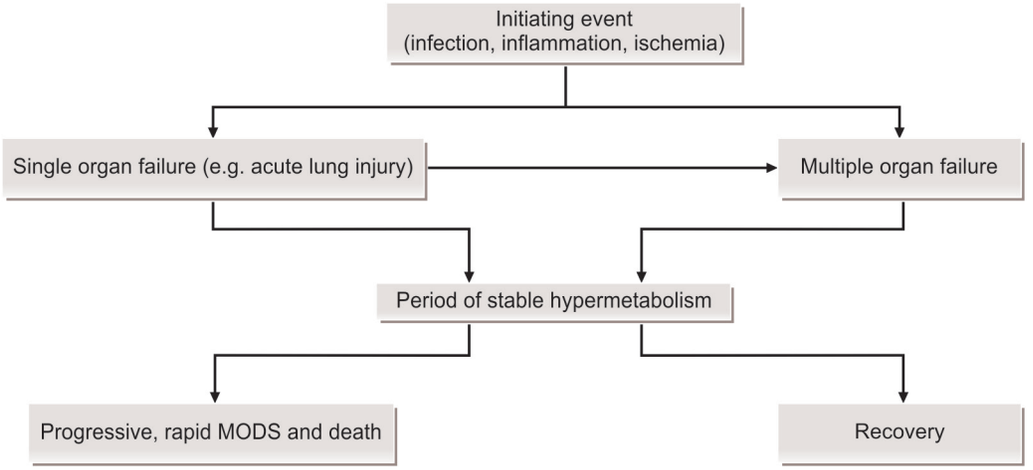
EPIDEMIOLOGY

As mentioned earlier, the incidence of MODS continues to show a steady rise. A busy, efficient, ICU which is equipped with good life-support systems and is engaged in looking after critically ill patients will have a high incidence of MODS. The incidence and mortality rate in the West is illustrated in Table 2. If MSOF is defined as severe acquired dysfunction in at least two organ systems lasting for at least 24–48 hours during the course of a critical illness, infection or injury, then MSOF complicates 7–15% of all ICU admissions in the West.[5,9] We have noted that approximately 10% of all the admissions in our ICU develop MSOF.

NATURAL HISTORY AND CLINICAL FEATURES

Sepsis, severe trauma or ischemia to tissues, shock from any cause and severe inflammation as in acute pancreatitis are important causes of multiple organ dysfunction and failure. In these conditions, the natural history of MODS in an ICU setting may evolve through the following four phases—(1) shock, (2) resuscitation, (3) a hypermetabolic phase and finally (4) the clinical evolution of multiple organ dysfunction, which culminates either in death or recovery. This need not however always be so. Polytrauma, sepsis, ischemia to a limb and even pancreatitis can result from the very start in the SIRS, progressing to a slow or quickly evolving multiple

Flowchart 2: Natural history of multiple organ dysfunction syndrome (MODS)



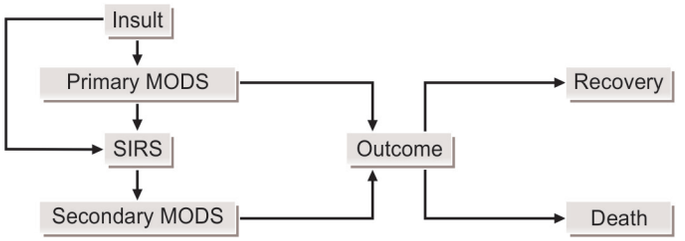
organ dysfunction without causing shock to start with. If shock does however occur as the first phase, resuscitation is generally achieved in a number of patients, provided that infection or any other etiological factor is controlled and the patients are adequately supported during this phase. In a small group of resuscitated patients the illness next enters a hypermetabolic phase. The natural history of MODS is illustrated in Flowchart 2.

The clinical features of the hypermetabolic phase include all the features of the SIRS—fever, leukocytosis, tachycardia and tachypnea.[6] In fact, the seeds of multiple organ dysfunction are sown during this stage, or probably even earlier. The hypermetabolic state that characterizes the SIRS may be associated with obvious evidence of a single organ dysfunction (typically the lung or kidney) or very subtle clinical or laboratory findings of early dysfunction of more than one organ system. Recovery can still ensue though the mortality with well-marked single organ dysfunction is around 10%.

The final stage of multiple organ dysfunction is characterized by sequential or at times, well-nigh concomitant failure of other organ systems. It is almost certain that at least in acute infections and sepsis there is global cellular injury; however, different organ systems manifest overt or clinical features of dysfunction at differing times. More often than not, the lung shows the first manifestation of dysfunction. Whether this is due to a special vulnerability of this organ system, or whether this early involvement is more apparent than real, is undecided. Lung dysfunction related to disturbed gas exchange is easily detected both on clinical grounds, and on standard laboratory measurements.

The tempo of the natural history is dependent both on the etiology and the host response to insult or injury. Multiple organ system dysfunction in our experience can evolve quickly, and kill the patient within a week despite the best of care and support. At other times, sequential organ failure is observed, and the natural history may extend from 2 to 6 weeks before death or recovery ensues.

Flowchart 3: Outcome of primary and secondary multiple organ dysfunction syndrome (MODS)



The ACCP or SCCM Consensus Conference[6] suggested that MODS develops by two relatively distinct, but not mutually exclusive pathways. Primary MODS is due to direct injury or insult to an organ system. Organ dysfunction occurs early, and is directly due to this insult. Examples of primary MODS due to a direct injury or insult to one organ system include pulmonary injury following inhalation of noxious fumes, or following contusion of the lungs as a result of trauma, coagulopathy induced by multiple blood transfusions and acute renal shutdown due to drugs. In primary MODS, the role of an abnormal and excessive host inflammatory response, both at the onset and during progression of the syndrome, is not so evident as in secondary MODS (Flowchart 3).

Secondary MODS is due to an indirect injury to one or more organ systems. It is in fact a consequence of the host response, which results in an immunoinflammatory response in organs distant from the site of the initial insult. Secondary MODS is observed in acute infections, sepsis, shock and trauma or ischemia to tissues.

Risk factors in the development of MODS have been arrived at from a study of 5,815 randomly selected ICU admissions from 13 United States medical centers, using the APACHE II scoring system.[8,9] The major risk factors for the development of this syndrome are: (i) severity of disease; (ii) presence of sepsis or infection at the time of ICU admission; (iii) age greater than 65 years.

Box 2: Clinical risk factors for the development of MODS

- Severity of disease (grading according to APACHE II score)
- Presence of sepsis or infection at the time of admission
- Age >65 years
- Severe, persistent shock of any etiology
- Major, prolonged surgery, trauma, presence of devitalized tissue
- Severe burns
- Persistent hypotension (>24 hours) after admission
- Persistent liver or renal dysfunction
- Uncontrolled diabetes
- Immunocompromised patients
- Malnutrition

Table 3: Stage I of MODS

General appearance	Normal or mildly restless
Cardiovascular function	Increased volume requirements
Respiratory function	Mild respiratory alkalosis
Renal function	Oliguria, limited diuretic responsiveness
GI function	Distension
Hepatic function	Normal or mild cholestasis
Metabolism	Hyperglycemia, insulin requirement
CNS	Confusion
Hematology	Variable

Source: Reference 16.

Table 4: Stage II of MODS

General appearance	Ill appearing, restless
Cardiovascular function	Hyperdynamic, volume-dependent
Respiratory function	Tachypnea, hypocapnia, hypoxemia
Renal function	Fixed output, minimal azotemia
GI function	Intolerance to enteral feeding
Hepatic function	Hyperbilirubinemia, prolonged PT
Metabolism	Severe catabolism
CNS	Lethargy
Hematology	Thrombocytopenia, leukopenia, leukocytosis

Source: Reference 16.

Table 5: Stage III of MODS

General appearance	Obviously unstable
Cardiovascular function	Shock decreased cardiac output, edema
Respiratory function	Severe hypoxemia, ARDS
Renal function	Azotemia, indication for dialysis
GI function	Ileus, stress ulceration
Hepatic function	Clinical jaundice
Metabolism	Metabolic acidosis, hyperglycemia
CNS	Stuporous
Hematology	Coagulopathy

Source: Reference 16.

Other major risk factors observed in our unit include severe, persistent shock from any cause, persistent hypotension, prolonged major surgery, trauma, burns, pre-existing chronic disease of a major organ system, in particular liver cell dysfunction, immunocompromised patients, and a background of poor nutrition. These factors have been listed in Box 2.

The clinical recognition of multiple organ dysfunction is easy to the trained eye. An important feature in the diagnosis of early dysfunction is the recognition of background factors known to cause the development and evolution of this syndrome.

Carrico and colleagues[16] have tabled a brief clinical description of increasing severity of multiple organ dysfunction (Tables 3 to 6). The greatest flaw in this tabulated description of Stages I, II and even III of MODS is the assumption that each organ system fails at the same pace and at the same time. This presumption is an exception rather than the rule. In clinical practice just two organ systems may show severe or Stage III changes, with barely any involvement of other organ systems for many days—at times right up to the time of death. Yet, in some instances, concomitant or a quickly sequential failure of one organ system after another may be observed.

Table 6: Stage IV of MODS

General appearance	Moribund
Cardiovascular function	Vasopressor dependent, edema, rising $S\dot{v}O_2$
Respiratory function	Hypercapnia, barotrauma
Renal function	Oligo-anuria, instability on dialysis
GI function	Diarrhea, ischemic colitis
Hepatic function	Transaminase elevations, deepening jaundice
Metabolism	Muscular wasting, lactic acidosis
CNS	Coma
Hematology	Uncorrectable coagulopathy

PATHOPHYSIOLOGY[17]

(See Chapter Sepsis and Septic Shock)

Multiple organ dysfunction syndrome can be considered to result from a combination of impaired host defenses, and inappropriate, uncontrolled host regulation of immunoinflammatory, vascular, neural, metabolic, endocrine responses, which have far-reaching deleterious effects

on the organ systems of the body. The body response to injury whether related to sepsis or non-infectious causes is remarkably similar. Also the type of organisms causing infection (e.g. Gram-negative bacilli, Gram-positive cocci, viruses, protozoa or fungi) does not make any difference to the final expression of the syndrome. Unfortunately the vicious downward spiral of worsening organ function culminating in death is not always necessarily arrested by identifying and treating the etiological factor responsible for the syndrome.

The initiating cause of SIRS and MODS can induce—

- Direct injury to cells.
- Indirect injury through activation of serum factors.
- Indirect injury due to cellular activation.
- Endothelial injury and dysfunction, which worsens inflammation and induces coagulation.
- Tissue hypoxia.
- Apoptosis.

Direct Injury to Cells

This is illustrated in sepsis when the lipopolysaccharide fraction of the endotoxin of Gram-negative organisms during the period of endotoxemia can directly damage endothelial capillary cells in different organs, and perhaps even directly impair tissue cell function.

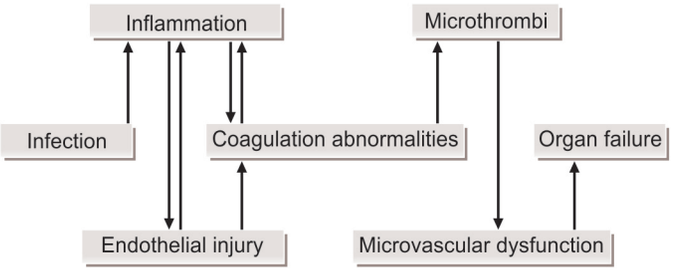
Activation of Serum Factors

Activation of complement can result not only from the effects of endotoxin in sepsis, but also from other diverse initiating factors, viz. trauma, ischemia or poor generalized tissue perfusion as in shock. Complement kinin-kallikrein coagulation and fibrinolysis cascades can lead to widespread tissue injury. Complement activated neutrophil mediated injury is also important in the genesis of organ dysfunction.

Cellular Activation[18]

Platelets, polymorphonuclear leukocytes and macrophages when activated can produce and release different mediators, which, if uncontrolled, can induce and amplify damage to cells in various organ systems of the body. Great attention has been focused on the role of activated mononuclear cells and on the activated macrophage system, both in the SIRS, and in the MODS. More than thirty different mediators, produced and released endogenously have been identified. These can have local and systemic actions. The role of cytokines in the regulation of the inflammatory response of the body to "injury" is of proven importance. The term "cytokine" refers to cell derived peptide molecules which cause a target cell to alter its functional activities. The tumor necrosis factor (TNF), interleukin-1 and interleukin-6 are cytokines credited with an important proinflammatory role in SIRS and MODS. Platelet-activating factor, products of arachidonate metabolism and, in particular, metabolites produced through the cyclo-oxygenase pathway have important effects on the vasculature, and on other mediators. It is just not the effect of individual mediators

Flowchart 4: Physiopathology of sepsis



that matters, but the interaction and inter-relation between them that is important. The polymorphonuclear cell, though a crucial factor in the defense against bacterial invasion, can also play an important role in mediating cell injury. Neutrophils can cause injury to other cells by the release of reactive metabolites to oxygen (superoxides, oxidants), and the release of proteolytic enzymes during degranulation.

Endothelial Injury

The role and metabolic activity of the endothelium is also of great importance in the development of SIRS and MODS. Injury to the endothelium can be direct as in endotoxemia or indirect as in shock. Endothelial injury promotes coagulation and reduces fibrinolysis that ordinarily counters the tendency to coagulation. Previously, inflammation caused by release of cytokines and proinflammatory mediators was considered the dominant feature in the cascade of events that led to MODS. The current concept is that inflammation, coagulation and fibronolytic abnormalities act together in the disease process. Investigations into the time course and extent of coagulation and fibrinolytic abnormalities in severe sepsis and their relation to endothelial dysfunction have pointed to the crucial role of an imbalance in hemostatic mechanisms. This imbalance results in a coagulopathy and microvascular thrombosis, which may well be a vital driving force in the evolution of progressive multiple organ dysfunction and death (Flowchart 4).

Tissue Hypoxia

Tissue hypoxia can lead to injury and even death of cells in multiple organ systems and is an important cause of MODS. A major casualty of severe sepsis is the cardiovascular system. There is cardiovascular dysfunction (both systolic and diastolic), systemic vascular changes, regional vascular dysregulation and microcirculatory damage and dysfunction. Regional maldistribution in blood flow and microcirculatory dysfunction and failure may be impossible to detect and may continue to progress if the underlying cause (e.g. sepsis) is not successfully treated. The end result is tissue hypoxia even when hemodynamic parameters with regard to the overall systemic circulation have been restored through fluid resuscitation and vasopressors. Adequate oxygen delivery by measures that ensure a central venous oxygen saturation of 70% results in a significant reduction in mortality.

Tissue hypoxia can also result from impaired mitochondrial oxygen utilization by the cells due to a direct effect on cell function by noxious agents or secondary to microcirculatory dysfunction. Both tissue hypoxia and impaired utilization of oxygen due to mitochondrial dysfunction lead to raised lactate levels.[19] Impaired utilization of oxygen by tissue cells ultimately leads to a rise in the central venous oxygen saturation.

Apoptosis

Apoptosis is programmed cell death. A pathological activation of programmed cell death appears to be a feature of MODS. Apoptosis is induced by an extrinsic (receptor dependent) or intrinsic (receptor independent pathway). The extrinsic pathway is activated by Fas receptor (CD 95) or the TNF receptor. The receptors of the extrinsic pathway activate procaspase 8 to active caspase 8, which in turn activates caspase 3 which is ultimately responsible for apoptosis. The intrinsic pathway is induced by DNA damage, the mitochondrial membrane potential being then altered by the signal protein p53, which mediates the activation of caspase 9. Active caspase 9 activates caspase 3 which again is the final step that leads to cell death.

In conclusion, the pathogenetic mechanisms responsible for diffuse cellular injury and MODS are as yet poorly understood. The host responses to infection or injury that lead to MODS are dynamic, variable, interconnected and according to a current concept, perhaps non-linear in nature.[20] If this be so, an analytical approach may fail to evaluate the emergent properties of this network or system. This may well explain the lack of response to various anti-mediator therapies observed in numerous clinical trials. *It appears that organs talk to each other and that cells within them do likewise at the molecular level. It is this communication system which probably adjusts the balance between health and disease*. We need to decipher this communication system, if we are to find means to arrest the downward spiral frequently observed in severe MODS.

Role of the Gut and Liver in MODS

What causes an ongoing stimulation of mediator response? This continues to exercise the minds of many researchers in this field. Attention is being increasingly focused on the gastrointestinal tract as a source that fuels the inflammatory response. The gut is an effective barrier which prevents bacillary organisms and their products from entering the systemic circulation and injuring the host. It is suggested that in shock, trauma, burns or sepsis, changes occur in this protective barrier, resulting in a bacterial translocation. This allows a continuous uncontrolled release of bacteria, antigens and endotoxin into the lymphatics and the circulation, to which the body responds by the stimulation and release of inflammatory mediators. The liver may ordinarily detoxify or destroy these products if the Kupffer cell function is adequate.[21] These Kupffer cells represent 70% of the fixed macrophage population of the body, and in addition influence hepatocyte functions such as protein synthesis. Ischemia to the gut from any cause also depresses the immunological function of the gut, further enhancing the activity of the bacterial flora within it. Factors predisposing to bacterial translocation are given in Box 3. The sequence of events in gut-liver axis leading to sepsis is illustrated in Figure 1.

Box 3: Factors predisposing to bacterial translocation

- Change in normal flora
- Impaired cell-mediated immunity
- Severe malnutrition
- Severe shock
- Total parenteral nutrition
- Sepsis—mainly intra-abdominal sepsis
- Severe burns
- Intestinal obstruction

The crucial role of the liver in the pathogenesis of MODS is evident in the above situation. A poorly functioning liver due to current or pre-existing liver disease, or a liver whose Kupffer cells are unable to cope with the load of bacteria or their products caused by translocation, can lead to an overwhelming invasion of the systemic circulation by bacteria and their products. These wreak havoc by their direct effect on endothelial cells and tissue cells, or act indirectly through stimulation of inflammatory mediators. Mechanisms that impair hepatocellular function in MODS are detailed in Box 4.

Metabolic Dysregulation in the SIRS[22]

Metabolism is controlled to a significant extent by inflammatory mediators, and is less responsive to the normal regulatory mechanisms within the body. As a consequence there is—

- A rise in energy demands manifested by increase in oxygen consumption, and an increased production of carbon dioxide with metabolic acidosis.
- Increase in gluconeogenesis and lipolysis.
- Energy production by the process of aerobic glycolysis.
- A severe catabolic state characterized by a loss in lean body mass that does not respond to exogenous aminoacid or protein administration. There is also a redistribution of the body nitrogen to the areas of active protein synthesis, e.g. viscera or wounds.[23]

SIRS and MODS are in continuum, and the transition from SIRS to MODS is often characterized by the following features—

- Worsening liver function, possibly affected by activated Kupffer cells.[21]
- Impairment of extraction and utilization of oxygen at the microcirculatory level, which could be related to capillary damage or to disturbed cellular function at the tissue level. Hypoxia to tissue cells leads to progressive worsening of organ function.
- The clinical expression of the above feature is an increase in the mixed venous oxygen saturation ($S\dot{v}O_2$) together with an increase in blood lactic acid levels.

Box 4: Factors which impair hepatocellular function in MODS

- Significant pre-existing liver cell disease
- Bacterial translocation
- Mesenteric/hepatic ischemia

PROGNOSIS

The greater the number of organ failure and longer the duration, the greater is the mortality (Table 2).[5,9] Knaus and colleagues[8,9] from a study of their large database, and using the APACHE II scoring system, noted that any single organ system failure lasting for more than 1 day, resulted in an inhospital mortality of approximately 40%; persistent failure in two organs over the same period led to a 60% mortality; failure of any three systems led to a mortality approaching 100%. This study also supported the view that a predisposition to MODS, and mortality due to MODS, increased with age (>65 years). The APACHE III system is an even more recently designed scoring system to objectively assess risk for mortality in critically ill hospitalized patients[24] (see Section I). It is a complicated system using seventeen physiological variables, and its utility vis-à-vis clinical judgment based on experience needs to be proved. With improved critical care and better support to all organ system, the current mortality is much less than that reported by Krauss et al. The current mortality rate increased with increasing number of organ dysfunctions as follows: no organ dysfunctions (10% mortality), 1 organ dysfunction (10–15% mortality), 2 organ dysfunction (20–25% mortality), 3 organ dysfunction (30–35% mortality).[25] *However, failure of more than three organs even today is reported in the West to have a mortality of close to greater than 80%.*

There are some important reservations that need to be discussed in relation to even current mortality figures reported from the West—

a. The outcome of the scoring system in predicting mortality in individual patients admitted to the ICU can be misleading. The scoring system may be wrongly computed and marked, leading to a nihilistic approach to potentially salvageable patients. Both the APACHE II and the Mortality Prediction Models (MPM) developed by Teres et al.[26] have a misclassification rate as high as 15%.
b. The dismal outcome predicted holds true for the advanced stage of MODS—i.e. when organ dysfunction and the natural history of the disease are very severe or well beyond the point of return.
c. Mortality figures with lesser degrees of multiple organ dysfunction, as judged for example by the use of SOFA scores, are not as dismal as those quoted above.

d. The mortality figures reported in severe multiple organ dysfunction occurring in the West do not necessarily apply to multiple organ dysfunction and failure occurring in tropical problems.[8,9] A severe degree of multiple organ dysfunction often involving three or more organ systems is thus often present in *P. falciparum* infections. The organ systems frequently involved are the CNS, the kidneys, the hematopoietic system, the lungs and the liver. The mortality with severe dysfunction, in our experience, is about 33% even when more than three organs are involved for over a week. In a similar fashion, in our experience, mortality in severe tetanus with multiple organ failure does not exceed 29%. Mortality in multiple organ failure in disseminated hematogenous tuberculosis lasting for many days is about 50%. Our last 4 patients with disseminated hematogenous tuberculosis and multiple organ failure, all survived; one patient had evidence of more than four organ system dysfunctions for over 3 weeks, and yet recovered. All our patients with severe typhoid infection causing sepsis and multiple organ failure recovered; all our patients with severe Gram-negative infection and multiple organ failure following ingestion of contaminated food, also recovered. Fulminant amebic infections and necrotizing amebic colitis causing multiple organ failure have a comparatively bad prognosis with a mortality rate of 50%.
e. In our rather small series of 50 patients with different fulminant tropical problems causing MODS, a SOFA score of 16 was associated with a 50% mortality. In contrast, a study by Vincent and colleagues, in which 74% of the patients with four organ failure had bacterial infection, a SOFA score of 16 was associated with greater than 80% mortality.[10] The improved mortality in MODS due to tropical problems could be related to prompt good critical care soon after the onset of symptoms, and the availability of specific therapy for many tropical problems—artesunate and quinine for malaria, a proven effective management protocol for severe tetanus, anti-TB drugs for disseminated hematogenous tuberculosis, ceftriaxone for typhoid, and specific drugs for amebic and leptospiral infections. However, the present impression that MODS due to tropical infections causes a lesser mortality compared to bacterial infections needs to be confirmed by a larger prospective study.
f. Any scoring system used for predicting prognosis is arbitrary. A scoring system must be stringent, but must also take into consideration milder or more moderate forms of MODS. A larger base of exact variables, and of various combinations of variables of organ dysfunction in relation to outcome, merits further study to predict a more realistic prognosis of MODS.
g. A nihilistic approach to severe MODS is against the basic tenet of critical care medicine. Many an individual patient has defied perfectly derived statistical figures, so that he or she survives when clearly expected to die.

MANAGEMENT

The treatment of MODS is unsatisfactory. There are three reasons for this—

1. The cause or underlying etiology responsible for initiating MODS very frequently cannot be eradicated. This is particularly so in patients with abdominal sepsis related to multiple perforations, which cannot be permanently tackled due to technical reasons. Unless the peritoneal leak from a diseased section of the bowel is permanently sealed, no treatment is of avail. The better the support and care offered to such unfortunate patients, the more protracted the agony prior to death. Another example is abdominal sepsis related to acute suppurative pancreatitis. Despite the best surgical techniques available, it may be impossible to totally eradicate all sources of infection in a critically ill individual.
2. When the cause of SIRS and MODS can be successfully treated, the chances of recovery significantly improve. Even so, a number of patients progress to worsening multiple organ dysfunction, and ultimately die.
3. Beyond a certain stage in the natural history of MODS, there is a point of no return, perhaps because the underlying mechanisms responsible for organ injury are self-perpetuating. Currently, we have no means to arrest this downward trend leading to death. This perhaps explains why successful treatment of the cause responsible for initiating the pathophysiological cascade does not necessarily lead to recovery.

The importance of possible prevention of this syndrome is thus self-evident.

PREVENTION

Only a few basic principles are outlined in this chapter. Perhaps the most important preventive measure is the rapid, appropriate resuscitation of shock, whatever its etiology. Since MODS is common in surgical patients, it is wise to optimize organ function before major surgical procedures, as this decreases the incidence of both perioperative and postoperative complications.[27] Accurate monitoring and maintenance of organ function during surgery, and above all good surgical technique in poor risk patients, go a long way in prevention of disastrous postoperative sequelae. The importance of appropriate management of early pulmonary dysfunction, so that ventilation-perfusion inequalities stand corrected, and adequate arterial oxygen saturation is maintained or restored, is being increasingly realized. One should never hesitate to offer ventilator support to achieve this objective.

Management protocols designed to support or treat one organ system should not result in possible dysfunction of some other organ system.

Selective gut decontamination using a combination of oral antibiotics (e.g. tobramycin, polymyxin, nystatin or amphotericin) continues to be used in many critical care units as a means of sterilizing the bowel and reducing the risk of nosocomial pneumonias, and translocation of bacteria

from the gut. Though a few prospective studies have shown a decreased risk for nosocomial infections, there has been no improvement in either the incidence or overall mortality of MODS.[28] Though Rocha and colleagues[29] showed fewer nosocomial infections, there was an increase in resistant bacterial isolates from the treated group, and there was no improvement in the cost-benefit ratio.

TREATMENT

The treatment of evolved MODS is basically supportive; the following five features need to be emphasized—

1. Eradication or at least control of the etiology responsible for the syndrome.
2. Maintenance of optimal oxygen transport to the tissues.
3. Metabolic support.
4. Support to organ systems viewed from an overall perspective.
5. Notwithstanding the grim prognosis forecast for patients with three or more organ failures lasting for 3 days or more, according to the APACHE II scores,[8,9] a nihilistic attitude to these patients is unjustified and ethically wrong.

Eradication or Control of Underlying Etiology

Recovery is impossible if the source or origin of this syndrome remains uncontrolled in a patient. An abscess must thus be drained however ill the patient or the source of acute peritonitis must be removed insofar as this is possible, or a full thickness burn excision with skin grafting must be undertaken in spite of the patient being critically ill.

Maintenance of Oxygen Transport

[See Chapter Sepsis and Septic Shock and Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome (ARDS)]. In severe MODS due to sepsis, oxygen consumption may be reduced in spite of adequate oxygen delivery, suggesting an inability of the tissues to utilize oxygen. The resuscitation of shock should therefore take into paramount consideration the maintenance of optimal oxygen transport. As mentioned in earlier chapters, increase in oxygen transport involves maximizing oxygen content and cardiac output. Oxygen content is increased by: (a) maintaining a high arterial PaO_2 (preferably ≥70 mm Hg), and an oxygen saturation of over 90% and (b) maintaining the hemoglobin at 10 g/dL. Cardiac output is optimized by taking into consideration the preload, contractility, and afterload, and by treating disturbances in rate and rhythm which may adversely affect the cardiac output. The concept of achieving a supramaximal delivery of oxygen by increasing cardiac output (through the use of inotropes) to supramaximal levels is no longer valid and can perhaps do more harm than good (see Chapter Overview of Shock Syndromes).

Metabolic Support

Patients with MODS suffer tremendous weight loss and lose a great deal of lean muscle mass during the course of their illness. This problem is indeed more acute when the syndrome evolves against a background of poor nutrition or malnutrition, as is often the case in third world countries. Our experience with MODS in tropical countries has convinced us that nutritional support reduces both morbidity and mortality. This is perfectly illustrated in the management of fulminant tetanus in patients from a poor strata of society with poor nutritional status.[30]

The principles of nutritional support in patients with SIRS and MODS are to some extent being revised. Current concepts are briefly enunciated below—

a. The objective in these hypermetabolic, hypercatabolic patients is to attain nitrogen equilibrium using nutritional formulae that offer the maximum benefit with the least morbidity.[31] It is now believed that too many calories and the wrong combination of caloric substrates can do more harm than good.[31]
b. It is not necessary to use excessive daily total caloric intakes—the recommendations vary greatly. We use 30 calories/kg bodyweight with not more than 5 g/kg per day as glucose or carbohydrates. Excessive carbohydrate intake should be avoided because of the higher risks of hepatic lipogenesis and excessive carbon dioxide production.
c. Fat emulsions (n-6 polyunsaturated fatty acids) are restricted to 0.5–1 g/kg per day. The use of larger quantities of fat emulsions chiefly consisting of n-6 long-chain polyunsaturated fatty acid triglycerides can lead to cholestasis, hypoxemia, bacteremia and immune suppression.[32]

   Arachidonic acid is an omega-6 polyunsaturated fatty acid which is produced from linoleic acid and is commonly found in soybean oil and safflower oil emulsions. Products of arachidonic acid metabolism include prostaglandins and leukotrienes. A few leukotrienes produce platelet aggregation and adherence of polymorphs to endothelial cells; excess prostaglandin-E_2 can reduce lymphocyte antigen responsiveness. These factors thus promote further immunosuppression commonly found in SIRS and MODS.[33] The use of lipids high in fish oil that contain omega-3 polyunsaturated fatty acids may reduce leukotrines and prostaglandin-E_2 production, as also perhaps reduce the release of interleukin-1 and TNF. These should theoretically benefit patients with evolving MODS.
d. Administration of proteins should not exceed 1–1.25 g/kg per day. The use of preparations with an increased content of branched-chain amino acids has allowed increased nitrogen retention with quick and smooth achievement of nitrogen equilibrium.[34] This is particularly useful in excessively hypercatabolic states during which the patients may lose more than 10 g nitrogen in the urine.
e. Good nutritional support should ensure a rising or normal range of hepatic protein synthesis as judged by plasma albumin and transferrin levels.
f. Administration of vitamins, minerals and trace elements is an integral feature of nutritional support.

Omega-3 fatty acids (found in fish oil), arginine and dietary nucleotides have been combined into special formulated

enteral feeds. A multicentric trial has shown significantly fewer acquired infections, a shorter hospital stay, improvement in protein metabolism and in immune responsiveness in patients receiving these specially formulated feeds.[35]

The above principles of nutritional support are applicable to both enteral and parenteral feeds. Enteral feeds are unquestionably superior, should be started as early as possible, and are always to be preferred.

Support of Organ Systems Viewed in an Overall Perspective

It is important to treat the patient as a whole and not to confine treatment to a specific organ system. This is often lost sight of even in very good ICUs, where superspecialists are very common and where each one thinks exclusively of the organ under his charge. *Not uncommonly the organ survives, but the patient dies. The relative importance of different problems in a patient should never be lost sight of, the one posing the maximum danger needs to be considered as a priority bearing in mind the patient as a whole.*

Nihilistic Approach to MODS

A nihilistic approach to MODS when three or more organs are involved is unjustified and wrong. The prognosis of MODS to an extent depends on the predisposing factors in a given patient, the nature and magnitude of the insult or etiological agent, the nature and magnitude of the host response (about which we know very little), the number and degree of organ involvement but also the combination of organ systems that are dysfunctional.

CHAPTER 53

Acute Kidney Injury

GENERAL CONSIDERATIONS[1]

The kidneys play a major role in fluid and electrolyte balance, and help to keep the H^+ ion concentration of arterial blood within physiological limits. Renal dysfunction is common in the critically ill, and when present, the morbidity and mortality are both significantly increased. Early detection of renal dysfunction, measures to correct the early dysfunction if this is at all possible, and/or measures to prevent further deterioration in renal function are of great importance in ultimate prognosis. Delay in recognition and management often results in increasing renal failure requiring dialysis till such time as kidney function improves.

Currently, by general consensus, the term acute renal failure (ARF) has been replaced by the term acute kidney injury (AKI). There is some justification in this as AKI takes into account various degrees of injury to the kidneys, whereas the term ARF lacks this concept. The term acute renal dysfunction is perhaps as good as or better than AKI; after all injury causes dysfunction and acute renal dysfunction also implies the possibility of various degrees of dysfunction. In this chapter, AKI and acute renal dysfunction are used synonymously.

An absolute requisite for the diagnosis of renal dysfunction (AKI) is an elevated plasma creatinine concentration. An early sign of renal dysfunction and impending failure is a fall in the urine output. Oliguria is defined as a fall in urine output to less than 400 mL/24 hours, or a fall in urine output to less than 20 mL/hour. *Though oliguria is a frequent accompaniment of AKI, the latter can also occur and progress (with increasing plasma creatinine levels), in the presence of a normal urine output.*

This chapter basically stresses the approach to the diagnosis and management of impending or progressive AKI in ill individuals in an intensive care unit setting. It next briefly deals with the epidemiology of AKI in the ICU and then discusses the current concepts and definitions that help to grade and quantify progressive kidney injury. Following this, there is a description of the bedside approach in the evaluation of acute oliguric kidney injury as also on the medical management and the management by dialysis of established and progressive AKI. The chapter then touches upon important clinical syndromes characterized by severe progressive renal failure; these are invariably critical illnesses requiring intensive care. Finally, there is a brief section on critical illnesses requiring intensive care in patients with underlying chronic renal failure.

CAUSES OF ACUTE KIDNEY INJURY

A rise in serum creatinine and non-protein nitrogenous products generally though not necessarily associated with oliguria can be due to prerenal causes, intrinsic renal disorders and to postrenal conditions characterized by obstruction to the renal outflow system (Box 1).

Acute kidney injury can be due to poor perfusion not severe enough to cause cellular injury or death, to an ischemic or toxic injury to the renal parenchyma, to tubulo-interstitial disease, to glomerular disease leading to impaired filtration, or to obstruction to the renal outflow tract. Azotemia caused by impaired perfusion is termed prerenal azotemia; azotemia caused by intrinsic renal injury is termed renal azotemia; azotemia due to an obstructive uropathy is termed postrenal azotemia. In critical care units AKI is most often due to prerenal causes (impaired perfusion) or due to intrinsic renal damage or injury. However, postrenal obstructive uropathies are also met with and may be easily missed if not kept in mind.

Box 1: Causes of acute kidney injury

- Prerenal causes—
  - Hypovolemia—
    - » Fluid or blood loss
    - » Sequestration of fluid into third space
    - » Loss of effective circulating volume in distributive shock (sepsis, anaphylaxis)
  - Low-output syndromes with poor pump function and low cardiac output
- Intrinsic renal diseases—
  - Acute tubular necrosis (after shock, sepsis, severe hemolysis or surgery)
  - Acute cortical necrosis
  - Toxic factors (drugs, heme pigment, contrast media)
  - Acute interstitial nephritis
  - Acute glomerulonephritis; acute pyelonephritis; other acute nephritic syndromes
  - Vascular causes (vasculitis, obstruction to large vessels, TTP, DIC, HUS, HPS, malignant hypertention)
  - Crystal precipitation (acute uric acid nephropathy)
  - Plasma cell dyscrasias (e.g. tubules obstructed by myeloma protein)
- Postrenal causes—
  - Ureteral or bladder outlet obstruction—mitotic lesions retroperitoneal fibrosis, calculi, hypertrophic prostate, Ca prostrate
  - Traumatic rupture of the bladder with extravasation of urine

Abbreviations: TTP, thrombotic thrombocytopenic purpura; DIC, disseminated intravascular coagulation; HUS, hemolytic-uremic syndrome; HPS, hemophagocytic syndrome.

Prerenal Causes

Prerenal causes act by inducing a fall in perfusion pressure within the vessels perfusing the kidneys. Important prerenal causes are hypovolemia, low-output syndromes related to acute heart failure, and severe vasodilatation with a reduction in the arterial blood pressure and perfusion pressure within the kidneys.

Hypovolemia has been discussed in an earlier chapter (see Chapter Fluid and Electrolyte Disturbances in the Critically Ill). It can be due to loss of extracellular fluid as in vomiting, diarrhea, burns and blood loss. Hypovolemia can also result from sequestration of fluid in the third compartment as in intestinal obstruction, pancreatitis, peritonitis, post intra-abdominal surgery and crush injuries to muscles. A fall in effective circulating volume also occurs in distributive shock (sepsis and anaphylaxis), characterized by peripheral vasodilatation, hypotension and a fall in renal perfusion.

Poor pump function of the heart, due to any etiology, is also an important cause of prerenal azotemia.

Intrinsic Renal Disorders

The *three important renal disorders* causing acute oliguric kidney injury in an ICU setting are—

1. Acute tubular necrosis (ATN).
2. Drug toxicity particularly related to the use of aminoglycosides.
3. Acute interstitial nephritis either allergic or infectious in etiology.

An important cause of ATN is prolonged unrelieved renal ischemia as in shock, severe sepsis and major surgery. Toxic causes as in poisoning can also result in ATN. Acute severe hemolysis results in ATN because of the toxic effect of heme pigments on renal tubular cells, blockage of renal tubules by pigment casts and impaired perfusion of kidneys. Acute glomerulonephritis and other nephritic syndromes are also important causes of AKI, but are uncommon in an intensive care setting. Acute fulminant pyelonephritis is at times a feature of urosepsis and results in AKI. Renal vascular disorders causing AKI, though again uncommon in the ICU, are easily missed. They include obstruction to large renal vessels (embolism or thrombosis) or to small vessels as in vasculitis of any etiology, thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation (DIC), hemolytic uremic syndrome (HUS), hemophagocytic syndrome and malignant hypertension. In oncology units, acute oliguric renal injury is observed following precipitation of uric acid within urinary tubules causing an acute uric acid nephropathy. Plasma cell dyscrasias (in particular myeloma) may present with quickly evolving renal dysfunction due to obstruction of renal tubules by protein deposits and to interstitial nephritis.

Drug toxicity causing interstitial nephritis is an important cause of AKI and ARF in the ICU. The need for taking a proper history of drugs the patient has received cannot be overstressed. Radiocontrast agents, aminoglycosides, amphotericin, nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors are the drugs most frequently observed to precipitate AKI. NSAIDs and ACE inhibitors induce a form of prerenal azotemia. NSAIDs inhibit cyclooxygenase, leading to a depletion of eicosanoids, which normally counteract the constrictive effect on afferent arteriolar tone due to increased renal adrenergic drive and lipid derived constrictors. Severe afferent arteriolar vasoconstriction in AKI can occur particularly in the presence of hypotension, volume depletion, sepsis or heart failure. ACE inhibitors reduce angiotensin II levels, leading to a lowering of renal perfusion pressure and a dilatation of efferent arterioles. This lowers glomerular filtration pressure and causes AKI, particularly in patients with bilateral renal artery stenosis or in unilateral renal artery stenosis with a contralateral diseased kidney. Generally, the prerenal azotemia induced by NSAIDs and ACE inhibitors is reversible if the drug is promptly stopped. The use of contrast media for imaging purposes is an important cause of acute renal injury. Contrast media act by causing renal vasoconstriction and medullary ischemia, as also by a direct toxic effect on renal tubules. Patients, who are volume depleted, diabetics and those with background renal disease, are at high risk to develop renal toxicity.

Box 2: Risk factors for acute kidney injury

- Age of onset >60 years
- Sepsis
- Cardiovascular failure
- Liver cirrhosis
- Respiratory failure
- Chronic heart failure
- Lymphoma or leukemia

Box 3: Risk factors for increasing mortality in acute kidney injury

- Age >65 years
- Male gender
- Acute oliguric renal failure
- Sepsis
- Nonrenal organ failure
- Thrombocytopenia
- Mechanical ventilation
- Associated comorbid states

Postrenal Conditions

Postrenal disorders include obstructive lesions within the renal outflow system. They include papillary necrosis, ureteric obstruction by calculi or retroperitoneal fibrosis or tumors, and bladder outlet obstruction commonly observed with prostatic hypertrophy and in prostate cancer. Extravasation of urine as after rupture of the bladder is another postrenal disorder presenting with acute oliguric kidney injury. Obstruction is an uncommon but important cause of acute oliguric renal injury, and should be considered in all patients who are known to have a solitary functioning kidney. Intrarenal obstruction to urine flow due to obstruction of renal tubules from various causes has been considered under intrinsic renal disorders.

EPIDEMIOLOGY

In the ICU, AKI is more often than not a feature, a part and parcel of multiorgan failure. It occurs quite frequently, being present in about 30% of ICU patients.[2-4]

The most common cause of intrinsic renal failure in the ICU is ATN, which is generally due to two important causes. These are poor renal perfusion as observed in hypotensive states and shock from any cause, and sepsis. Impaired perfusion often leads to prerenal azotemia, but if impaired perfusion persists for long and stands uncorrected, or if there is a very sharp fall in perfusion due to marked hypotension for even a brief period, as is seen, for example, during major surgical procedures, ATN may well result. Sepsis is an equally important cause of ATN and is in part due to action of cytokines on renal structure and function. ATN can also occur secondary to the use of nephrotoxic antibiotics, as a postsurgical complication and following the use of contrast media. The etiology of ATN can well be multifactorial as is often observed in sepsis, where hypotension, the noxious effect of cytokines, the use of nephrotoxic antibiotics and use of contrast dyes for imaging may all play a varying role to result in ATN.

It is a common observation that in a patient who has multiorgan failure but in whom kidney function for some reason is well preserved, the prognosis for recovery is better than in a patient with multiorgan failure which also involves the kidney. This observation may be misleading as severe renal involvement in multiorgan failure may merely be a marker of the severity of the illness, which could be associated with an increased mortality. Recent studies have however observed that AKI does in fact, contribute to mortality in the setting of contrast nephropathy and cardiac surgery.[5,6]

Increasing renal dysfunction, i.e. increasing severity of AKI leads to a worsening prognosis and increasing mortality. As will be explained later, RIFLE (risk, injury, failure, loss and end-stage kidney disease) severity grades correspond to increasing mortality. It has been reported that patients with a maximum score of RISK have a mortality rate of 8.8% as compared to a mortality rate of 11.4% for INJURY, and a mortality rate of 26.3% for FAILURE. Patients who did not have AKI had a mortality rate of just 5.5%.

Risk Factors for Developing Acute Kidney Injury in the Intensive Care Unit

Mendonca and associates[7] observed that there was a high risk of developing AKI if the patient has the following seven characteristics on admission. These are indicated in Box 2.

Risk Factors for Increasing Mortality in Acute Kidney Injury

These include an older age greater than 65 years, male gender, acute oliguric renal failure, sepsis, nonrenal organ failure, thrombocytopenia, mechanical ventilation, associated comorbid states (Box 3).

The most important risk factor contributing to increased mortality in AKI is the associated failure of other organ systems, notably the cardiovascular, respiratory and hepatic. This is a universally accepted fact. However, the mortality figure with increasing organ failure varies in different studies. Liand and colleagues[8] noted a mortality of 53% with two organ failures, 80% with three organ failures and 100% with five organ failure. This does not hold true with reference to multiorgan failures related to the severe tropical infections (see Chapter Multiple Organ Dysfunction Syndrome and Chapter Community-Acquired Fulminant Infections Requiring Critical Care).

DEFINITIONS

It is important to be aware of changing concepts in relation to ARF. The conventional definition of ARF is an acute decrease

Table 1: Acute kidney injury staging: the RIFLE system

Stages	*Serum creatinine increase*	*Urine output criteria*
Risk	≥150–200%	<0.5 mL/kg per hour for >6 hours
Injury	>200–300%	<0.5mL/kg per hour for >12 hours
Failure	>300% or serum creatinine >4 mg/dL or GFR decrease by 75%	<0.3 mL/kg per hour for >24 hours or anuria >12 hours
Loss	Complete loss of kidney function >4 weeks	
End-stage	Complete loss of kidney function >3 months	

Abbreviation: GFR, glomerular filtration rate.

Table 2: Acute kidney injury staging: the AKIN system

Stages	*Serum creatinine increase*	*Urine output criteria*
I	≥0.3 mg/ dL or ≥150–200%	<0.5 mL/kg per hour for >6 hours
II	>200–300%	<0.5 mL/kg per hour for >12 hours
III	>300% or acute renal replacement therapy	<0.3 mL/kg per hour for >24 hours or anuria >12 hours

Source: Mehta RL, Kellum JA, Shah SV, et al. Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury. Crit Care. 2007;11(2):R31.

in renal function characterized by an abrupt fall in the glomerular filtration rate (GFR), with retention of creatinine, urea and other waste products in the blood, together with a disturbance in the fluid and electrolyte metabolism of the body.

Renal dysfunction however can be mild, moderate or severe and the above definition takes no account of this all important clinical fact. In other words, the conventional definition does not allow one to quantify or characterize renal failure and has therefore been a hindrance to both clinical and basic research in this field.

The term AKI was proposed in preference and as an alternative to ARF by the Acute Kidney Injury Network (AKIN) so as to take into consideration the entire range of renal dysfunction. This concept was based on data showing that even very mild renal dysfunction, characterized by a small increase in serum creatinine influences outcome. The Acute Dialysis Qualitative Initiative (ADQI) developed subsequently evidence-based guidelines for prevention and treatment of ARF so as to allow comparison of results between different study groups and to advance research.[9] This group proposed a consensus categorized definition—the RIFLE criteria. These criteria quantified ARF and were validated and shown to correlate with hospital mortality and patient outcome in several large studies. Following the RIFLE criteria, AKIN proposed a revision of the RIFLE criteria[10-12] so as to take into consideration smaller changes in creatinine not taken into account by RIFLE. The RIFLE and AKIN criteria are given in Table 1 and Table 2.

There are certain differences between the RIFLE system of staging and the later introduced AKIN system.

- The AKIN system (Table 2) recognizes three stages—
  - Stage 1: corresponded to stage R of the RIFLE system.
  - Stage 2: corresponded to stage I of the RIFLE system.
  - Stage 3: corresponded to stage F of the RIFLE system.
- The diagnosis of AKI in the AKIN staging could be made if the serum creatinine rose by just 0.3 mg/dL from the baseline or if there was oliguria for more than 6 hours. However, there should be adequate volume replacement and urinary tract obstruction should be excluded before the low urine output is taken as a marker for AKI. It should be kept in mind that oliguria as a marker for AKI can be misleading as nonoliguric AKI is commonly observed in the ICU.

The importance of taking into consideration the absolute rise in creatinine was based on the finding in several studies that such increments in serum creatinine are associated with a high mortality.

The AKIN staging system states that the increments of serum creatinine described in stages 1, 2 and 3 should occur during a period of no more than 48 hours, compared to 7 days laid down in the RIFLE system.

The RIFLE and AKIN criteria for AKI help to identify patients with increased risk of death and renal replacement therapy.[9,10,13] The greater the increase in staging of AKI in a patient or in a group of patients, the greater the risk of death. There is evidence[14] that even after AKI resolves there is an increased risk of cardiovascular disease or chronic renal disease and mortality in these patients.

In the following further discussion on AKI, the term ARF when used signifies AKI, sufficiently severe to reach the "failure" stage of the RIFLE staging or stage III of the AKIN staging system.

There has been for some years a search for biomarkers to predict impending AKI as also to assess the severity of injury. Identification of impending or early AKI through the use of appropriate biomarkers could be useful as intervention may perhaps help to stop or control it. Biomarkers that are being researched upon are serum cystatin C, urine interleukin (IL) 18, tubular enzymes such as N-acetyl-glucoaminidase, neutrophil gelatinase-associated lipocalm (NGAL) and kidney injury molecule. Further research is necessary to validate the use of these markers for diagnostic purposes. *NGAL is the biomarker most commonly used to identify patients with early kidney injury, even before there is a rise in the serum creatinine.*

BEDSIDE APPROACH FOR THE EVALUATION OF ACUTE KIDNEY INJURY IN THE ICU (BOX 4)

Acute kidney injury generally comes to the attention of the physician either because of the finding of a raised serum creatinine or blood urea nitrogen (BUN) level or because of oliguria. It needs to be however restressed that all forms of AKI—prerenal, renal and postrenal—can be nonoliguric in nature. A normal urine output is therefore not a reliable indicator of adequate renal function. As pointed out earlier, nonoliguric kidney injury is particularly observed following

Box 4: Evaluation of a patient with acute kidney injury

- Thorough clinical examination with maintenance of input/output charts—
  - History of administration of nephrotoxic drugs or nephrotoxic insult in the recent past
- Urine analysis
- Serum creatinine and BUN levels; creatinine clearance test
- Other urinary and blood indices of renal function—urine osmolality
- Urinary sodium (mEq/L) fractional excretion of sodium
- Evaluation of circulatory hemodynamics
- Imaging studies—particularly for kidney size, uropathy
- Renal biopsy (in rare selected problems)

Abbreviation: BUN, blood urea nitrogen.

the use of aminoglycosides. The approach to diagnosis and management in both oliguric and nonoliguric AKI is similar. A patient with AKI who is nonoliguric is at an advantage compared to the oliguric patient because fluid and electrolyte management is easier. There is a greater leeway for fluid administration and lesser danger of fluid overload.

Clinical Evaluation

A clinical evaluation is always of utmost importance—

- The background factors and the etiology of oliguria with azotemia should be ascertained through a careful history, a thorough clinical examination and other relevant investigations. Intake/output charts should be evaluated. The role of nephrotoxic drugs should be kept in mind. The history of a recent hypotensive episode or a recent nephrotoxic insult, for example, the use of a contrast dye in radiological investigations, is an important pointer to the cause and nature of AKI.
- In a patient admitted to the ICU with a rise in serum creatinine, it is important to determine whether the renal injury is acute or chronic. A sudden oliguria always points to an acute disturbance in renal function.
- It is vital to determine whether oliguria with azotemia is due to prerenal factors, due to intrinsic renal disease or due to postrenal causes. All prerenal causes of oliguria, if left uncorrected, have the potential to cause intrinsic renal damage (ATN). Hence the presence of prerenal etiological factors by no means exclude intrinsic renal damage. For this a careful evaluation of the urine should be performed as outlined below.

Urine Evaluation

When diminished renal perfusion is the cause of oliguria with azotemia, there is an increase in sodium reabsorption by the renal tubules with a marked decrease in urinary sodium excretion to usually below 20 mEq/L. The urine osmolality is higher than 500 mOsm/kg H_2O. An examination of urinary sodium concentration of a random urine sample is therefore of great help.

Conversely, intrinsic renal disease causing acute oliguric renal injury (as in ATN) is associated with impaired sodium absorption by the renal tubules, with an increase in the urinary excretion of sodium. A random urine sample in these patients generally shows a urine-sodium concentration of above 40 mEq/L. Urine concentrating ability is also abnormal, resulting in isosthenuria and a urine osmolality less than 350 mOsm/kg H_2O.

There are however certain important provisos to the above statements. A urinary sodium greater than 40 mEq/L or more can occur in prerenal azotemia and oliguria if the effect of a recently given diuretic persists, in patients who have coexisting tubular abnormality, or in patients who have chronic renal disease characterized by impaired sodium absorption. A higher urinary sodium excretion can also be due to the presence of nonabsorbable anionic substances in the urine, such as bicarbonate in patients with metabolic acidosis, and certain penicillins which obligate the excretion of cations like sodium. Use of osmotic diuretics like mannitol will also result in increased sodium excretion. Finally, elderly persons can also show a comparatively high urinary sodium excretion in the presence of diminished renal blood flow. Therefore, though the urinary sodium concentration is an important pointer that helps distinguish prerenal from renal azotemia, it should not be considered in isolation. All the factors listed above should be taken into consideration before arriving at a responsible conclusion.

Fractional Excretion of Sodium

The fractional excretion of sodium (FENa) represents the fraction of sodium filtered at the glomerulus that is excreted in the urine.[15] It is determined by comparing the urinary sodium clearance to the urine creatinine clearance.

$$\text{FENa} = \frac{\text{U/P Na}}{\text{U/P Cr}} \times 100$$

where U is the urinary concentration and P the plasma concentration. In prerenal azotemia, the FENa is less than 1%; in AKI due to renal causes, it is greater than 2%.

The FENa is the best and most reliable single urinary test for AKI,[15,16] but again should not be considered in isolation. Acute oliguric kidney injury following the use of contrast agents, rhabdomyolysis, myoglobinuria and sepsis can be associated with the FENa less than 1%.[15]

In patients with prerenal azotemia, the use of diuretics will obscure the significance of the FENa values. In these patients the fractional excretion of urea or a urine to plasma ratio of creatinine higher than 40 is indicative of prerenal azotemia.[17]

Microscopic Examination of the Urine

Microscopic examination of the sediment of a freshly voided urine sample is elementary but of great value.

- The presence of tubular epithelial cells and of epithelial cell casts (in particular muddy brown casts) suggests ATN.
- In prerenal azotemia, the urinary sediment shows non-specific hyaline casts or finely granular casts.

Table 3: Laboratory findings distinguishing prerenal azotemia from acute tubular necrosis (ATN)

Parameters	*Prerenal azotemia*	*ATN*
Urine sodium (mEq/L)	<20	>40
Urine/plasma creatinine	>40	<20
Fractional excretion of Na	<1	>2
Urine sediment	Normal or nonspecific hyaline casts	Renal tubular epithelial casts, muddy brown casts

- In acute interstitial nephritis the urine shows many white blood cells and white blood cell casts.
- In acute glomerulonephritis and in any other pathology causing the "nephritic syndrome" the urine contains albumin, plenty of red blood cells, white blood cells and above all red blood cell casts.
- The presence of bacteria with a positive culture showing a high colony count, points to an infection in the urinary tract.
- Modest proteinuria (up to 1 g/dL) is common in many forms of AKI, but proteinuria in the nephrotic range (>3.5 g/dL) is most often due to glomerular disease, except when associated with Bence-Jones proteinuria in multiple myeloma. Urine protein electrophoresis will distinguish between Bence-Jones protein and albumin in a suspected case of multiple myeloma (Table 3).

Determining Degree of AKI

In patients with AKI it is important to determine the degree of renal dysfunction and also to determine the changes in the internal milieu brought about by renal dysfunction.

Blood Creatinine Levels

This is the simplest and most valuable guide to renal dysfunction. It is currently accepted that even a rise as little as 0.3 mg/dL above the base line signifies renal dysfunction and injury. Even so, the normal GFR must be reduced by about half before there is a significant rise in the serum creatinine levels. Modest degrees of renal dysfunction may thus go undetected if a creatinine clearance test is not done. During the acutely evolving phase of renal injury, serum creatinine levels may rise by 2 mg/dL every 24 hours. More rapid increases can occur in rhabdomyolysis. A misleading increase in serum creatinine without a fall in the GFR may occur when cephalosporin or certain ketones (acetoacetate) interfere with the calorimetric method used for its measurement.[18] Cimetidine and trimethoprim-sulfamethoxazole compete with tubular secretion of creatinine and result in increased creatinine values without a fall in the GFR.[18]

Blood Urea

Urea is the major nitrogen-containing metabolite of protein metabolism and is excreted chiefly by the kidneys. About 35–50% of filtered urea is reabsorbed by the tubules. In the presence of hypovolemia or decreased renal perfusion from any prerenal cause, the reabsorption of urea can increase to as high as 90%. In contrast, creatinine is not reabsorbed by the renal tubular cells. When measured as BUN in mg/dL, the normal ratio of BUN to creatinine in serum is 10:1. An increase in this ratio to 20:1 or more points to prerenal azotemia. Blood urea levels are also related to the amount of protein intake and degree of protein catabolism. Inadequate caloric intake, corticosteroid administration, and the stress of a hypermetabolic critical illness can result in endogenous protein catabolism, and increase in blood urea levels even with normal renal function. GI hemorrhage with the resulting absorption of blood protein is another important cause of elevated blood urea levels (Box 5).

Box 5: Causes of elevation of BUN or serum creatinine elevation without reduction in the glomerular filtration rate

- Increased urea levels—
  - GI bleeding
  - Hypercatabolic illnesses—burns, high fever, tetanus, seizure disorders
  - Increased protein intake or parenteral nutrition
  - Drugs: corticosteroids
- Increased creatinine levels due to increased biosynthesis of creatinine—
  - Rhabdomyolysis
  - Drugs: cimetidine interferes with tubular creatinine secretion

Abbreviation: GI, gastrointestinal.

Creatinine Clearance Test

Creatinine clearance test using a 24-hour urine collection is a reliable index of renal function.

$$\text{Creatinine clearance (mL/min)} = \frac{\text{Urine creatinine (mg/dL)} \times \text{Urine volume (mL/min)}}{\text{Serum creatinine (mg/dL)}}$$

Other Urinary and Blood Indices

Other urinary and blood indices are often used to distinguish between prerenal azotemia and acute oliguric renal injury. The urine osmolality, the urine/plasma urea nitrogen ratio, and the urine/plasma creatinine ratio increase in prerenal azotemia, whereas urine sodium and the fractional excretion of filtered sodium remain low. The indices which help to distinguish between prerenal azotemia and azotemia due to intrinsic renal causes (as in ATN) have already been discussed earlier.

Serum Electrolytes

Estimation of serum sodium, potassium, chloride, bicarbonate, calcium, magnesium and phosphate should be done. Their monitoring forms an important feature in the management of AKI.

Arterial pH and Blood Gas Analysis

It should always be done to determine the presence and degree of acidosis, as also to determine any abnormality in blood gas exchange within the lungs.

Evaluating Circulatory Hemodynamics

The hemodynamics of the circulation should be carefully evaluated. A central venous line is invariably inserted in these patients and provides a guide to the central venous pressure. In oliguric patients, it is important that the filling pressures are maintained at an optimal level. When there is doubt about hypovolemia with low left-sided filling pressures contributing to azotemia, a Swan-Ganz catheter may need to be inserted to determine the pulmonary capillary wedge pressure. A volume load can then be so adjusted as to keep this wedge pressure around 12–15 mm Hg.

Imaging Studies

- An ultrasound imaging is invaluable for the following reasons—
  1. It gives the size of the kidneys—small kidneys suggest underlying chronic renal disease.
  2. It can pick up ureteric obstruction and hydronephrosis, and is invaluable in the diagnosis of oliguria due to postrenal causes.
  3. In fulminant urinary infections, an ultrasound examination helps in the detection of a renal or perinephric abscess.
- An abdominal X-ray demonstrates the presence of radio-opaque kidney stones and may pick up other associated diseases within the abdomen.
- Imaging studies involving the use of contrast dyes are contraindicated in ARF because of the toxicity of the contrast dye to the kidneys. A retrograde pyelography may however be necessary in patients with obstruction to the ureter resulting in postrenal oliguria and renal failure. A computed tomography study may help to localize a perinephric abscess or diagnose a fulminating pyelonephritis.

Renal Biopsy

A renal biopsy is avoided in critically ill patients with ARF except—

- When there is strong suspicion of acute vasculitis, or a rapidly evolving autoimmune disorder and
- In patients with ATN in whom renal failure fails to resolve within 6–8 weeks.

MANAGEMENT PROTOCOL FOR ACUTE OLIGURIA IN CRITICALLY ILL PATIENTS

- It is important to ensure that urinary catheters in critically ill patients do not get blocked, thereby giving a false impression of oliguria.
- It is vital to ensure that the hemodynamic status of the patient is satisfactory. He should have a normal circulating volume, normal filling pressures in the right and left heart chambers and an adequate cardiac output. In critically ill patients, on rare occasions, one may have to ascertain this with a Swan-Ganz catheter and give enough volume infusion to maintain the pulmonary capillary wedge pressure around 15 mm Hg. The pump in other words must be optimally primed.

  If oliguria persists despite the pump being fully primed, and if facilities so exist, the cardiac output should be measured. If this is found to be low, the cause of this should be ascertained. Cardiac output can be increased by using inotropic support with dopamine (5–10 μg/kg per minute) or dobutamine (10–20 μg/kg per minute); at times both can be used together.

  If the cardiac output is normal or high, but the patient is hypotensive as with sepsis or other forms of distributive shock, the vascular resistance is increased with dopamine at 10–15 μg/kg per minute or the use of nor-epinephrine or vasopressin.
- Whilst the patient's hemodynamic state is brought to as optimal a level as possible, a clinical assessment and the urinary evaluation described earlier is simultaneously carried out to determine if there is any intrinsic renal damage causing ARF. The importance of estimating urinary sodium concentrations and FENa values has already been emphasized.
- The persistence of oliguria with an increase in serum creatinine levels in the presence of normal hemodynamics suggests AKI. An attempt is often made at this stage to induce an increased urine output through the use of loop diuretics given as a continuous titrated intravenous (IV) infusion. The use of both IV loop diuretics and of low-dose dopamine in the management of AKI is discussed in the next Section "Management of Persistent Oliguric AKI".

Drugs in Patients with Persistent Oliguria

All nephrotoxic drugs should be withheld. Aminoglycosides in particular should always be stopped right at the start when oliguria and azotemia first appear. Carbapenems and aztreonam are effective in countering Gram-negative sepsis including that due to *Pseudomonas pyocyaneus*. If amphotericin B is being used to counter systemic fungal infections, the drug should be stopped and an alternative non-toxic or less nephrotoxic anti-fungal used. If this is not possible, it should be used at half or quarter of the usual dose. A list of drugs which are preferably stopped or not administered in ARF is given in Box 6.

If for any reason it is necessary to administer drugs that are nephrotoxic, their dosage is modified as per the creatinine clearance. A list of common ICU drugs excreted by the kidneys, with modifications in their dose, is detailed in Table 5 of Chapter Antibiotic Therapy in the Intensive Care Unit.

Box 6: Drugs which should be discontinued in acute renal failure (alternative drugs in parenthesis)

- Nephrotoxic drugs—
  - Aminoglycosides (imipenem/aztreonam)
  - Amphotericin B (fluconazole)
  - Pentamidine (trimethoprim-sulphamethoxazole)
- Drugs causing allergic interstitial nephritis—
  - Penicillin and allied drugs (erythrocin/vancomycin)
  - Cephalothin, vancomycin
  - Trimethoprim-sulphamethoxazole (pentamidine)
  - Cimetidine (sucralfate, other antacids)
  - Nonsteroidal anti-inflammatory drugs (paracetamol)

MANAGEMENT OF PERSISTENT OLIGURIC AKI

Prevention

The poor outcome of patients suffering from progressive AKI has led to the trial of several drugs both with the view to prevent and/or ameliorate the condition. Preventive measures have been tried in particular with regard to the frequent occurrence of contrast-induced nephropathy. IV furosemide and IV mannitol both as preventive and treatment of contrast induced nephropathy have led to worse outcomes. Dopamine and atrial natriuretic peptide have also proved ineffective. Acetylcysteine and fenoldopam have been found to decrease the incidence of contrast-induced nephropathy in high risk patients. *The current recommendation for prevention of contrast-induced nephropathy, particularly in high-risk patients, is adequate hydration with normal saline or sodium bicarbonate, 1,200 mg of acetylcysteine twice daily on the day before and the day of the procedure and the use of low osmolar contrast media.*

Dopamine in AKI

Dopamine has long been used in the prevention and treatment of AKI. It has now been shown that dopamine is ineffective and should not be used. In patients with early renal dysfunction, renal creatinine higher than 1.8 mg/dL and urine output less than 0.5 mL/kg per hour, dopamine neither alters peak creatinine values nor decreases the need for renal replacement therapy nor reduces mortality. Besides being clinically ineffective, the drug can produce harmful side effects—arrhythmias, myocardial and gut ischemia. *Currently, the drug has no role in the prevention and treatment of AKI.* Low dose (2–3 μg/kg per minute) may induce a diuresis in some patients with AKI but this in no way improves ultimate outcome. The most the drug can do through its diuretic action is to allow a better leeway for the management of fluid and electrolyte balance.

Furosemide in AKI

Diuretics, in particular loop diuretics like furosemide are frequently used in AKI in an attempt to increase urine flow and convert oliguric into nonoliguric AKI, the latter entity having a better prognosis. Current work has observed that though the use of loop diuretics in early or established AKI allows a better management of fluid, electrolyte (in particular of hyperkalemia or hypercalcemia) balance, there is no proven role of these diuretics either in prevention or management of AKI. *If therefore furosemide is used temporarily to allow better fluid electrolyte management, it should not be allowed to delay the initiation of renal replacement therapy if this is indicated.*

Atrial Natriuretic Peptide

Short-term benefits of atrial natriuretic peptide (ANP) (BNP type natriuretic peptide) on perioperative renal function include lesser rise of creatinine, a lesser reduction of GFR and a greater urine output after surgery. The drug cannot be recommended until further studies have proven its use.

SUPPORTIVE TREATMENT

The treatment of AKI is unfortunately merely supportive.

The principles of management are—

- To maintain body homeostasis with particular reference to fluid, electrolyte and acid-base balance.
- Hemodynamic management to restore and maintain hemodynamic stability.
- To maintain nutrition.
- To recognize and treat complications occurring in the course of the illness.
- To use specific treatment for some forms of acute glomerulonephritis.
- To use dialysis when indicated, and to decide on the type of dialysis best suited to the patient.

Maintaining Homeostasis

Acute tubular necrosis is the most common form of oliguric ARF observed in critical care units. The oliguric phase may last for a period ranging from a few days to as long as 4–6 weeks. This is followed by a period or phase of relative diuresis.

Fluid Balance

The greatest danger is fluid overload. The fluid intake should not exceed the urine output plus the fluid output from other sources (e.g. nasogastric suction, fluid loss from diarrhea, sweating, surgical drains) plus the insensible water loss. In a well-nigh anuric patient who has no fluid loss from other sources, the fluid intake should not exceed 500–700 mL.

In a patient who already has been in oliguric renal failure some days prior to admission to the ICU, it is often impossible to determine the degree of fluid imbalance present prior to hospitalization. In these patients, as also in critically ill patients in whom AKI amounting to ARF is a complication of severe underlying disease (e.g. acute lung injury or sepsis), it is often necessary to measure the central venous pressure through a central venous catheter, and occasionally in complicated problems, the left heart pressures through a

Box 7: Sodium content of important body fluids

- Sweat: Na^+ 20–100 mEq/L
- Gastric fluid: Na^+ 30–90 mEq/L
- Diarrhea: Na^+ 50–110 mEq/L
- Small bowel ostomy: Na^+ 70–150 mEq/L
- Biliary drainage: Na^+ 120–170 mEq/lL

Swan-Ganz catheter. The left heart pressures if measured should not exceed 15–18 mm Hg.

Critically ill patients may require large quantities of IV fluids for hyperalimentation, administration of vasopressors and antibiotics. Fluid overload is certain in these patients and methods involving dialysis are then necessary to ensure that fluid overload does not occur.

Sodium Balance

Sodium balance is maintained by replacing the sodium that is lost. Urinary losses of sodium can be exactly measured by 24 hour collection of urine. An approximate method of estimating urinary sodium loss is by determining the sodium concentration in a random sample and multiplying this by the urine volume over 24 hours. GI losses are difficult to measure but can be roughly estimated. The approximate sodium content of body fluids is given below in Box 7.

In oliguric renal failure, hyponatremia is the most frequent electrolyte abnormality; this is invariably a dilutional hyponatremia due to a fluid overload.

Potassium

Except in individuals who lose a large quantity of fluid through nasogastric suction or diarrhea, hyperkalemia is always to be anticipated and promptly corrected. Potassium should be invariably restricted in these patients except in those who have potassium losses from the above-mentioned sources (see Section Fluid and Electrolyte Disturbances in the Critically Ill).

Acid-Base Balance

Uremic acidosis is an expected feature of oliguric renal failure, and is related to protein catabolism. 1 mEq of H^+ ion is retained for every gram of protein catabolism, and on a normal diet, 70 mEq of H^+ ions are produced in the body. With poor renal function H^+ ions accumulate and cause acidosis. Patients may develop a substantial base deficit higher than 15 mEq/L, and the pH may drop to below 7.2 in spite of a compensatory fall in the $PaCO_2$ produced by hyperventilation. It is necessary to correct significant acidosis with 50–100 mEq of IV sodium bicarbonate (see Chapter Acid-Base Disturbances in the Critically Ill). If serum calcium levels are low, it is prudent to administer 10 mL of calcium gluconate intravenously before administering sodium bicarbonate.

Lactic acid acidosis often occurs in critically ill patients with severe kidney injury amounting to ARF, particularly in those with sepsis. Lactic acid production in very ill patients may be as high as 50 mEq per hour, and can reduce plasma bicarbonate at the rate of 1–2 mEq/L per hour. In the presence of marked oliguria, replacement of large quantities of bicarbonate almost always results in fluid overload and in hypernatremia, requiring dialysis. All efforts should be made to optimize oxygen transport and tissue perfusion in these patients.

Calcium, Magnesium and Phosphates

It is important to maintain these electrolytes within normal limits. Hypocalcemia may occur following the use of IV bicarbonate, but otherwise tetany is rare. Hypercalcemia is observed in kidney injury associated with multiple myeloma.

Magnesium excretion is reduced, and magnesium containing antacids should be avoided.

Phosphate levels increase with increasing duration of oliguric renal failure. When serum phosphate levels exceed 6 mg/dL, aluminum hydroxide 30 mL 8 hourly is effective in binding phosphates within the gut. Once phosphate levels are less than 6 mg/dL, calcium carbonate can be given in a dose of 500 mg 8 hourly, after meals.

If IV alimentation is used for the purposes of nutrition, it is best to avoid phosphates in the IV fluids till such time as the high phosphate levels have returned to normal.

Maintaining Hemodynamic Stability

Appropriate management to ensure hemodynamic stability is of paramount importance. The tendency to overinfuse fluids in the early stage of AKI is to be avoided as it can result in pulmonary congestion and ultimately to ARDS. Not uncommonly AKI is part and parcel of a multiorgan dysfunction syndrome which includes cardiovascular dysfunction. Complicated problems require not only a central venous pressure (CVP) line, but also a Swan-Ganz catheter to estimate left sided filling pressures. These pressures are to be considered as guides to fluid replacement, yet sometimes can be misleading. *Noncardiogenic pulmonary edema can occur even when the left sided filling pressures are within normal limits. If this is not promptly realized a full blown ARDS may complicate the situation.*

Maintain Nutrition[19]

In an intensive care setting, patients with oliguric AKI are invariably catabolic. It is important to minimize negative nitrogen balance. Overfeeding unfortunately does not for several reasons correct the negative nitrogen balance. In fact, it is better to underfeed than overfeed these patients. The total caloric requirement should be 20–30 kcal/kg per day. Increasing caloric intake above this level not only fails to correct nitrogen balance but also induces hyperglycemia and hypertriglyceridemia and a positive fluid balance.

The mechanism of increased catabolism in these patients is increased insulin gluconeogenesis fuelled by protein catabolism. Liberation of proinflammatory cytokines and catecholamines contributes further to the catabolic state.

Enteral feeding is the preferred form of nutritional support as it helps preserve the integrity of the gut. In the past, protein restriction was advised to control uremic symptoms, but this can do more harm than good, as it can cause a marked negative nitrogen balance. In patients with AKI who do not need dialysis a protein intake of 0.8–1 g/kg per day is adequate. In patients with AKI on renal replacement therapy an intake of 1–1.5 g/kg per day is advisable. There are many who advocate a large protein intake but this could again do more harm than good; also a larger protein intake does not get rid of the negative nitrogen balance.

The rest of the calorie requirement is divided roughly between carbohydrates and fats. Essential fatty acids such as omega-3 polyunstaurated fatty acids and aminoacids, such as arginine, have been found to stimulate the immune system and are believed to be beneficial.

If for any reason enteral feeds are not possible, parenteral feeding should be started early. This is of essence in the management of severely catabolic patients with marked AKI. All such patients require dialysis or hemofiltration to allow necessary administration of increased quantities of fluid associated with parenteral nutrition and to allow a larger protein intake without producing uremic symptoms. Appropriate nutritional support is vital as it helps in renal recovery and improves overall survival in AKI.

Recognize and Treat Complications

Complications may arise as a result of the primary disease causing ARF, or may be directly related to ARF. Rapidly progressive ARF has a high morbidity even when it occurs as a primary event. It can ultimately so derange homeostatic mechanisms, as to lead to multiple organ failure and death.

Important complications associated with acute oliguric renal failure are listed in Box 8. They should be anticipated, if possible prevented, and when they do occur, should be promptly treated.

Dose adjustments of all drugs during acute oliguric renal failure are of great importance, else drug toxicity is inevitable. Uremic patients bleed easily. GI bleeding is common; bleeding from other sites due to platelet dysfunction also occurs. If this is observed, or if more effective hemostasis is required for any operative or invasive procedure, the prophylactic use of desmopressin acetate 0.3 µg/kg intravenously or the use of sufficient quantity of cryoprecipitate and platelet concentrates shortens the bleeding time appreciably. Prophylaxis against GI bleeding due to acute erosive gastritis is generally recommended. Sucralfate is preferable to the use of other antacids. In the presence of active bleeding, a H_2-antagonist or omeprazole should be used.

Kidney recovery in ATN is heralded by the onset of the diuretic phase. In some patients diuresis may be as high as 5–6 L/day. Blood creatinine and urea may remain high for some days in spite of the diuresis. Fluid and electrolyte balance should be maintained as per the principles outlined above. With progressive recovery, homeostasis is finally achieved.

Box 8: Complications associated with acute kidney injury

- Metabolic—
  - Hyperkalemia
  - Hyponatremia
  - Hypocalcemia
  - Hyperphosphatemia
  - Hypermagnesemia
  - Acidosis/Alkalosis
  - Hypoglycemia
- Gastrointestinal (GI)—
  - Nausea, vomiting, diarrhea
  - GI hemorrhage, paralytic ileus
- Cardiovascular—
  - Fluid overload with water retention
  - Hypertension
  - Congestive cardiac failure
  - Pulmonary edema
  - Cardiac arrhythmias
  - Myocardial infarction
  - Pericarditis
- Hematologic—
  - Anemia
  - Platelet dysfunction
  - Bleeding from various sites
- Neurologic—
  - Neuromuscular irritability
  - Mental obtundation and coma
  - Seizures
- Multiple organ dysfunction
- Infections—
  - Sepsis
  - Pneumonia
  - Catheter-related infections
  - Urinary tract infections
  - Wound infections

Specific Treatment for Certain Specific Forms of Glomerulonephritis

Specific treatment for some forms of autoimmune glomerulonephritis, immune-complex disease and acute renal disease due to various forms of vasculitides includes the use of cytotoxic agents, corticosteroids, antiplatelet drugs and plasma exchange.

Use of Dialysis[20]

Dialysis enables homeostasis of fluid, electrolytes, acid-base and nitrogen balance, when this is difficult or impossible with the medical measures outlined above. Certain principles of management need to be stressed upon—

- The cause of ARF should as far as possible be determined and postrenal causes should be excluded before commencing dialysis.

- Attention should be given to preserving and maintaining a satisfactory hemodynamic state, so that renal perfusion is adequate.
- Sepsis should be vigorously treated.
- The dosage of all drugs administered to the patient are modified according to the degree of renal failure and the type of dialysis in use.
- Three types of dialysis (renal replacement therapy[21]) are available—
  - Intermittent hemodialysis.
  - Continuous hemofiltration/hemodiafiltration.
  - Peritoneal dialysis (intermittent or continuous).

They work on the principle of enabling water and solute clearance through a semipermeable membrane and discarding the waste products so produced. The mode of replacement therapy chosen for a particular patient depends on the nature and degree of homeostatic imbalance, the hemodynamic status and the background disease or complications present.

Indications for Dialysis

Fluid overload This is the most important indication for dialysis. When fluid overload produces increasing pulmonary congestion and edema, dialysis needs to be performed urgently.

In hemodynamically stable patients, intermittent hemodialysis provides the quickest method of removing fluid, 1–2 L/hour by ultrafiltration. In hemodynamically unstable patients peritoneal dialysis or continuous hemofiltration is safer and therefore preferable. The amount of fluid removed can be carefully titrated; generally 1–2 or more liters are removed over 24 hours and this can be repeated daily if necessary till fluid balance can be attained. Thus a large quantity of fluid can be removed over a few days. In continuous hemofiltration (CHF) the ultrafiltrate is isosmotic with plasma.

Electrolyte abnormalities Hyperkalemia is an important indication for dialysis, if it is marked, persistent or rapidly progressive. Rapid potassium removal is only possible by machine hemodialysis, the clearance rate of potassium being 100–200 mL/minute. Peritoneal dialysis or continuous hemofiltration does not allow a clearance rate of potassium greater than 20 mL/minute, and these forms of dialysis should be used to counter modest hyperkalemia or for maintaining potassium balance.

Toxic serum levels of calcium, magnesium and phosphates are also rapidly corrected by hemodialysis. Severe hypophosphatemia may complicate all forms of dialysis, if phosphates are absent in the diet or in the IV alimentation fluids.

Acid-base abnormalities Uremic acidosis and lactic acid acidosis can both be temporarily corrected by hemodialysis. Acidosis recurs quickly (particularly in patients with lactic acid acidosis) in the inter-dialysis period. Continuous arteriovenous hemofiltration provides continuous correction of acidosis, and is the treatment of choice in septic patients in ARF, who have both fluid overload and a lactic acid acidosis.

Uremic symptoms Dialysis is indicated with BUN levels higher than 100 mg/dL, particularly in the presence of uremic symptoms—pericarditis, encephalopathy, bleeding tendency, neuromuscular irritability and seizures.

The current practice is to initiate dialysis early rather than late in AKI. It is bad medicine to await serious complications of uremia before starting dialysis. *Most ICUs would consider dialysis when any one of the following is present—severe oliguria (<5 mL/kg per day), anuria for over 12 hours, pulmonary edema not responding to a diuretic, metabolic acidosis with a pH less than 7.2, uremic symptoms such as increasing obtundation or encephalopathy or pericarditis, or severe GI symptoms. The presence of any two of the above would be considered by most as a clear indication for dialysis.*

It must be however remembered that an over-aggressive approach to the very early commencement of dialysis in ARF does not necessarily equate with a reduction in mortality. In fact an over-aggressive approach in units that lack either experience or expertise can do more harm than good.

Intermittent hemodialysis may be necessary every other day or even daily, in hypercatabolic patients. Dialysis needs to be continued till recovery ensues. In ATN, this usually takes place within 2–8 weeks. Dialysis should be withheld if there is evidence of irreversible vital organ failure or severe irrecoverable cerebral damage.

Modes of Dialysis[22]

The mode of renal replacement therapy in an ICU for a given patient depends not only on the underlying medical problem but also on local resources, expertise and experience. We increasingly tend to use continuous hemofiltration/hemodiafiltration in preference to intermittent hemodialysis. Peritoneal dialysis is not indicated in the management of patients with ARF requiring dialysis, except in those where vascular access is unavailable or impossibly difficult. Continuous hemofiltration/hemodiafiltration offers the following advantages—

- Use of biocompatible membrane.
- Greater hemodynamic stability.
- Ability to control the quantum of removal of water over prolonged time.
- A leeway for increased fluid intake necessary both for hyperalimentation and for administering drugs intravenously.
- Prevention of both cerebral edema and increase in intracranial pressure.

A brief description of intermittent hemodialysis, peritoneal dialysis and continuous hemofiltration is given below. The techniques and the details regarding vascular access and performance of different forms of dialysis are best left to the nephrologist and trained nursing staff. The physician in the ICU must however be aware of the principles underlying the effectiveness, advantages and disadvantages of each form of

dialysis and the complications that can be encountered during dialysis in the ICU.

Hemodialysis

Advantages and Effectiveness

The major advantage of hemodialysis is its highly efficient solute removal, and its ability to remove fluid overload within a short period of time. Most modern dialyzers allow 150–200 mL/minute of urea clearance with blood flows between 200 mL/minute and 300 mL/minute. More rapid solute clearance can be obtained with newer filters when operated at a higher flow of 400 mL/minute. As much as 1–3 L of fluid can be removed per hour; fluid withdrawal is however limited by the patient's hemodynamic state. *A very rapid fluid withdrawal can produce disastrous consequences in critically ill patients*. Ordinarily a 4-hour hemodialysis should reduce pretreatment urea levels by about 50%.

Disadvantages

The major disadvantage is the rapidity of fluid withdrawal which is unsuitable in a hemodynamically unstable patient. The need for a large-bore vascular access and the need for anticoagulation are other disadvantages. The latter specially poses problems in patients who are actively bleeding.

Complications[23]

The following complications are often met with during or immediately after hemodialysis—

Hypotension Hypotension is related to poor tolerance of fluid removal. Poor tolerance to the acetate used in the dialysate fluid can potentiate hypotension. Fortunately, acetate is no longer used in the dialysate fluid. Bicarbonate based dialysates are always preferred in hemodynamically unstable patients and are now in universal use.

Hypotension resistant to volume replacement, together with respiratory distress, can in rare instances be due to relative bio-incompatibility between cuprophane and cellulose-based membranes. This has been dubbed the first use syndrome, and is treated with subcutaneous epinephrine and IV aminophylline. Definitive management consists in using more biocompatible materials.

Hypotension during dialysis should be treated by decreasing the blood flow, and administering a volume load with either colloids like albumin, or crystalloids like dextrose or normal saline.

Arrhythmias Cardiac arrhythmias are particularly prone to occur in hemodynamically unstable patients. Digitalis toxicity is another cause and is precipitated by the rapid lowering of serum potassium levels. Abnormalities in serum levels of magnesium and calcium, hypoxia and myocardial ischemia are other causes of cardiac arrhythmias. Cardiac arrest is a dreaded complication in critically ill patients. Arrhythmias should be promptly recognized and treated.

Hypoxemia Arterial hypoxemia can be due to two causes—

1. The loss of CO_2 through the dialyzer with subsequent diminishing of the respiratory drive. Oxygen administered through nasal prongs corrects the hypoxia.
2. The occurrence of the first-use syndrome due to activation of complement and of leukoagglutination within the lungs can cause severe bronchospasm with hypoxia. Dialysis needs to be promptly discontinued, and the bronchospasm should be countered by nebulization with duolin, IV hydrocortisone and if required by IV aminophylline.

Hemorrhage If serious hemorrhage occurs, previously administered heparin should be neutralized by protamine. One milligram of protamine ordinarily neutralizes 100 International Units of heparin. Protamine infusions should preferably be limited to a maximum of 15 mg over 5 minutes, to minimize the risk of anaphylactic reactions.

Dialysis disequilibrium syndrome This syndrome is characterized by headache, nausea, twitchings, mental obtundation, delirium and seizures, following rapid correction of severe uremia. Shorter duration of treatment to start with, using slower blood flow rates of less than 200 mL/minute, helps to minimize or prevent this syndrome.

Peritoneal Dialysis

The only indication for peritoneal dialysis (PD) is in patients with AKI in whom vascular access is difficult or impossible. In these patients, peritoneal dialysis remains the only alternative. Hemodynamically unstable patients can withstand peritoneal dialysis without further compromise of their circulatory system, as the rate of fluid removal is much slower than with hemodialysis.

The effectiveness of peritoneal dialysis is not as good as intermittent hemodialysis. Solute removal depends on the volume of the dialysate and dwell time within the peritoneal cavity. An aggressive schedule incorporates 2 L exchange every hour, providing 24 L of urea clearance per day. Less aggressive schedules involving 2 L exchanges every 4 hours, result in 8–10 L of urea clearance per day. Fluid removal depends on the concentration of glucose in the dialysate and the dwell time allowed. Higher concentrations of glucose (4.25% solutions) can provide a fluid removal of 500 mL/hour. A major advantage of this technique is that no anticoagulation is required. The method therefore is safer than hemodialysis in bleeding patients.

Severe fluid overload producing pulmonary edema is however best managed by intermittent dialysis or continuous arteriovenous hemofiltration.

Disadvantages and Complications[24]

- An important disadvantage and complication is impaired drainage. Problems can be particularly serious when the catheter allows unimpeded inflow, but the outflow is markedly reduced. This may be due to malpositioning

of the catheter or a ball-valve obstruction produced by omentum wrapped round the perforations in the catheter.

- Infection with resulting peritonitis is a serious complication. As opposed to peritonitis resulting from intrinsic disease, dialysis-induced peritonitis can be successfully managed by intraperitoneal antibiotics. When suspected, the WBCs in the effluent should be estimated. A WBC count greater than 100 granulocytes/μL points to infection. Gram stain of the effluent for organisms is also of help. A suitable antibiotic is added to the dialysate depending on the nature of infection present. The choice and dosage of antibiotics in the dialysate should be decided upon by the nephrologist. Gentamicin is preferred for Gram-negative infections, and vancomycin or cefazole for staphylococcal infections.
- Protein loss can be considerable in peritoneal dialysis.
- Compromised pulmonary function due to elevation of the diaphragm and hydrothorax is frequently observed. Peritoneal dialysis cannot be effectively used in breathless patients with pulmonary disease.
- Abnormal blood sugar levels and electrolyte disturbances may be induced during peritoneal dialysis.
- Peritoneal dialysis is very slow and ineffective in patients who are severely hypercatabolic, and who are in ARF, or when dangerous abnormalities in fluid and electrolyte balance need very prompt correction.

Continuous Hemofiltration

Continuous hemofiltration (CHF) is being increasingly used as the mode of dialysis in critically ill patients who have a large fluid overload, and in those who are hemodynamically unstable. It is also indicated when the use of IV alimentation necessitates the administration of large volumes of fluid.

In CHF, a highly permeable membrane acts as an artificial glomerulus by permitting hydrostatically driven ultrafiltration. The ultrafiltration leads to loss of water, solutes, urea and waste products in the ultrafiltrate. This method of solute clearance is termed convective clearance.

A large volume of fluid can be removed in a fluid-overloaded critically ill patient, without inducing hypotension or other circulatory disturbances because treatment lasts continuously throughout the day. The procedure can be carried out at the bedside and this is an added advantage. The need for an access to large vessels for excellent nursing and for continuous anticoagulation with heparin are the main drawbacks.

Continuous Arteriovenous Hemofiltration

This is perhaps the most commonly used mode of hemofiltration. In continuous arteriovenous hemofiltration (CAVH) blood is driven through the filter by the patient's own blood pressure, either via a large bore femoral artery cannula or via the arterial limb of an arteriovenous Scribner shunt. The blood traverses the biocompatible permeable filter, undergoes ultrafiltration and is returned to the circulation via a cannula in the femoral vein or via the venous limb of the Scribner shunt. Solute clearance and removal of nitrogenous waste products are not as efficient as in hemodialysis. Even so, significant and often adequate clearance of nitrogenous waste products is achieved because treatment is continuous throughout the day.

Continuous Arteriovenous Hemodiafiltration

Numerous modifications have been incorporated to improve solute clearance in the continuous arteriovenous hemodiafiltration (CAVHD) circuit. The most effective way of increasing solute clearance is to add dialysate flow countercurrent to the hemofiltration current. This can double solute clearance through diffusion of solutes. This technique is termed continuous arteriovenous hemodiafiltration.

Continuous Venovenous Hemofiltration and Hemodiafiltration

In continuous venovenous hemofiltration (CVVH), access to the circulation is obtained via a double lumen catheter inserted into the femoral or subclavian or internal jugular vein. Blood is pumped by a roller pump from the arterial limb of the double lumen catheter into the filter and after ultrafiltration and purification returns to the circulation via the venous limb of the double-lumen catheter.

If a counter-current diastolic flow is added to the CVVH current, solute clearance is further increased. This technique is termed continuous venovenous hemodiafiltration (CVVHD).

Large amount of fluid can be removed by the various techniques of continuous hemofiltration. A careful hourly measurement of fluid removed in relation to fluid replaced is mandatory and a frequent estimation of serum electrolytes is also necessary. Good nursing and constant attention are required for good results.

CLINICAL SYNDROMES ASSOCIATED WITH AKI

Pigment Nephropathy Due to Rhabdomyolysis or Acute Hemolysis[25] (Box 9)

Rhabdomyolysis is observed most frequently after severe traumatic crush injuries. In an intensive care setting it also occurs in patients with fulminant tetanus, acute polymyositis, acute myositis and rarely in severe leptospiral infections. Myoglobinuria with precipitation of myoglobin casts in renal tubules is the cause of acute renal injury and failure. Volume depletion from any cause (e.g. crush injuries) promotes precipitation of myoglobin within the tubules. Rhabdomyolysis is associated with painful muscles, and elevated creatinine kinase and aldolase levels in the blood.

Acute severe hemolysis in our part of the world is most frequently due to three causes—

1. The inadvertent administration of incompatible blood transfusion.
2. The use of certain drugs in patients who are G6PD deficient.
3. Acute hemolysis in falciparum malaria and black water fever.

Box 9: Important causes of rhabdomyolysis

- Exercise
- Tetanus
- Status epilepticus
- Trauma, crush injuries
- Heat stroke, hyperthermia
- Polymyositis, dermatomyositis
- Acute infective myositis
- Ischemia to the muscles of a limb
- Myopathies
- Drugs and toxins

Acute viral and *Salmonella* infections can also induce severe hemolysis in G6PD deficient patients with resulting acute renal shutdown. The presence of severe anemia, a high reticulocyte count, rise in serum bilirubin and a low haptoglobin are features of acute hemolysis. In the absence of detectable red blood cells on urinanalysis, a dipstick test positive for heme is diagnostic of myoglobinuria or hemoglobinuria. Patients with myoglobinuria and hemoglobinuria have dark brown and at times almost black urine. The serum in patients with myoglobinuria is clear, whilst in severe hemoglobinuria the spun serum sample is pink, free hemoglobin is detected in the serum and the serum enzymes particularly the lactate dehydrogenase (LDH) are raised.

Treatment

The most important step is to restore circulating volume quickly and to attempt a forced diuresis with mannitol 250 mL intravenously or furosemide 250–500 mg intravenously. Hydration with forced diuresis should aim for a urine output over 100 mL/hour. Alkalinization of the urine with IV sodium bicarbonate in patients with acute hemolysis may prevent precipitation of the heme pigment within the renal tubules.

Once oliguric renal failure has set in, it is unwise to persist with repeated use of mannitol or furosemide. Treatment is then continued on the lines mentioned earlier.

Hypocalcemia and severe hyperkalemia are frequent features of rhabdomyolysis and acute hemolysis.

Hepatorenal Syndrome[26]

This syndrome is characterized by renal failure with normal tubular function in a patient with chronic liver disease. It usually afflicts patients with alcoholic cirrhosis. Renal failure is related to increased preglomerular vascular resistance which leads to a reduced GFR, with diversion of blood flow away from the renal cortex. This occurs even in the presence of a normal or increased cardiac output. Oliguria, a low urine sodium concentration, a highly concentrated urine, a progressively increasing azotemia and the frequent presence of hyponatremia are characteristically observed. Renal failure in cirrhotic patients is precipitated by hemorrhage or paracentesis or diuretic therapy or following a slight fall in the intravascular volume following diarrhea. It can occur without any fall in arterial blood pressure.

Prevention is of crucial importance, as treatment of the fully evolved hepatorenal syndrome is of no avail. Hypovolemia should be prevented in cirrhotic patients, and if it does occur should be promptly treated. Treatment of hepatic failure is on the usual lines. Infection should be recognized and treated; nephrotoxic drugs such as aminoglycosides and NSAIDs should be stopped. Mannitol has been tried to expand intravascular volume, but is of little use and may result in intracellular acidosis. High doses of furosemide fail to act. Dialysis does not help and may in fact precipitate hypotension, shock and GI bleeding. In a fully evolved hepatorenal syndrome death is inevitable, and is preceded by hypotension, hyponatremia and mounting azotemia.

Syndromes with Pulmonary and Renal Involvement

A quickly evolving renal failure requiring intensive care occasionally occurs in association with a pulmonary pathology. Thus, pulmonary vasculitides are often associated with progressive renal failure. A classic example is Wegener's granulomatosis[27] associated with an arteriolitis within the kidneys or associated with a rapidly progressive glomerulonephritis. Other pulmonary vasculitides with renal involvement include the Churg-Strauss syndrome, polyarteritis nodosa and small vessel vasculitis. Autoimmune disorders which involve the lung and produce renal failure include systemic lupus erythematosus (SLE) and the Goodpasture's syndrome. Sepsis from any cause can result in acute lung injury and produce progressive renal dysfunction and failure. In the tropics, fulminant falciparum infection is an important cause of multiple organ dysfunction, with the CNS, the lungs and the kidneys bearing the brunt of the infection. A few poisons including organophosphorus poisons, the herbicide Paraquat can produce pulmonary edema and anuria due to ATN.[28]

Diagnosis is dependent on a careful consideration of the clinical features, radiological examination of the lungs, special diagnostic tests, a lung biopsy and in some instances a kidney biopsy. The antineutrophilic cytoplasmic antibody (ANCA) test is positive in Wegener's granulomatosis and in small vessel vasculitis. The anti-nuclear factor (ANF) and anti-DNA tests are positive in SLE. Immunofluorescent studies of material from kidney biopsy show IgG-immune complex deposits in SLE. The diagnosis of Goodpasture's syndrome can be made by detection of antiglomerular basement membrane antibodies in the serum. A kidney biopsy shows the presence of linear immunofluorescence in the glomerular basement membrane in Goodpasture's syndrome.

Treatment in acutely ill patients is difficult if a diagnosis is not established. ARF should be treated on lines mentioned earlier. Severe hemoptysis and progressive renal failure in Goodpasture's syndrome are treated with corticosteroids (pulsed doses of methylprednisolone, 15–20 mg/kg per day for 3 days, are used initially in critically ill patients), cyclophosphamide (1.5 mg/kg body weight) and plasmapheresis.

Acute renal failure occurring in severe forms of Wegener's granulomatosis and other forms of severe vasculitides is treated with corticosteroids and cyclophosphamide, as in the Goodpasture's syndrome.

Pulsed doses of methylprednisolone are used for rapidly evolving renal failure in SLE.

In poisonings involving the lungs and the kidneys, gastric lavage with the use of charcoal adsorbents is of use. Charcoal hemoperfusion and continuous arteriovenous hemofiltration may be tried in suitable cases.

Acute Kidney Injury in the Transplant Patient[29,30]

(Also see Chapter Critical Care of the Transplant Patient)

Renal failure may occur early in a transplant recipient—sometimes within 10 days of the transplant or late (after 10 days of the transplant). AKI progressing to ARF occurring early can be due to—

- Hyperacute immune rejection of the graft.
- ATN of the transplant.
- Problems related to surgery, e.g. obstruction, leak or infection.

Cyclosporine toxicity particularly in those receiving high IV doses of the drug presents with hypertension and prerenal azotemia; this should be differentiated from the other causes of ARF listed above.

Acute kidney injury progressing to ARF occurring in the late period after transplant may be due to acute immune rejection, renal artery stenosis, ureteric obstruction, infections, cyclosporine toxicity or recurrence of the original renal disease. Tacrolimus, an immunosuppressant often used after a renal transplant can also be a cause of acute renal injury. Blood levels of immunosuppressants in particular, cyclosporine and tacrolimus should be measured at periodic intervals. High blood levels are associated with increased nephrotoxicity.

Acute rejection of the transplant is diagnosed by the presence of tenderness and swelling over the transplanted kidney, fever, a fall in the urine output and increasing azotemia. Imaging studies and nuclear scans help in distinguishing between the different causes of ARF in a transplant patient. At times, a kidney biopsy may be necessary to reach a definitive diagnosis.

Management is specialized, and should be in consultation with a nephrologist and the transplant surgeon.

Critical Illnesses in Patients on Chronic Dialysis

Patients on maintenance dialysis are often admitted to a critical care unit for an acute illness. The following problems are frequently encountered—

Acute Hypertension

This is often caused by an increased ingestion of salt and water by the patient in the interdialysis period. Acute left ventricular failure and hypertensive encephalopathy may occur. These complications mandate admission to an ICU and appropriate treatment. Pulmonary edema is generally unresponsive to diuretic therapy and requires removal of the extra fluid by dialysis.

Acute Hypotension and Arrhythmias

Acute hypotension, arrhythmias and even cardiac arrest may occur at times during or immediately after hemodialysis, necessitating emergency transfer to the ICU. If the patient is hypotensive, he should be given a volume load. A brady rhythm is countered by IV atropine 0.5–1 mg. Sudden atrial fibrillation with a very rapid ventricular rate needs IV amiodarone (see Chapter Tachyarrhythmias in the Intensive Care Unit).

Upper Gastrointestinal Bleeds

These are extremely common; antacids containing magnesium are best avoided and the dose of H_2 blockers may need to be adjusted.

Electrolyte Disturbances

Occasionally, a patient is admitted for acute hyperkalemia or acute acidosis (see Sections Fluid and Electrolyte Disturbances in the Critically Ill Patient). Hyperkalemia can pose a serious life-threatening emergency, requiring prompt recognition and treatment.

Acute Hypoglycemia

This is observed at times in patients with chronic renal failure. Sudden drowsiness, mental obtundation, abnormal behavior, unconsciousness, generalized seizures or even focal neurological signs should alert the clinician to this possibility. We have observed recurrence of hypoglycemia after the discontinuation of IV dextrose. An increased incidence of hypoglycemia observed in our patients may perhaps be related to the fact that glucose is not used in the dialysate fluid, and that glucose may be lost from the blood during dialysis with resultant hypoglycemia. This is more frequently observed in diabetics on insulin.

Use of Acetate in the Dialysis Fluid

Acetate is no longer used in the dialysate fluid. In early years when it was used, life-threatening clinical features during or immediately after hemodialysis were sometimes observed. The patient became increasingly breathless due to severe acidosis; hypotension, arrhythmias and cardiac instability were also observed. The problem now does not occur as acetate has been replaced by bicarbonate in the dialysate fluid.

Acute Infections

Patients in chronic renal failure on maintenance dialysis are immunosuppressed and are prone to infections (see Section The Immunocompromised Patient). Antibiotics have more prolonged therapeutic levels in these patients, and nephrotoxicity of antibiotics and other drugs is not of major importance in these patients.

Infection of the vascular access is common in patients on hemodialysis. Though pain, local erythema and tenderness are common over the access site, physical signs may be minimal. Systemic sepsis following bacteremia may originate from an apparently noninfected site of vascular access. This should always be kept in mind in patients with systemic

infection. Successful treatment of infection of the access site is generally possible with prolonged administration of antibiotics. Antibiotic regimes for such infections generally include vancomycin, since this drug is poorly dialysable and a single dose results in adequate serum levels for 7 days.

Thrombosis of a Vascular Access Site

Thrombosis of a vascular access site is another complication observed in critically ill patients who are on chronic dialysis. At times a prolonged period of hypotension results in thrombosis. At other times, infection at the site or venipunctures at or near the site leads to thrombosis. Venipunctures should always be done on the contralateral arm and avoided on the arm which has a graft or a surgically fashioned fistula. If an access site is found to be thrombosed (absent thrill or bruit), immediate surgical consultation is necessary. Thrombolytic therapy with IV urokinase may at times obviate the need for surgical treatment.

Fluid and Electrolyte Restriction in Patients on Chronic Hemodialysis

Fluids should be restricted from 700 mL to a maximum of 1 L. The degree of fluid restriction is dictated by the tendency of the patient to develop hypertension or pulmonary edema during the interdialysis period.

Nutritional Requirements

Once on dialysis, the patient is encouraged to eat well. Protein requirements are about 1 g/kg per day. In an average adult, total caloric requirement is about 2,000 calories per day or 35 kcal/kg per day.

CHAPTER 54

Critical Care in Acute Hepatic Failure

INTRODUCTION

Acute hepatic failure (AHF) is the clinical syndrome produced by sudden and severe liver cell dysfunction in a previously healthy individual. It is characterized chiefly by hepatic encephalopathy and coagulopathy. Severe loss of liver cell function sets into motion a downward spiraling multiorgan dysfunction syndrome that culminates fatally. Death can occur even when the liver has begun to recover. Hepatotropic viruses are the most common cause of acute hepatic failure in India and Southeast Asia, whereas in the West (the UK, the USA) the most common cause of AHF is acetaminophen toxicity. AHF has a high mortality and treatment is largely supportive. Liver transplantation is the only proven and definitive option for patients who are not likely to recover. AHF accounts for 5–6% of liver transplants. Many patients die before a suitable organ can be identified.

Critical care is mandatory in a patient with sudden severe liver cell dysfunction. Critical care is also often necessary in patients with chronic liver disease (as in cirrhosis), who develop acute encephalopathy or a severe gastrointestinal (GI) bleed, or a complicating infection, or who become oliguric or azotemic.

The term fulminant hepatic failure (FHF) and acute hepatic failure (AHF) are often used interchangeably. AHF is defined as the presence of severe hepatic dysfunction and the presence of encephalopathy (regardless of grade) and coagulopathy [internationalized normalized ratio (INR) >1.5] within 8 weeks of the appearance of symptoms in patients with no previous history of underlying liver disease. The above was the original definition of AHF proposed in 1970s by Trey and Davidson. Since then other different classifications have emerged (Box 1).[1-3]

Box 1: Various classifications of acute hepatic failure

- *Trey and Davidson*[1]—
  - Fulminant hepatic failure: development of HE and coagulopathy within 8 weeks of onset of symptoms
- *British classification*[3]—
  - Acute liver failure (includes only patients with encephalopathy)
  - Subclassification depending on the interval between jaundice and HE—
    - » Hyperacute liver failure: 0–7 days
    - » Acute liver failure: –28 days
    - » Subacute liver failure: 29–72 days
    - » Late-onset acute liver failure: 56–182 days
- French classification—
  - Acute hepatic failure: a rapidly developing impairment of liver function
  - Severe acute hepatic failure: prothrombin time or factor V concentration below 50% of normal with or without HE
- Subclassification—
  - Acute hepatic failure: HE within 2 weeks of onset of jaundice
  - Subfulminant hepatic failure: HE between 3 and 12 weeks of onset of jaundice

Abbreviation: HE, hepatic encephalopathy.

The interval between the appearance of hepatic encephalopathy (HE) and jaundice forms the basis of these classifications, allowing grouping of patients with regard to similar causes, clinical features and prognosis.

What was the basis of the British and French Classification formulated after that of Trey and Davidson? These subsequent

Box 2: Recommendation of International Association for the Study of the Liver (IASL) Subcommittee for the definition and classification of AHF and SHF

Nomenclature—
- AHF: occurrence of HE within 4 weeks after onset of symptoms
- SHF: development of ascites and/or HE from 5 weeks to 24 weeks after onset of symptoms

Diagnostic criteria of liver failure—
- AHF: Encephalopathy
- SHF: Encephalopathy and/or progressive ascites

Maximum interval between onset of icterus and features of liver failure—
- AHF <4 weeks
- SHF >4–24 weeks

Subclassification—
- Etiological to indicate specific cause of AHF
- Temporal to indicate the rapidity of encephalopathy—
  - Hyperacute—Encephalopathy within 10 days of icterus.
  - Fulminant—Encephalopathy between 10 days and 30 days of the onset of jaundice
- Not otherwise specified

Abbreviations: AHF, acute hepatic failure; SHF, subacute hepatic failure; HE, hepatic encephalopathy.

classifications were based on the observation that in the West patients with AHF who developed encephalopathy within a week to 10 days of the onset of jaundice had significantly higher survival rates than similar patients who had encephalopathy after 1 week or 10 days of the onset of jaundice. This observation influenced the selection of patients with AHF for liver transplantation.[4]

In contrast to this observation, an important study in India[5,6] showed that in India patients with AHF presented with encephalopathy within 3 weeks of the onset of jaundice and 4 weeks after the onset of symptoms and that the rapidity of the onset of the encephalopathy did not influence survival.[7] In this study when liver failure occurred more than 4 weeks after the onset of an acute hepatic illness, the presentation was that of progressive ascites; encephalopathy was an extremely rare presenting feature at this stage. These patients had subacute hepatic failure (SHF), with the majority dying within a period of 6 months. Similar patients have been described in the West as having late onset hepatic failure (LOHF). To resolve geographical differences with regards to definition, sub-classification, the International Association for the Study of the Liver (IASL) has recommended a new set of definitions and subclassification of AHF and SHF (Box 2).

ETIOLOGY

World wide, viral hepatitis is the most common cause of AHF. Viruses A, B, C, D, E, can each produce fulminant hepatitis. The proportion of fulminant cases (AHF) due to each of the major viruses A, B, C, E varies with the geographical area under study. All published reports from the Indian subcontinent have identified hepatitis viruses as the etiological agent in 95–100% of patients with AHF.[5,8,9] The same holds true for all Eastern countries, in particular for developing countries. Patients with AHF in India and Eastern countries therefore constitute by and large a homogenous group, since other etiological factors (i.e. nonviral factors) are infrequently observed. This is in contrast to Western countries where patients with AHF form a more heterogeneous group, since besides hepatic viruses, other etiological factors are also observed. The reason for this difference is chiefly the marked endemicity of hepatic viruses in the East. Hepatitis A and E viruses are endemic in India and other Eastern countries. There are about 40 million Hepatitis B virus (HBV) and 10 million Hepatitis C virus (HCV) carriers in India.[10,11]

The most common hepatitis virus causing AHF in the Indian subcontinent and in the developing eastern countries and Africa is Hepatitis E, the virus being responsible for 23–41% of patients with AHF. Hepatitis B is the next most important cause of AHF in India, being responsible for 11–27% of such cases.[12] Hepatitis E virus is very rare in the West but Hepatitis B has been incriminated as the most important hepatic virus causing AHF in the West and in Australia.[13,14] Hepatitis A virus is responsible for 2–8% of patients with AHF both in the East and West.

Hepatitis C virus is reported to cause AHF in a little over 4% of patients in India.[5] However, reports from Japan and Taiwan have implicated Hepatitis C as the etiological agent in 50% of patients with non-A non-B AHF.

Hepatic B can cause AHF through several mechanisms—
- Primary hepatitis B infection.
- Reactivation of hepatitis B in patients with chronic hepatitis B virus infection.
- Superinfection with hepatitis D virus or other hepatic viruses.
- Infection with hepatitis B mutants.
- Occult or cryptic hepatitis B infection.

Primary hepatitis B virus infection can be missed because a number of patients have negative serum hepatitis B surface antigen (HBsAg) and serum HBV-deoxyribonucleic acid (DNA). Acute HBV infection is diagnosed notwithstanding the above by the presence of IgM antibodies to hepatitis B core antigen. Absence or low level of HBsAg and HBV-DNA in primary hepatitis B infection is associated with a better prognosis and a lower rate of recurrence after orthotropic liver transplantation.
- *AHF after reactivation of hepatitis B virus* is chiefly seen in immunocompromised patients. This form of the disease manifests in a subfulminant form and has a poor prognosis.
- *Coinfection with HBV and hepatitis D virus (HDV) or superinfection by HDV* can also lead to AHF. AHF has been also observed in 2.5–6% patients infected with virus D. The diagnosis of HDV is made by the presence of HDV antigen, IgM antibodies to HDV and the detection of HDV-ribonucleic acid (RNA).

Box 3: Important drugs causing AHF

- Isoniazid
- Valproate
- Halothane
- Phenytoin
- Sulfonamides
- Propylthiouracil
- Amiodarone
- Disulfiram
- Dapsone
- Bromfenac
- Troglitazone
- Zidovudine
- Lamivudine
- Lamotrigine
- Gatifloxacin
- Methotrexate

Abbreviation: AHF, acute hepatic failure.

Box 4: Causes of AHF

- Viral Hepatitides—Hepatitis A, B, C, D, E, G—
  Other viruses—
  - Human herpesvirus
  - Cytomegalovirus
  - Epstein-Barr virus
  - Dengue virus
  - Herpes simplex virus
  - Varicella-zoster virus
  - Paramyxovirus
  - Parvovirus B19
  - Adenovirus
  - Yellow fever virus
- Drugs (see Box 3)
- Other infections—
  - Leptospiral
  - *P. falciparum*
  - Disseminated tuberculosis
- Vascular—
  - Ischemic
  - Veno-occlusive disease
  - Budd-Chiari syndrome
- Malignancy—
  - Malignant infiltration
  - Non-Hodgkin's lymphomas
- Miscellaneous—
  - Wilson's disease
  - Autoimmune hepatitis
  - Acute fatty liver of pregnancy
  - Reye's syndrome

- *Hepatitis B virus mutants* A number of patients with AHF show no positive serological markers. Mutations in the hepatitis B core region could result in the production of Hepatitis Bc antibodies that may not be detected by the usual enzyme-linked immunosorbent assay (ELISA) kits supplied today.
- *Occult or Cryptic Hepatitis B virus infection* These patients with AHF though negative for HBsAg and anti HBc IgM, have HBV-DNA detectable by polymerase chain reaction (PCR) studies either in the serum or liver tissues.[15-17] The incidence of occult or cryptic infection is low, except in Japan where the reported incidence is as high as 50%.[15]

Other viruses in rare instances have been reported to cause fatal hepatic necrosis, particularly in immunocompromised patients. The more commonly implicated viruses are cytomegalovirus (CMV), human herpes virus- 6 (HHV-6), Epstein-Barr virus (EBV), herpes simplex virus (HSV), hepatitis G virus.[18,19]

In Africa and other endemic tropical countries the yellow fever virus is to be always kept in mind as a cause of AHF.

In India and other tropical countries, AHF can be due to leptospiral infection and rarely due to fulminant *Plasmodium falciparum* infection as well.

After viral infections, idiosyncratic drug reactions are the most common cause of AHF in India. Drug induced liver damage is also a significant cause of death in patients with AHF in Western countries. The most frequently incriminated drugs in India are isoniazid, in particular isoniazid administered in conjunction with rifamipicin, antibiotics, nonsteroidal anti-inflammatory drugs, antidepressants, herbal or dietary supplements and immunomodulating agents (Box 3).[20] Dose, duration, hepatic metabolism of the drug may all be important in the development of drug-induced liver cell injury.

Poisonings causing AHF are rare in our country. In contrast paracetamol poisoning (with suicidal intent) is the most frequent and most important cause of AHF in the West—particularly in the United Kingdom (60%), USA and Europe (15–20%). Acetaminophen overdose accounts for 30–35% of AHF in the United States. Besides the use of the drug with suicidal intent, overdose of the drug over several days with intent to relieve pain or high fever can also cause poisoning resulting in AHF. Doses not considered toxic (<4g/day in adult, <8 mg/day in infants), might cause hepatotoxicity if other comorbid factors exist, such as alcohol ingestion, fasting, malnutrition, underlying chronic hepatic disease. Hepatic toxicity in paracetamol poisoning reaches a maximum 1 or 2 days after the overdose and the rise in liver enzymes together with a rise in INR reach their peak on the 3rd day. A continued rise in INR after the 3rd day is associated with 90% mortality. The peculiarity in liver dysfunction observed with acetaminophen poisoning is the comparatively very modest rise in bilirubin in contrast to the very high level of the liver enzymes and the high INR (Box 4).

In India, phosphorous poisoning in children due to the ingestion of fire crackers containing phosphorus, and a combination of phosphorus and arsenic poisoning due to ingestion of rat poison (suicidal attempt) are rare but important causes. Ingestion of wild poisonous mushrooms is one other rare cause of AHF. Industrial poisons and solvents can cause AHF, but these are rarely encountered.

In an intensive care setting progressive liver cell failure is at times seen in patients with cardiac disease and a very low cardiac output. This is due to ischemia to the liver perhaps combined with severe hepatic venous congestion.

Severe shock from any cause can also result in ischemic liver injury and failure. The prognosis remains good if the primary cause of shock can be corrected. The association of severe sepsis causing shock with AHF worsens the prognosis.

Acute fatty infiltration of the liver in full term pregnant women and eclampsia may also present with AHF. Acute Wilson's disease should always be excluded in patients less than 40 years old, particularly in the presence of hemolysis and when all viral markers are negative. Acute autoimmune hepatitis can also cause FHF and the diagnosis may be impossibly difficult if auto-antibodies are negative.

Budd-Chiari syndrome, veno-occlusive disease are other rare causes of AHF; they carry a dismal prognosis. Other causes of AHF are non-Hodgkin's lymphoma, involving the liver and extensive malignant metastasis involving the liver. Reye's syndrome is only rarely observed in the pediatric population since the use of aspirin has been curtailed in children. Finally, we have seen AHF rarely in patients with disseminated hematogenous tuberculosis massively involving the liver.

Miscellaneous cardiovascular, vascular, metabolic and other disorders stated above are responsible for 2–10% of patients with AHF.

In 10–12% of patients with AHF no cause can be detected in spite of a meticulous search. These are termed cryptogenic AHF. The possibility that AHF in these patients could be due to undetected Hepatitis B mutants, to occult or cryptic Hepatitis B infection, or to new hepatitis viruses as yet undiscovered, must be kept in mind.

CLINICAL FEATURES

The illness typically starts with nonspecific symptoms such as malaise, nausea, vomiting in a previously healthy individual. Abdominal pain may occur particularly in children; it may be acute and first felt in the right iliac fossa. Occasionally an appendectomy is performed with disastrous postoperative sequelae. These nonspecific symptoms are quickly followed by jaundice, rapid onset of an altered mental state that can progress to increasing obtundation and coma. Jaundice, an altered mental state and a coagulopathy characterized by a prolonged prothrombin time or an increased INR are the hallmarks of AHF. Fetor hepaticus is generally present. The liver to start with is palpably enlarged and tender but as the disease progresses it shrinks so that it is no longer palpable. The liver dullness on percussion is also progressively reduced. The constellation of the above mentioned clinical features are distinct from those observed in patients with chronic hepatic insufficiency regardless of the etiology.

Important laboratory features include a rise in serum bilirubin, high levels of liver enzymes, a lowered blood sugar, respiratory alkalosis and/or metabolic acidosis.

If the patient recovers the serum bilirubin starts to fall and the INR gradually normalizes. Clinically, the state of altered consciousness improves. If the disease progresses, the bilirubin level continues to rise and the INR also continues to increase. The degree of rise in liver enzymes is not a guide to prognosis, nor does a fall in liver enzymes necessarily indicate recovery. In fact the liver enzymes often fall with worsening disease, reflecting severe hepatic necrosis, with few liver cells alive to produce enzymes.

The course of AHF is beset with numerous complications. These include cerebral edema, renal failure, pancreatitis, acute respiratory distress syndrome (ARDS), cardiorespiratory failure and a coagulopathy that can lead to hemorrhagic complications. Supervening sepsis is frequently observed. The overall feature is that of multiple organ failure, not a single organ system being spared. Death can occur from any one of these complications but is most frequently due to cerebral edema or to supervening infection.

The following section to start with describes hepatic encephalopathy which is the hallmark of AHF. It then goes on to briefly discuss the other important complications observed in AHF.

Hepatic Encephalopathy

Encephalopathy is an essential clinical feature of AHF, distinguishing AHF from acute severe hepatitis. The time of onset of encephalopathy after the appearance of jaundice distinguishes AHF from subacute fulminant hepatic failure (SAHF).

The neuropsychiatric manifestations that characterize encephalopathy are often sudden in onset and rarely may precede the occurrence of clinical jaundice. Excitability, delusions, nightmares, drowsiness alternating with a markedly hyperkinetic state may be observed. At times, the excitability can be manic in nature. Spontaneous seizures may occur. The slightest stimulation (as an attempt to examine the patient) may provoke shouting and violent behavior. Flapping tremors may be observed to start with, but disappear with increasing obtundation. If the disease progresses, deep coma eventually results, the patient being unresponsive to all painful stimuli.

Disturbances in the conscious state should be charted and the encephalopathy graded as follow—

- Grade 1⟶Confused, altered mood or behavior with psychometric deficit.
- Grade 2⟶Drowsy, increasing behavioral changes.
- Grade 3⟶Stuporose, confused, incoherent but still obeying simple commands.
- Grade 4⟶Coma—cannot be aroused.

The prognosis in patients with Grade 1 and Grade 2 encephalopathy is good, whereas the prognosis in Grade 3 and Grade 4 encephalopathy is very poor.

The pathophysiology of hepatic encephalopathy is unclear and is probably multifactorial. Elevated ammonia

levels and increased ammonia within the brain[21,22] play an important role. Additional factors leading to encephalopathy include elevated levels of short chain fatty acids, false neurotransmitters, benzodiazepines and γ-aminobutyric acid. The electroencephalography (EEG) typically shows high amplitude wave forms at 5–7 cycles per second pointing to diffuse slowing of cortical activity. Subclinical seizure activity is often present, emphasizing the importance of EEG monitoring.

Seizure activity has been related to an excessive build-up of glutamine within the central nervous system (CNS). Glutamine synthesized within the cells is transported into the mitochondria where it is metabolized by glutaminase to glutamine and ammonia. The progressive increase in ammonia within the mitochondria leads to an increase in their permeability and to oxidative damage of mitochondrial constituents. Glutamine is therefore considered to be the "Trojan Horse" that allows a build-up of ammonia within the cell mitochondria.[23] The glutamine derived within the mitochondria causes swelling of astrocytes leading to disturbed function.

Cerebral Edema

Cerebral edema is often the most common immediate cause of death in AHF. It is caused by several possible contributing factors.[24,25] These include—

- Cerebral hyperemia.
- Disruption of the blood brain barrier resulting in vasogenic edema.
- Cytotoxic effects of ammonia, glutamine and other amino acids.
- The effects of proinflammatory cytokines.
- Loss of autoregulation of cerebral blood flow, related to a dysfunction of the sodium potassium ATPase pump.

Patients with AHF often develop relative or absolute cerebral hyperemia because perfusion is not well matched to the reduced cerebral metabolic rate. Indicators of the above are either a decrease in the transcranial oxygen content difference (arterial oxygen content—jugular bulb oxygen content) to less than 4 mL/dL or an increase in the systolic blood flow velocity in the middle cerebral artery. Serial transcranial Doppler ultrasonographic recordings of cerebral blood flow velocity help detect hyperperfusion or hypoperfusion which suggest impaired cerebral autoregulation.[26] Cerebral ischemia and neurological damage can occur if the cerebral perfusion pressure (mean systemic arterial pressure–intracranial pressure) is not maintained above 40–50 mm Hg.

Increasing cerebral edema leads to brainstem dysfunction. The clinical features of cerebral edema and brainstem dysfunction include deepening disturbance in conscious state, systolic hypertension, hyperventilation, myoclonic jerks, convulsions, dysconjugate eye movements, skew deviation of eyes and decerebrate rigidity. Decerebrate posturing can occur spontaneously or on stimulation. Plantars are generally flexor but an extensor response may occur. Depressed brainstem function ultimately leads to absent dolls eye movements, and absent vestibulo-ocular reflexes. The pupils are dilated and react sluggishly. A loss of pupillary reflex is terminal. Ultimately increasing edema leads to brainstem or uncal herniation and death.

Coagulopathy

The coagulopathy in AHF is due to inadequate production of coagulation factors. There is a decrease in levels of factors II, IV, VII, IX and X with a prolongation of prothrombin time (an increase in INR) and activated partial thromboplastin time (APTT). An imbalance between procoagulant and anticoagulant factors can lead to excessive thrombosis in the smaller vessels of various organ systems or to the picture of disseminated intravascular coagulopathy (DIC). AHF also often causes enhanced fibrinolytic activity. The combination of deficient clotting factors and enhanced fibrinolytic activity leads to bleeding—from injection sites, from the GI tract, from body orifices and into organ systems. Bleeding is often worsened by the frequent presence of thrombocytopenia (<50,000/mm^3) and by impaired platelet function.

Hypoglycemia is common with worsening liver cell function. Drowsiness and other features of hypoglycemia if unrecognized are mistaken for increasing severity of hepatic encephalopathy. Hypoglycemia is due to depletion of glycogen stores and impaired neoglucogenesis; it may be refractory to the infusion of intravenous dextrose.

Other metabolic complications include metabolic acidosis, hyponatremia, hypokalemia, hypophosphatemia, and lactic acid acidosis.

Renal Failure

Acute renal failure is observed in 30–70% of patients. It is multifactorial in etiology—hypovolemia, sepsis, DIC and the use of nephrotoxic drugs are all contributory factors.

Cardiorespiratory Failure

Persistent hypotension, arrhythmias point to cardiac dysfunction, while increasing tachypnea with a partial pressure of oxygen in the blood (PaO_2) less than 60 mm Hg point to respiratory failure. The occurrence of ARDS is an ominous complication.

Gastrointestinal dysfunction includes gastric dilatation, ileus, colonic distension, GI bleed. Acute hemorrhagic necrotizing pancreatitis is a well known complication that hastens the end.

Sepsis

Supervening nosocomial infection is of frequent occurrence in patients with Grade 3, Grade 4 encephalopathy. Infections can be due to Gram-negative or Gram-positive organisms or due to fungal infections. Infections hasten the end and add to the severity of the multiorgan dysfunction syndrome. In one prospective study of 50 patients, 80% had culture positive infection and in half of the remaining patients, infection was suspected but cultures were negative.[27]

Box 5: Diagnostic evaluation of AHF

- History, including history of drugs and possible poisons ingested; clinical examination
- Hematological—Hb, platelet count, CBC, blood group, bleeding time, prothrombin time, quantitative estimation of clotting factors
- Biochemical—Blood glucose, serum bilirubin, AST, ALT, serum proteins, blood urea, serum phosphates, serum electrolytes, serum calcium, serum magnesium, serum amylase
- Microbiology—Hepatitis B antigen and IgM anticore antibody, antiserum delta, hepatitis A (IgM) antibody, Hepatitis C (IgM) antibody, Hepatitis C DNA, blood, sputum, urine cultures; smear for malarial parasites, IgM for leptospiral antigen
- Arterial Blood Gas Analysis—Arterial pH and arterial blood gas measurements
- Others—ECG, X-ray of chest and abdomen, ultrasound of the abdomen, EEG
- PCR tests for other hepatitis producing viruses—notably CMV, EBV, herpes group of viruses
- A toxicology screen, e.g. acetaminophen blood levels
- In special cases—autoimmune markers—ANA, ASMA
- Serum ceruloplasmin levels, if Wilson's disease is suspected

Abbreviations: CBC, complete blood count; AST, aspartate aminotransferase; ALT, alanine aminotransferase; DNA, deoxyribonucleic acid; ECG, electrocardiography; EEG, electroencephalography; PCR, polymerase chain reaction; CMV, cytomegalovirus; EBV, epstein-barr virus; ANA, antinuclear antibodies; ASMA, anti-smooth muscle antibody.

The syndrome of AHF is thus characterized by severe progressive multiple organ dysfunction. Amazingly, if recovery of liver function occurs, complete recovery ensues.

INVESTIGATIONS (BOX 5)

The grading of encephalopathy, and intake-output charts should be carefully maintained.

Biochemical investigations should include serum bilirubin, serum transaminases [Aspartate aminotransferase (AST), Alanine aminotransferase (ALT)], serum alkaline phosphatase, and serum proteins with the albumin:globulin ratio. The serum transaminases though high to start with, fall with worsening liver function, as there is less viable liver tissue left. The prothrombin time (PT) is extremely useful both for gauging the degree of liver cell dysfunction, and as a prognostic guide. A PT more than double the control carries a bad prognosis. The blood ammonia level is frequently raised in HE and coma. Serum electrolytes, Ca, P, Mg, urea, creatinine, glucose and serum amylase should also be done; biochemical tests should be repeated as and when necessary. Arterial pH and blood gas estimation is important.

Hematological investigations include hemoglobin estimation, blood and platelet count, and blood group. Relevant tests for clotting factor disturbances and DIC are also done.

Microbiological tests include viral markers for hepatitis A, B, C, D and E. These include tests for hepatitis B surface antigen, IgM anticore antibody, serum antidelta, hepatitis A IgM antibody, hepatitis C IgM antibody, hepatitis D IgM antibody and hepatitis E IgM antibody. Hepatitis C antibodies may be absent as they may take some weeks to be detected. Hepatitis C RNA by the PCR should therefore be done. It has already been pointed out that in fulminant hepatitis due to virus B infection the hepatitis B surface antigen may be cleared and therefore negative. The IgM antibody to the core antigen should always be done to prove the diagnosis. Serum HBV DNA is usually negative. Rapid viral clearance indicates a good immune response and perhaps a better prognosis. The possibility of Hepatitis B mutants or cryptic Hepatitis B infection should be kept in mind.

In tropical countries, a smear for *P. falciparum* infection, and serology for leptospiral infection should always be done.

Where the etiology remains unclear, serology and PCR tests for other hepatitis producing viruses (listed under etiology) should be performed—notably cytomegalovirus (CMV), EBV, herpes group of viruses. Few hospitals in our country have facilities and expertise to perform these tests.

A toxicology screen needs to be done in suspected poisoning; this includes an acetaminophen blood level if overdosage with the drug is thought possible.

When the usual viral markers for hepatitis are negative, autoimmune markers—antinuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA) should be done. Serum ceruloplasmin levels become necessary if Wilson's disease is being considered (e.g. in patients less than 40 years without any explanation for AHF).

Blood cultures are necessary, particularly if secondary infection is suspected. Similarly, cultures of urine, sputum or other body secretions should be done and repeated as and when necessary. Electrocardiography (ECG), X-ray chest, ultrasonography (USG) of the abdomen to monitor liver size, are necessary. Imaging studies of the head are generally of not much use, other than to detect an intracranial bleed. Cerebral edema is not necessarily detected on computed tomography (CT) or magnetic resonance imaging (MRI).

If available, a portable EEG is useful to gauge the degree of hepatic encephalopathy. Increasing unconsciousness is characterized by increasing amplitude and decreasing frequency of the EEG tracings. Triphasic waves are observed in deep coma; these waves are only observed in patients over 20 years of age, and are of ominous significance. Decreasing amplitude of the EEG tracing is observed in terminal cases; finally there is a total absence of rhythmic activity.

DIAGNOSIS

Diagnosis is generally easy. An early mistake is to suspect an acute abdomen when the onset is characterized by nonspecific symptoms, fever, vomiting and acute abdominal pain. Even when icterus is absent these patients invariably demonstrate a rise in the serum transaminases.

Neuropsychiatric manifestations of HE occasionally may precede a rise in serum bilirubin. We have witnessed a diagnosis of acute mania (for which psychotropic drugs were administered) in a patient with hepatic encephalopathy who died from AHF due to virus A infection within 4 days of the illness.

In areas endemic to *P. falciparum* infection, particularly when the patient has high fever, blood smear examination for malarial parasites should always be done.

In patients with severe muscle pain, conjunctival injection and urinary findings suggestive of glomerulonephritis, leptospiral infection should be kept in mind. The dengue virus is also reported occasionally to produce extensive hepatic necrosis. The blood tests are positive for both dengue antigen and IgM antibodies to the virus.

Immunocomprised patients are susceptible to uncommon viral infections (cytomegalovirus, herpes virus in particular) that may cause fulminant hepatitis.

MANAGEMENT

Intensive care is mandatory in AHF. It is best to admit the patient to a good intensive care unit (ICU) as soon as definitive neuropsychiatric features become evident. It is wrong to avail of intensive care facilities only when the patient is comatose, as critical care in the early phases may prevent the evolution into deep coma in some patients with severe hepatic necrosis. Even though the survival rate in a good ICU setting has improved, the mortality is still forbiddingly high. Once in ICU the physicians should get in touch with a liver transplant unit for a possible hepatic transplant. In fact ideally, any patient with acute liver disease should be treated in an ICU within a liver transplant center or transferred to an ICU in a liver transplant center as quickly as possible. This is well-nigh impossible in Mumbai as there is no transplant unit that can take on this responsibility. Transfer to Delhi and Chennai (where liver transplant centers are present) is difficult for very ill patients. Also there is a great scarcity of cadaver liver transplants in India, rendering successful liver transplantation in AHF in our country (outside cities with good transplant centers) a remote possibility.

A short summary of the management protocol is given in Box 6.

Box 6: Management of acute hepatic failure

- Overall critical care—
  - Nasogastric tube
  - Central venous line for administration of IV fluids and monitoring of CVP
  - Self-retaining catheter for monitoring of urine output
  - Monitoring of temperature, pulse, BP, CVP, ECG, intake-output charts
- Maintain fluid, electrolyte and acid-base balance
- Management of hepatic encephalopathy—
  - Avoid sedation or diuretics
  - Stop protein feeds
  - Amoxycillin 500 mg qds + metronidazole 400 mg thrice daily given through nasogastric tube
  - Lactulose 10–30 mL 8 hourly orally
  - Daily large bowel wash or enema
- Reduce cerebral edema with IV mannitol
- Treat hypoglycemia using continuous IV infusion of 10–20% dextrose
- Management of bleeding tendencies—
  - Transfusion of packed RBCs, fresh frozen plasma, cryoprecipitate, Vitamin K, specific deficient clotting factors as required
- Maintenance of nutrition—stop or sharply reduce proteins
- Give carbohydrates, strained vegetable soup, IV 20% dextrose, Vitamins B and C and multivitamins
- Correct hypoalbuminemia with IV salt-free albumin infusions
- Support other organ systems
- Control of infection
- Diagnose and treat complications
- Consider (when facilities available) a liver transplant in selected cases

Abbreviations: IV, intravenous; BP, blood pressure; ECG, electrocardiography; CVP, central venous pressure.

General Measures

The patient is barrier-nursed in the ICU; special care, with nurses and attendants using masks and gowns, is necessary. Patients with fulminant virus B hepatitis should be nursed by staff vaccinated against the HBV.

In a drowsy patient, or in a patient with a disturbed sensorium, the following general measures are promptly implemented—

- A nasogastric tube is passed and the stomach deflated. Vigorous suction of the nasogastric tube is avoided; the stomach is best kept empty by gravity drainage.
- A self-retaining catheter is introduced into the bladder to allow an accurate intake-output chart to be maintained.
- A central venous line is introduced for administration of IV fluids, and for monitoring central venous pressure (CVP). The earlier this line is inserted, the safer it is. Even in comatose bleeding patients, a central line is mandatory, despite the risk of bleeding that the procedure may entail.

Monitoring of the Patient

Clinical monitoring should include a chart of the grade of disturbed consciousness, the presence and degree of flapping tremors, the presence of fetor hepaticus, the liver size as obtained by palpation, as also by percussion of liver dullness in the thorax, the presence of free fluid within the abdomen, the degree of icterus, and the physical examination of the various organ systems of the body. Special emphasis should be laid on close monitoring of the respiratory rate, heart rate and rhythm, blood pressure, CVP, ECG, temperature and the intake-output chart.

Hepatic Encephalopathy

Sedation is avoided as far as possible; even the mildest sedation can appreciably increase the depth of coma. The patient however should be nursed in very quiet surroundings. Protein feeds are totally stopped. Metronidazole 400 mg 8 hourly is given orally through the nasogastric tube; amoxycillin 500 mg qds may also be given. Neomycin is best avoided because of possible nephrotoxic and ototoxic effects. It should be noted that metronidazole can be neurotoxic in hepatic failure. Rifaximin (800–1200 mg/day) is also effective against ammonia producing gut flora. It is however expensive and has not been recommended for routine use.

Lactulose 10–30 mL 8 hourly is administered orally, and the dose so adjusted as to allow 2–4 semisolid stools/day. Lactulose reaches the cecum unchanged, where it is broken down by bacteria to fatty acids. The drop in fecal pH promotes the growth of lactose fermenting organisms, but suppresses the growth of ammonia-forming bacteria. Lactulose may also detoxify short-chain fatty acids produced in the presence of blood and proteins within the gut. It significantly increases the colonic output of bacterial mass and soluble nitrogen; the latter thus becomes unavailable for absorption as ammonia.

Lactulose may cause significant diarrhea leading to hypernatremia and to volume depletion. The latter is to be avoided at all costs, as it compromises circulation and adversely affects renal function. Lactulose by enema (300 g in 500 mL normal saline) every 6 hours is given in patients with AHF who cannot tolerate oral or nasogastric administration.

A large bowel (colonic) wash or enema is given daily to evacuate the large bowel of nitrogenous products. In patients who have a GI bleed, lost blood should be promptly replaced. Lactulose and/or a mild purgative helps to hurry intestinal contents, and a bowel wash removes nitrogenous products released from the blood within the colon.

Furosemide should be avoided, and fluid and electrolyte balance should be well maintained; if disturbed, it should be quickly restored to normal. Endogenous benzodiazepine-like substances have been recovered from the cerebrospinal fluid (CSF) in patients with AHF. Flumazenil is a benzodiazepine receptor antagonist that has been used in a dose of 15–20 mg to provide temporary relief in patients with HE.

Exchange transfusion, charcoal hemoperfusion, plasmapheresis have all been tried to reduce serum ammonia levels but none of these procedures have been shown to increase survival.

Cerebral Edema

Cerebral edema combined with intracranial hypertension form the commonest cause of death in AHF when the intracranial pressure (ICP) is above 30 mm Hg. The optimal management of cerebral edema necessitates the maintenance of a balance between the mean arterial pressure and the ICP to preserve adequate cerebral perfusion. ICP monitoring may help in diagnosis and management of intracranial hypertension, especially in Grade 3 and Grade 4 encephalopathy. We have never used ICP monitoring; its use has not been shown to decrease mortality.[28] If monitored the ICP should be kept below 20 mm Hg and the cerebral perfusion pressure over 50 mm Hg. It is important to note that an arterial ammonia level over 200 ug/dL predicts brain herniation.[29]

Box 7: Preventive and therapeutic interventions for patients with cerebral edema and intracranial hypertension

- General measures—
  - Head of bed elevation to 30° angle, and maintain patient's neck in neutral position
  - Endotracheal intubation for grade III or IV hepatic encephalopathy
  - Minimize tactile and tracheal stimulation, including airway suctioning
  - Avoid hypovolemia and hypervolemia
  - Avoid hypertension
  - Avoid hypercapnia and hypoxemia
  - Monitor and maintain ICP <15 mm Hg
  - Maintain CPP >50 mm Hg
  - Monitor and maintain $SvjO_2$ between 55% and 85%
  - Use serial transcranial Doppler monitoring to titrate therapy
- Management of intracranial hypertension—
  - Mannitol boluses, 0.5–1.0 g/kg body weight or the use of hypertonic saline
  - Hyperventilation titrated to a $PaCO_2$ of 28–30 mm Hg
  - Induce moderate hypothermia to 32–33°C
  - Achieve serum sodium levels of 145–155 mEq/L
  - Induce coma with propofol or pentobarbital titrated to burst suppression of 5–10 cycles/sec
  - CVVH for oliguria and hyperosmolarity (>310 mOsm/L)

Abbreviations: CPP, cerebral perfusion pressure; CVVH, continuous veno-venous hemofiltration; ICP, intracranial pressure; $SvjO_2$, jugular bulb oxygen saturation.

Monitoring jugular bulb oxygen saturation through a jugular bulb venous catheter is also of help. A jugular bulb venous oxygen saturation less than 55% denotes cerebral ischemia; a saturation more than 85% generally denotes cerebral hyperemia. Intervention to prevent or counter intracranial hypertension can be made with the help of the above measurements.

Current recommendations to counter or prevent cerebral edema are briefly given below (Box 7)—

- Maintain the bed at a 30º angle with the patient's head in the midline.
- Episodes of increased intracranial hypertension should be countered by an IV bolus of 0.5–1 mL/kg mannitol. Between 100–150 mL of mannitol may be repeated twice in the day, though it is best not to exceed 400 mL. Decerebrate posturing, disturbances in ocular gaze, deepening of the unconscious state, systolic hypertension occurring singly or in combination are manifestations of increased intracranial hypertension. Corticosteroids have not been shown to be useful in reducing cerebral edema in patients with AHF.

- Coughing, prolonged suction through the endotracheal tube or tracheostomy should be avoided as these are associated with a rise in ICP.
- Hyperventilation so as to keep the partial pressure of carbon dioxide in the blood ($PaCO_2$) at 28–30 mm Hg can reduce ICP but the effect of this wears off in 24–48 hours.
- Excessive cerebral vasoconstriction can reduce perfusion. This can be detected by serial transcranial Doppler studies. Induction of mild hypothermia (core temp 32–33°C) induced by surface cooling or by the use of a special endovascular catheter has been shown to reduce ICP and cerebral blood flow and improve cerebral perfusion pressure in AHF.[30] Care must be taken to avoid shivering during induced hypothermia.
- There are reports that parenteral sodium pentothal or IV propofol can further reduce both cerebral blood and cerebral metabolic rate in refractory patients. We have never attempted this procedure as we are unconvinced whether the benefits outweigh the risk involved and also whether this intervention improves the final outcome.
- Hypertonic saline has been tried to induce hypernatremia with a view to countering cerebral edema (serum Na 145–155 mEq/L). There are many critical care units in the West that today prefer hypertonic saline to mannitol for reducing an increased ICP. If used, serum Na should be carefully monitored to prevent an acute rise in the serum Na. Indomethacin IV bolus has been reported in a few instances to reduce cerebral blood flow; this is by and large an unproven therapy and may perhaps do more harm than good.

Coagulopathy

Bleeding should be countered by titrated infusions of fresh frozen plasma (FFP) and by the infusion of packed red blood cells (RBCs). Administration of FFP does not improve survival; repeated infusions can cause volume overload with the added risk of transfusion induced lung injury. Massive bleeds are perhaps best countered by the infusion of recombinant factor VII. A worsening of coagulation parameters always denotes worsening liver function. Prevention of bleeding to a degree is possible by—

- Avoiding local trauma, including avoidable needle punctures.
- Avoiding a tracheostomy.
- Draining stomach contents by gravity rather than by suction.
- Avoiding corticosteroids.
- Using oral sucralfate, proton pump inhibitors or H_2 receptor antagonists intravenously prophylactically in the prevention and treatment of GI bleeding.

Renal Failure

The presence of renal failure in patients with AHF denotes a grave prognosis. Renal failure due to acute tubular necrosis occurs in close to 70% of patients with AHF. The mechanisms responsible for renal failure include—

- Renal hypoperfusion due to hypovolemia, hypotension.
- Evolution of a systemic inflammatory response syndrome.
- Evolution of the hepatorenal syndrome.
- Toxic effects of the etiological agents e.g. acetoaminophen, phosphorus, poisonous mushrooms and toxic effects of nephrotoxic drugs or radiographic contract agents.

Careful monitoring of urine output vis-à-vis fluid intake, serum creatinine, urinary Na concentration is important. Diuretics or renal dose of dopamine are of no use in prevention or treatment of renal failure. Continuous venovenous hemofiltration (CVVH) may be necessary to preserve fluid electrolyte balance. CVVH is preferred to hemodialysis as it avoids rapid fluid shifts and sudden changes in ICP that tend to occur with intermittent hemodialysis.

Maintenance of Fluid and Electrolyte Balance

Fluid and electrolyte balance should be assiduously maintained. Serum sodium levels tend to be low in acute hepatic failure. Severe persistent hyponatremia is a pointer to impending cell death. Hyponatremia due to obvious salt loss from the body (as with the use of diuretics) is corrected by the use of normal saline; hypertonic saline should be avoided as far as possible.

Hypokalemia and metabolic alkalosis are frequently observed. The latter potentiates ammonia toxicity. Hypokalemia is due to nasogastric suction, loss of K^+ from the urine and stools, to the use of IV dextrose-insulin, and to a poor intake of potassium. In the presence of a good urine output, 80–120 mEq of potassium may need to be given in an infusion daily. In the terminal stages, or in the presence of renal failure, hyperkalemia is observed.

Serum calcium levels may be low; 10 mL of 10% calcium gluconate may need to be given intravenously once or twice daily.

Total fluid intake should balance urine output and the loss of other secretions. The CVP should be maintained around 7–8 cm H_2O, and should as far as possible not exceed 12 cm H_2O. Salt-free albumin is often given intravenously to counter hypoalbuminemia, and to maintain an effective circulating volume.

Nutrition

All dietary protein should be stopped till recovery ensues. A few days to a few weeks of protein deprivation is well tolerated by these patients. 1500–2000 calories are supplied daily as 20% dextrose through a gastric drip. Strained vegetable soup, also given through the nasogastric tube, provides the necessary minerals and some additional carbohydrates. 20% dextrose is given intravenously through a central line; potassium may be added to the dextrose drip. If blood sugar levels are high, an appropriate dose of insulin may be added to the dextrose infusion. Vitamins B, C and K, together with a multivitamin preparation are also given intravenously daily.

Vegetable proteins are started only when recovery is evident. Ten grams are given orally to start with; this is gradually increased as recovery progresses.

In massive hepatic necrosis, there is an increase in the plasma levels of the aromatic amino acids methionine, tyrosine, and phenylalanine, and a decrease in the branched chain amino acids leucine, isoleucine and valine. Infusion of branched chain amino acids has been recommended in the management of hepatic coma, but is not of proven value. Branched chain aminoacids contained in specially made formulations, can also be used orally.

Hypoglycemia

Persistent intractable hypoglycemia is of ominous significance,[31] and can cause sudden death in these patients. It is countered by a continuous infusion of 20% dextrose. 100 mL of 50% dextrose may need to be given in addition, and should be repeated when blood glucose levels are below 70 mg/dL.

Acid-Base Disturbances

Lactic acid acidosis is frequent in patients who are deeply comatose. It may occur even with a normal arterial blood pressure, and is perhaps due to arteriovenous shunting, to capillary endothelial damage, and to poor uptake and utilization of oxygen by tissue cells. This is also of ominous significance, and is countered by improving oxygen delivery or transport to the optimal level. The use of sodium bicarbonate grants only a temporary reprieve.

In the early phases of acute hepatic failure, respiratory alkalosis is common. In the presence of hypokalemia, a mixture of respiratory and metabolic alkalosis may produce a significant increase in the pH. Potassium should be replaced by a slow IV infusion. Metabolic acidosis ultimately occurs either due to lactic acid acidosis, or to uremic acidosis, or to both factors. Mixed acid-base disorders may be frequently observed.

Respiratory Failure

Respiratory failure requires expert management. Lung function is impaired for various reasons. Infection, aspiration of gastric contents, atelectasis, and non-cardiogenic pulmonary edema, all play a part and contribute to a low PaO_2. Patchy shadows develop within the lung and continue to increase. Acute lung injury (ARDS) is the most dreaded of all complications, as it is always fatal when it occurs secondary to fulminant hepatic disease.

It is vital to secure the airway by endotracheal intubation, as soon as the gag reflex is impaired and the patient is slightly obtunded. We prefer the early use of mechanical ventilation to ensure full oxygen saturation of arterial blood. ARDS is a dreaded complication and requires skillful handling (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome). *It is worth noting that, in a patient with acute hepatitis, an unexplained increase in the respiratory rate may be an early sign of impending acute hepatic failure.*

Circulatory Failure

Volume depletion should be guarded against and promptly corrected. Large quantities of volume infusion to maintain blood pressure, often precipitate acute lung injury (ARDS). If filling pressures are adequate and arterial blood pressure is still below 100 mm Hg, inotropic support with dopamine and/or vasopressor support with norepinephrine should be commenced.

Arrhythmias are frequent in the terminal phase. Hypokalemia and hyperkalemia are easily correctible causes of dangerous arrhythmias.

Infection

Infections are common and may be easily missed unless the intensivist has a high index of suspicion. Fever and leukocytosis may be absent. Worsening encephalopathy, hypotension, hemodynamic instability, a fall in oxygen saturation or just overall worsening of the clinical condition should promptly arouse suspicion, particularly when liver function has started to recover prior to the setback.

Urinary infection, respiratory infection and sepsis iatrogenically introduced through central lines and catheters, are frequent in spite of the best intensive care offered to these patients. Patients with acute hepatic failure are immunocompromised to some extent, and acute Gram-negative bacterial sepsis is often observed. Appropriate antibiotics are invariably necessary. Aminoglycosides should not be used as far as possible in the presence of renal dysfunction. Blood cultures, cultures of catheter tips, bacteriological examination of urine and sputum, are always performed. Fungal infections may be overlooked as blood cultures are not always positive. They should be suspected when the patient deteriorates after an initial improvement, and in the presence of leukocytosis, renal dysfunction and pyrexia not responding to antibiotics. Antifungal agents should be used with care because of potential hepatic and renal toxicity. Scrupulous attention to aseptic suction through the endotracheal tube, and to careful handling and protection of central venous lines must be given to prevent iatrogenic infection.

Acute Pancreatitis

This is a dreaded complication of fulminant hepatitis. It should be suspected in the presence of—

- Severe upper abdominal pain.
- A sudden deterioration in the clinical state.
- A marked tenderness in the abdomen.
- Rapid development of free fluid within the abdomen.

A marked rise in serum amylase is observed in most, but not all patients. Pancreatitis in AHF can be due to the hepatitis virus, to shock, sepsis, corticosteroid therapy, or bleeding within the pancreas. It carries virtually a hopeless prognosis.

It should be noted that corticosteroids are not found to be of any use in AHF; in fact they may well produce further complications—gastric erosions, infection, pancreatitis.

Therapy Directed to the Specific Etiology Causing AHF

If the etiology of AHF in a patient has been determined, specific therapy can be offered (depending on the etiology) so as to lessen or reverse the liver injury. If specific therapy is available it should be given promptly.

Acetaminophen Poisoning or Overdose

N-acetyl cysteine (NAC) is a specific antidote for acetaminophen poisoning. The drug is given intravenously within 8–10 hours after an acute overdose. It prevents hepatotoxicity through the replenishment of glutathione. NAC may however remain effective, but to a much lesser extent up to 72 hours after acetaminophen ingestion.

Non-acetaminophen Induced AHF

NAC has been found to be useful also in non-acetaminophen induced AHF and should therefore be administered is all patients with AHF. The drug has been shown to result in increased survival, and to reduce brain edema; it has been shown to benefit oxygen delivery, oxygen consumption and the overall hemodynamic profile.

A randomized controlled trial of NAC by the US Liver Failure Study Group in patients with non-acetaminophen induced AHF showed improved transplant free survival.[32] In a randomized controlled trial NAC appeared to improve spontaneous survival when given during stages I and II of encephalopathy in patients with non-acetaminophen liver cell failure. These patients included those with drug-induced liver injury and hepatitis B infection.

Mushroom Poisoning

Patients with acute liver failure secondary to mushroom poisoning should be promptly given penicillin G intravenously in a dose of 500,000–1 million units/kg per day. Silibinin is even more efficacious than penicillin. Though available in Europe and South America, it is not available in the United States or in India.

Viral Hepatitis

Nucleotide analogues should be considered for hepatitis B associated liver cell failure (if a significant viral load is detected in the blood) and for prevention of post-transplant recurrence. Patients with proven or suspected herpes virus or Varicella zoster virus as the cause of AHF should be given acyclovir—10 mg/kg IV every 8 hours. Cytomegalovirus infection causing AHF should be treated with gancyclovir with appropriate dosing.

Wilson's Disease

This is an uncommon cause of AHF. Early diagnosis is critical, otherwise the disease is always fatal. A high bilirubin (mg/dL) to alkanine phosphatase (IU/L) ratio should arise suspicion of this disease. Copper lowering measures including the use of penicillamine should be tried. Plasmapheresis, hemofiltration and albumin dialysis serve merely as temporary measures before liver transplantation. These patients invariably need liver transplantation.

Autoimmune Hepatitis

The presence of autoimmune antibodies confirm the etiology. But autoimmune antibodies may be absent in close to 30% of cases. Liver biopsy through the transjugular route is recommended to confirm or disprove the diagnosis when autoimmune hepatitis is suspected in the absence of autoimmune antibodies.

Corticosteroid therapy is instituted—either methyl prednisolone 20–40 mg IV 8 hourly or 60 mg prednisolone/day orally. Patients should be considered for a transplant even when corticosteroids are being administered.

Acute Fatty Liver of Pregnancy

For acute fatty liver of pregnancy causing the HELLP (hemolysis-elevated liver enzymes-low platelets counts) syndrome prompt delivery of the fetus generally leads to recovery. If hepatic failure persists after delivery, the patient is recommended liver transplantation.

Acute Ischemic Injury

Treatment is directed toward cardiovascular support and to the management of shock causing severe ischemic injury to the liver.

Mortality

For patients with AHF due to acetaminophen overdose, hepatitis A virus infection, shock or pregnancy related acute liver failure, the short-term survival without transplantation is over 50%. The short-term transplant free survival in AHF due to drugs, HBV infection, autoimmune hepatitis, Wilson's disease, Budd-Chiari syndrome and due to indeterminate causes is less than 25%. Bad prognostic features which should prompt consideration for a hepatic transplant have been listed in the King's College Criteria System (see below). These criteria have however been criticized on the basis of low sensitivity and negative predictive values, especially in patients with AHF due to causes other than acetaminophen toxicity.

A brief mention must be made of other scoring systems. The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system is found to be as good as the King's College criteria in predicting death in acetaminophen induced AHF.[33]

The Cliché scoring system[33] involves estimation of various clotting factors. This requires high technical expertise and is not suited to developing countries. Other prognostic markers include the degree of hepatic necrosis as judged by a liver biopsy performed through the transjugular route, the amount of fresh frozen plasma required to correct coagulopathy and the determination of sensory evoked potentials.

PROGNOSIS AND CRITERIA FOR LIVER TRANSPLANTATION

AHF associated with Grade 4 encephalopathy has over 80% mortality without an orthotropic liver transplant. Prognosis depends on age, etiology, severity of liver cell necrosis, the degree of coagulopathy and encephalopathy, and the duration of the illness. Serum phosphate levels more than 1.2 mmoL/L on days 2 and 3, and blood lactate levels more than 3 mmoL/L are believed to be associated with a poor prognosis. Finally, Model for End-stage Liver Disease (MELD) score more than 32 denotes poor survival.

The fact remains that the main definitive treatment for AHF is a liver transplant. The successful use of orthotropic liver transplant has made it imperative to determine prognostic indicators to select patients who are most likely to benefit from orthotropic liver transplantation. Donor liver transplants play an important role in a few liver transplant centers. In India liver transplantation is being performed in different centers, those with the maximum experience and with results comparable to good centers in the West being in Delhi and Chennai. Mumbai unfortunately lags behind in this field. The paucity of cadaver donors (though this has improved substantially) and the poor infrastructure which hinders the prompt use of donor organs for transplant purposes in patients with AHF are some of the hurdles that afflict transplant liver surgery in India.

There are many prognostic systems that lay down criteria for liver transplantation in patients with AHF. The most frequently used scoring system consist of criteria laid down by King's College (King's College criteria).[34] These are tabled in Box 8.

In transplant centers, the chief contraindications to hepatic transplant include a cerebral perfusion pressure less than 50 mm Hg for more than 2 hours despite therapy, ongoing sepsis, fraction of inspired oxygen (FiO_2) requirement more than 60%, uncal herniation with dilated pupils, and brain damage caused by an intracranial bleed. Patients desperately needing a transplant may need to wait for lack of a donor organ, and may die before this is available. The current strategies in good transplant centers that help to tide over this possible waiting period are the use of artificial or bioartificial livers, hepatocyte transplantation and extracorporeal perfusion.

Box 8: King's College criteria for liver transplant

Acetaminophen overdose—
- Arterial pH <7.3 (irrespective of grade of encephalopathy or
- PT >100 sec (INR >6.5)
- Serum creatinine >3.4 mg/dL (>300 µmoL/L)
- Patients with Grades III and IV hepatic encephalopathy

Non-acetaminophen liver injury—

PT >100 sec (INR >6.5) (irrespective of grade of encephalopathy) or any three of the following variables—
- Age <10 or >40 years
- Non-A, non-B hepatitis, halothane hepatitis, idiosyncratic drug reactions
- Jaundice >7 days before onset of encephalopathy
- Serum bilirubin ≥17.4 mg/dL (300 UmoL/L)
- PT >50 seconds

Abbreviations: INR, international normalized ratio; PT, prothrombin time.

CRITICAL CARE OF COMPLICATIONS IN CHRONIC LIVER CELL FAILURE

Patients with chronic liver cell dysfunction need intensive care when they develop an acute hepatic encephalopathy (i.e. acute on chronic liver failure), a severe GI bleed, an acute infection, or develop oliguric renal failure. More than one of these complications often coexist in the same patient.

Acute Hepatic Encephalopathy

Acute hepatic encephalopathy in a cirrhotic patient may occur spontaneously in the natural course of events, usually as a terminal feature in a patient who has ascites and is deeply jaundiced. More often than not, acute encephalopathy in cirrhotics is precipitated by factors which further depress liver cell function, and increase nitrogenous material within the gut. These precipitating factors should be sought for, recognized and rectified as a matter of immediate priority after admission to the ICU.

Precipitating factors—

- Use of furosemide or other diuretics, volume loss, and subtle electrolyte disturbances even in the absence of significant hypovolemia. These can trigger acute neuropsychiatric features.

  Paracentesis involving removal of a large quantity of ascitic fluid is an important precipitating cause of coma. Again electrolyte imbalance following removal of large quantities of electrolytes and water, hypotension and changes in the hepatic circulation may be contributory factors. These changes are not necessarily reflected by disturbances in serum electrolytes.
- Fluid and electrolyte loss from vomiting, diarrhea or from inadequate fluid intake.

  The above precipitating factors can be corrected by IV infusions of fluid and electrolytes, and restoring electrolyte balance. Correction of hyponatremia and hypokalemia are of prime importance. Hypovolemia can be quickly corrected by the IV infusion of salt free albumin. Hypotension, which persists after volume replacement should be treated by inotropic (dopamine) and/or vasopressor support.

  Therapeutic paracentesis for ascites should not be performed in patients who are severely ill with chronic

Box 9: Selection of patients for therapeutic paracentesis

- Tense ascites
- Preferably with edema
- Child's Grade B
- Serum bilirubin <10 mg/dL
- Platelets >40,000/mm^3
- Serum creatinine <3 mg/dL
- Urinary sodium >10 mEq/24 hour
- PT >50 seconds

liver cell dysfunction, as this can precipitate both hepatic encephalopathy and acute oliguric renal failure.

The indications and precautions for therapeutic paracentesis[35] are tabled in Box 9.

- Gastrointestinal bleeds or blood loss from any other source is one of the most important precipitating factors. It may be occult and may not manifest immediately. A rectal examination may reveal the presence of melena and should always be performed as part of a routine examination. Coma in these patients may be due to hypovolemia, hypotension, presence and absorption of increased proteins and their breakdown products from blood within the gut, and also to anemia if there is a significant drop in the hemoglobin. Even a mild GI bleed in decompensated cirrhotics needs to be replaced by a blood transfusion. A laxative to evacuate the intestinal contents of blood, and a bowel wash, should also be promptly given.
- *Infection* This is an important precipitant; its source and nature should be sought for, identified and treated. Commonly, infection involves the lungs and urinary tract. Spontaneous bacterial peritonitis is characterized by the presence of infected ascitic fluid in the absence of a recognizable cause of secondary peritonitis.[36] It can result in a rapidly evolving acute encephalopathy in cirrhotics, and should always be suspected when a patient with cirrhosis deteriorates suddenly without any apparent cause. The clinical features include pyrexia, diffuse or localized abdominal pain on palpation. These features may however be absent, and the diagnosis is made only when a high index of suspicion results in the examination of ascitic fluid which shows more than 250 polymorphs/mm^3. The association of a pH less than 7.3 and polymorphs more than 500/mm^3 in the ascitic fluid, is diagnostic of bacterial peritonitis.[37] The infection is generally blood borne and usually monomicrobial. Patients with cirrhosis are immunocompromised and prone to bacteremia. Ascitic fluid is a good culture medium for bacterial growth. If the opsonic activity of ascitic fluid is very low, there is poor opsonic coating of bacteria within the fluid; bacteria are therefore not destroyed by polymorphs, and produce a peritonitis. Culture of ascitic fluid in our limited experience, is rarely positive. At times infection of the peritoneum is not blood borne, but occurs through the gut wall, pointing to poor immune defenses that allow a breach of the gut wall by intestinal flora. Infecting organisms are Gram-negative *E. coli* or *Streptococci.*

  Broad-spectrum antibiotics (third generation cephalosporin, cefotaxime) should be used under the following conditions—
  - When clinical features are typical of spontaneous bacterial peritonitis.
  - When the ascitic fluid shows polymorphs more than 250/mm^3 and the clinical picture is compatible with a bacterial peritonitis.
  - When the ascitic fluid shows a polymorph count more than 500/mm^3 even in the absence of symptoms or signs of peritonitis. Therapeutic paracentesis should be done.

  Prognosis is grave; it depends on the severity of bacterial infection of the peritoneum, the degree of underlying liver cell dysfunction, and the degree of clinical deterioration precipitated by the infection. The survival rate over a year in those patients who are discharged from the hospital, is dismal, being less than 2–38%.
- *Stress* in the form of surgery, trauma, fracture, shock or anesthesia can further depress hepatic function.
- *Acute alcoholic bouts* Ingestion of alcohol precipitates drowsiness and coma both by producing an associated acute alcoholic hepatitis, and by depressing cerebral function. Sudden alcohol withdrawal can also precipitates neuropsychiatric disturbances which may be difficult to distinguish from hepatic encephalopathy.
- *Sedatives*, even if mild or in small doses, are an important cause of neuropsychiatric symptoms and acute encephalopathy. They should be strictly avoided in all cirrhotics.
- *Constipation*, sometimes triggers encephalopathy probably by increasing the nitrogenous content within the bowel and providing for a larger source of ammonia products.
- *A large protein meal* acts in a similar fashion, and its effect is accentuated by the presence of constipation.

Hepatic encephalopathy is treated on the lines already elaborated upon in acute hepatic failure. It is obvious that the prognosis is better if a precipitating factor is identified and quickly corrected.

In the absence of a past history it is often difficult to determine whether acute encephalopathy, jaundice and deranged liver cell functions are due to acute hepatocellular dysfunction in a patient with a previously normal liver, or are due to acute on chronic liver cell failure. A poor nutritional state, a firm enlarged spleen, a firm and at times irregular liver with presence of spider nevi, point to acute on chronic liver cell dysfunction.

Neuropsychiatric features in acute on chronic liver cell failure are commonly misdiagnosed as acute alcoholic

intoxication or alcohol withdrawal syndrome. A wrong diagnosis of a manic or depressive psychosis may also be made. Symptoms are at times bizarre, and may be transient lasting for only 8–12 hours. We have seen such abnormal neuropsychiatric behavior necessitating admission, after ingestion of a large meal or following constipation, in patients with cirrhosis. A good clinical examination for gynecomastia, liver palms, spider nevi, and for other clinical and biochemical evidence of liver cell dysfunction will always clarify the diagnosis.

Severe Gastrointestinal Bleeding

Acute GI bleeding in a cirrhotic patient is a dreaded emergency requiring critical care. GI bleeds are most commonly due to bleeding esophageal or gastric varices. They could also result from acute gastroduodenal erosions, a Mallory-Weiss syndrome, or a chronic peptic ulcer. The present discussion is related to the diagnosis and management of variceal bleeding in cirrhotics in an ICU setting (Flowchart 1).

Diagnosis of Variceal Bleeding

The diagnosis is made because of hematemesis or melena or both in a cirrhotic patient. If the patient is in hospital, fresh or altered blood may be present on aspiration of the nasogastric tube if this is already in place. The bleeding however may not be always evident. A slow ooze may fill the gut with blood before the bleed is recognized. A rectal examination may demonstrate melena and may allow an earlier diagnosis to be made in a cirrhotic who shows clinical deterioration.

The possibility of an upper GI bleed (generally variceal in origin) should always be suspected if a cirrhotic develops a sudden encephalopathy, becomes hypotensive and shows features of hypovolemia or has a sharp fall in urine output.

Variceal hemorrhage constitutes the second most overall common cause of upper GI bleeds. Varices in the upper GI tract are present in almost all patients with advanced cirrhosis of liver with portal hypertension. The varices that bleed are generally present in the lower esophagus and stomach. The propensity for variceal bleeding is chiefly determined by the pressure gradient in the hepatic veins.

Mortality of variceal bleeding in spite of improvement in medical management is 20% in the first 6 weeks.[38] The rebleeding rates are as high as 30–40% in the first 6 weeks and is associated with a 30% mortality.[39]

As soon as variceal bleeding is suspected (and this is the most likely cause in a cirrhotic) terlipressin or somatostatin or the somatostatin analog octreotide should be administered. If possible, pharmacological therapy should be administered during transport or immediately on admission to the hospital. These drugs can arrest or control hemorrhage in varices in more than 60% of patients and can also help endoscopic visualization by reducing active bleeding. Terlipressin is the only drug shown to reduce mortality.[40,41] It is administered IV in a dose of 2 mg every 4–8 hours followed by half this dose for 5–7 days. Somatostatin is also useful and acts through splanchnic arteriolar constriction, thereby reducing the inflow of blood into the portal venous circulation. The dose is 250 mg IV as a bolus, repeated every 3 hours followed by an infusion of 250 ug/hour for 5–7 days to prevent rebleeding.[42]

Octreotide has a longer half-life compared to somatostatin and is administered as a 50–100 mg IV bolus followed by a continuous infusion of 25–50 μg/hour. Both somatostatin and octreotide have the same effect in controlling variceal bleeding, yet when used alone they do not decrease mortality.[43,44] The use of these drugs should always be promptly followed by endoscopy.

In many units in peripheral hospitals outside main cities neither terlipressin, somatostatin nor octreotide are available. When unavailable vasopressin can be given to control variceal bleeding. It is administered in an IV infusion starting at 0.4 U/minute, the infusion rate being increased to 1 U/minute depending on the clinical response. Side effects of vasopressin include myocardial ischemia, cerebrovascular accidents, limb ischemia and hyponatremia. These are dangerous complications and occur in a significant number of patients. Therefore, it is important to concurrently administer IV nitroglycerin in a titrated dose (10–30 μg/minute). Vasopressin reduces or arrests variceal bleeding in 80% of patients but it does not decrease mortality, perhaps because of vascular constriction with resulting ischemia to other organ systems.

Antibiotics should be administered if there is any suspicion of infection. Many units prefer to use prophylactic antibiotics as they have been shown to reduce the incidence of infection as also reduce early rebleeding and improve survival in these patients. Ceftriaxone is the drug most commonly used. Fluoroquinolones form an alternative particularly in patients with a history of penicillin allergy.

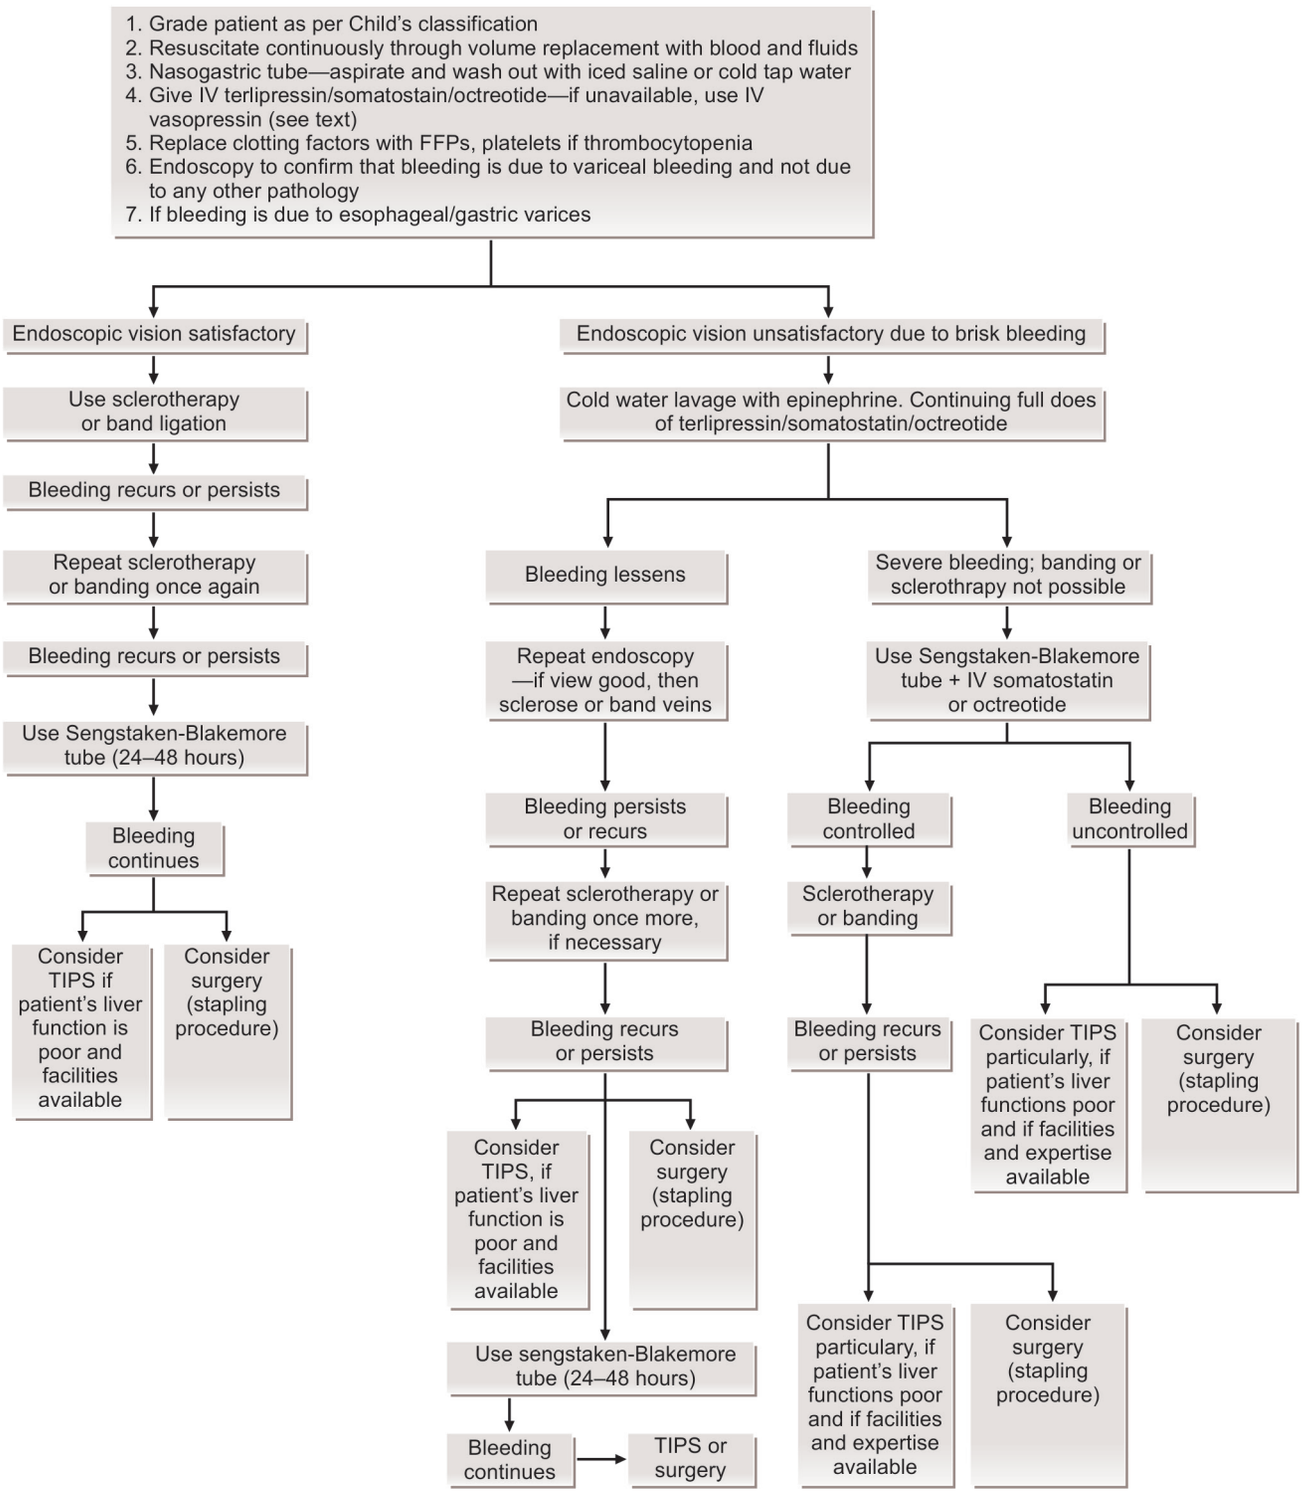
Endotracheal intubation may be necessary to secure the airway in obtunded patients, if there is a risk of aspiration and in the presence of impending hepatic encephalopathy.

While the above mentioned pharmacological therapy is in progress, the patient should simultaneously receive resuscitation with crystalloids and packed RBCs to quickly correct hypovolemia and restore a normovolemic state. Uncorrected hypovolemia or delay in correcting hypovolemia can cause complications, in particular renal failure. Yet, overcorrection so as to cause a hypervolemic state should be avoided as this could perpetuate or even exacerbate variceal bleeding.

Many of these cirrhotic patients are deficient in clotting factors and have an INR well above normal as also a raised APTT. Fresh frozen plasma should be administered to decrease the PT to acceptable levels (if possible, INR of 1.4–1.6). Advanced cirrhosis is associated with low fibrinogen levels for which several units of cryoprecipitate need to be given. Uncorrected clotting abnormalities will allow variceal bleeding to continue.

Following resuscitation, and the pharmacologic therapy indicated above, endoscopy should be performed to determine the exact source of bleeding. Though esophageal

Flowchart 1: Management of variceal bleeding



1. Grade patient as per Child's classification
2. Resuscitate continuously through volume replacement with blood and fluids
3. Nasogastric tube—aspirate and wash out with iced saline or cold tap water
4. Give IV terlipressin/somatostain/octreotide—if unavailable, use IV vasopressin (see text)
5. Replace clotting factors with FFPs, platelets if thrombocytopenia
6. Endoscopy to confirm that bleeding is due to variceal bleeding and not due to any other pathology
7. If bleeding is due to esophageal/gastric varices
Endoscopic vision satisfactory
Use sclerotherapy or band ligation
Bleeding recurs or persists
Repeat sclerotherapy or banding once again
Bleeding recurs or persists
Use Sengstaken-Blakemore tube (24–48 hours)
Bleeding continues
Consider TIPS if patient's liver function is poor and facilities available
Consider surgery (stapling procedure)
Endoscopic vision unsatisfactory due to brisk bleeding
Cold water lavage with epinephrine. Continuing full does of terlipressin/somatostatin/octreotide
Bleeding lessens
Repeat endoscopy —if view good, then sclerose or band veins
Bleeding persists or recurs
Repeat sclerotherapy or banding once more, if necessary
Bleeding recurs or persists
Consider TIPS, if patient's liver function is poor and facilities available
Consider surgery (stapling procedure)
Use sengstaken-Blakemore tube (24–48 hours)
Bleeding continues
TIPS or surgery
Severe bleeding; banding or sclerothrapy not possible
Use Sengstaken-Blakemore tube + IV somatostatin or octreotide
Bleeding controlled
Sclerotherapy or banding
Bleeding recurs or persists
Consider TIPS particulary, if patient's liver functions poor and if facilities and expertise available
Consider surgery (stapling procedure)
Bleeding uncontrolled
Consider TIPS particularly, if patient's liver functions poor and if facilities and expertise available
Consider surgery (stapling procedure)

and gastric varices are undoubtedly the commonest source of bleeding in cirrhotic patients, in close to 20–25% of patients GI bleeding may occur from a non-variceal source.

Endoscopic treatment of esophageal varices consists of sclerotherapy or band ligation, depending on the experience and expertise of the endoscopist. Band ligation is today the treatment of choice as it reduces the risk of a recurrent bleed (compared to sclerotherapy) and has fewer complications. Banding may however at times be impossibly difficult in a patient with massive bleeding. In these patients sclerotherapy needs to be attempted. Complications following sclerotherapy include mucosal ulcers that have

opened in submucous venous channels. Rebleeding is seen in 30% of cases, either from remaining varices or ulcers. The former require sclerotherapy; omeprazole helps to arrest bleeding from ulcers. Esophageal strictures can result from chemical esophagitis and acid reflux. Rarely perforation of the esophagus or even an esophagobronchial fistula may result. Pulmonary complications include aspiration pneumonia, pleural effusion, mediastinitis. Pyrexia is frequent after sclerotherapy and bacteremia may occur during or following the procedure necessitating the use of appropriate antibiotics.

Band ligation (the varices being identified, ligated and strangulated by the application of O-bands through the endoscope) is comparatively free of complications. Ulcers may occur at the site of previous bands and torrential hemorrhage can occur if the band slips.

The success of endoscopic treatment is 80–85%, roughly similar to the use of vasoactive drugs.[45-48] However, despite similar success rates, a recent Cochrane meta-analysis concluded that band therapy or sclerotherapy could not be recommended as a first-line therapy and that it should be used only when pharmacological treatment has failed. In practice, pharmacological therapy is followed by endoscopic treatment.

Gastric varices generally bleed less than esophageal varices and are treated with sclerotherapy with *histoacryl* glue. Complications include ulceration of the mucosa and embolic events from the glue.[49]

If in spite of the above procedures bleeding persists or is too profuse to allow emergency endoscopic banding or sclerotherapy, an attempt is made to arrest the bleeding by the insertion of the Sengstaken-Blakemore tube. This is a four-lumened tube that has an esophageal and gastric balloon,[50] a tube in the stomach and a fourth lumen for continuous aspiration of the esophagus above the esophageal balloon. The lubricated tube is passed orally into the stomach which is emptied, and the gastric balloon is inflated with 250 mL air and is doubly clamped. The gastric tube is aspirated continuously. The esophageal balloon is inflated to a pressure of 40 mm Hg slightly more than the expected portal vein pressure. Firm traction is exerted on the tube with the help of a suitable device, for 24 hours. Traction is then released and the esophageal balloon deflated; the gastric balloon is kept inflated for a further 24 hours. If bleeding recurs, the esophageal balloon may be reinflated and traction reapplied for a further 24–48 hours, or till emergency band ligation, sclerotherapy or surgery can be done.

In experienced hands, the Sengstaken-Blakemore tube often temporarily stops variceal bleeding and allows emergency banding or sclerotherapy. It is the only immediate expedient available for stopping profuse life-threatening blood loss. Unfortunately it requires great expertise for correct use, and complications are frequent. These include asphyxia due to migration of the esophageal balloon upward into the pharynx, ulceration of the esophagus and aspiration pneumonia.

However, if bleeding persists in spite of the Sengstaken-Blakemore tube and band ligation or sclerotherapy is not possible, or if the bleeding continues following band ligation or sclerotherapy, transjugular intrahepatic portosystemic shunt (TIPS) or emergency surgery is warranted.

TIPS[51]

The transjugular intrahepatic portosystemic shunt (TIPS) is a comparatively new non-operative therapeutic option for the management of severe variceal bleeding particularly in patients with poor liver function (Grade C of Child's classification), awaiting a liver transplant. TIPS once securely placed reduces the hepatic vein pressure gradient and stops bleeding in 90–100% of cases. The emergency placement of TIPS is however associated with a high mortality (50%), and a high incidence of hepatic encephalopathy. It is important to attempt TIPS to arrest variceal bleeding only if full medical treatment (use of vasoactive drugs, sclerotherapy or banding) has failed. The procedure is performed under sedation and local anesthesia using ultrasound control. The middle hepatic vein is catheterized through the transjugular route and a needle is inserted through the catheter (under ultrasound guidance) and through the liver parenchyma, into a main portal vein branch. A guide wire is introduced through the needle and the catheter advanced into the portal vein. The needle is removed and the portal vein gradient measured. The needle tract is dilated by a balloon, and a self-expanding metal stent is inserted and expanded to 8–12 mm. A portosystemic shunt is thus established; reduction in portal vein pressure should arrest variceal bleeding. TIPS seems more effective in controlling and preventing variceal bleeding than band ligation or sclerotherapy.

Complications chiefly include hemorrhage (intra-abdominal, biliary, or through the liver capsule), infection, and stent stenosis or occlusion. Early occlusion is seen in 12% and is usually due to thrombosis within the shunt. Shunt occlusion results in recurrence of variceal bleeding. Late occlusion is due to intimal proliferation at the hepatic venous end of the stent. Other complications are—TIPS encephalopathy (due to portosystemic shunt), renal failure (due to excessive intravenous contrast used). Hepatic infarction can occur from misplacement of the stent into the right hepatic artery.

Emergency Surgery

Emergency surgery for bleeding esophageal varices has been considerably reduced following the use of vasoactive drugs, endoscopic banding or sclerotherapy, balloon tamponade and TIPS. When these fail or if the expertise for performing TIPS is unavailable in patients who rebleed after banding or sclerotherapy, emergency surgery is warranted. Esophageal transection using the stapling procedure is the surgery of choice. Stapling arrests hemorrhage, but death occurs in 30–40% of patients from hepatocellular failure. Alternative emergency surgical procedures are a mesocaval or portocaval shunt. Both are associated with a high mortality and a high incidence of hepatic encephalopathy in Grade C patients. In our setup we rarely advocate emergency surgery in patients categorized as under Grade C of Child's classification.

Prevention of Bleeding

Propranolol decreases the risk of recurrent variceal bleeding but has little effect on survival. It is of value in gastropathy. Isosorbide mononitrate also reduces the risk of variceal bleeding. Both propranalol and isosorbide mononitrate should be used as a preventive measure.

Various portal-systemic shunt procedures are used to prevent recurrent gastroesophageal variceal bleeding. These include portocaval, mesocaval or splenorenal shunts. For poor risk patients the mortality is 50%; in good risk patients it is about 5%. Hepatic encephalopathy is an important complication of portocaval shunts. Myelopathy with paraplegia and a Parkinsonian picture are other complications.

Hepatic transplant is the optimal solution to recurrent bleeding varices in cirrhotic patients. Previous sclerotherapy or portosystemic shunts do not affect post-transplant survival.

Complications of variceal bleeding include hypotensive shock, hepatic encephalopathy, supervening infection, aspiration pneumonia and renal failure. Prompt treatment of variceal bleeding reduces the incidence of these complications.

Acute Infections

Patients with chronic liver cell dysfunction need intensive care if there is a serious, often life-threatening infection. Bacteremia with sepsis is an important, life-threatening complication in these patients. The source of bacteremia is generally undetermined. The role of translocation of bacteria from the gut in patients with impaired liver cell function may have a significant role both in initiating and perpetuating sepsis. As mentioned earlier, acute infection involving any organ system, invariably worsens liver cell function and may well precipitate hepatic encephalopathy. In cirrhotics, body responses to infection may not be as vigorous as in patients who are normal to start with. Fever may be low grade, physical findings may be meagre, and leukocytosis may be absent. In the absence of a definite source of infection, the possibility of a specific bacterial peritonitis should always be excluded by examination of the ascitic fluid (see previous section of this chapter). Patient care demands the prompt use of empiric therapy with antibiotics after blood cultures and other relevant cultures and microbiological tests have been sent for examination. The antibiotics frequently used are a third generation cephalosporin or ciprofloxacin. If there is a possibility of a staphylococcal infection, vancomycin needs to be added (see Chapter The Immunocompromised Patient).

Acute Oliguric Renal Failure

Acute renal failure could be due to prerenal causes or to acute tubular necrosis. Prerenal causes include hypovolemia, blood loss, hypotension from any cause, or fluid and electrolyte disturbances. Paracentesis of a large volume of ascitic fluid or overvigorous diuretic therapy often precipitates oliguric renal failure. Acute tubular necrosis may occur in some of these patients. The hepatorenal syndrome as mentioned earlier, is characterized by progressive acute oliguric renal failure in the presence of normal tubular function.

Table 1: Iatrogenic causes of oliguric renal failure (and their treatment) in chronic liver cell failure

Causes	*Treatment*
• Drugs—	
– Diuretics or Lactulose	Volume expansion
– Non-steroidal antiinflammatory drugs	Stop drugs
– Aminoglycosides	Stop drug
– Cyclosporine	Hemodialysis
• Paracentesis of large volume of ascitic fluid	Volume expansion
• Volume depletion (blood loss or vomiting or diarrhea)	Volume replacement

Volume replacement, replacement of blood loss to improve the urine output, should be prompt. The prognosis of a fully evolved hepatorenal syndrome is well-nigh hopeless. Iatrogenic and other potentially correctible problems causing oliguric renal failure are listed in Table 1. They should be carefully assessed and as far as possible corrected. Even so, the prognosis in the presence of azotemia is grim.

CHAPTER 55

Acute Pancreatitis

INTRODUCTION

Acute inflammation of the pancreas can be of varying severity. Mild or acute edematous pancreatitis has a good prognosis and recovery almost always ensues. These patients can be managed in the general wards of a hospital. However, in about 30% of patients the inflammation is severe and necrotizing, and often complicated by retroperitoneal sepsis. The mortality in necrotizing pancreatitis approaches 50%. Critical care is mandatory in these patients. It ensures early aggressive resuscitation, close monitoring of the patient, and prompt diagnosis and management of complications frequently observed in the fulminant forms of the disease.

ETIOLOGY

The two important causes of acute pancreatitis are gallstone disease and excessive alcohol consumption. Pathogenesis in gallstone disease may be related to obstruction of the pancreatic duct during passage of a gallstone. This obstruction results in ductal hypertension which through rather obscure mechanisms leads to zymogen activation. Activated pancreatic enzymes cause pancreatic inflammation, tissue destruction and various complications observed in the disease.

The pathogenesis of pancreatic inflammation in alcohol abuse, is obscure. Alcohol may have a direct action on acinar cells or may produce spasm of the sphincter of Oddi, with ductal hypertension. Alcohol-induced pancreatitis is directly related to the quantity and duration of alcohol consumption.

Pancreatitis may occasionally follow abdominal surgery, particularly surgery on the biliary tree. Early detection may be difficult, as the clinical features in these patients are often atypical. Persistent pain or unexpected prolonged ileus following abdominal surgery should raise the possibility of pancreatitis.

Box 1: Etiology of acute pancreatitis

- Gallstones
- Alcohol
- Following surgery, especially after biliary tract surgery
- Trauma
- Post-endoscopic retrograde cholangiopancreatography (ERCP)
- Pancreatic tumors
- Drugs—corticosteroids
- Hypercalcemia
- Hyperlipidemia
- Autoimmune pancreatits
- Infections, e.g. mumps, coxsackie virus
- Polyarteritis nodosa and other collagen disorders
- Low flow states/embolic
- Idiopathic

Endoscopic retrograde cholangiopancreatography (ERCP) results in acute pancreatitis in 2% of cases.

There are numerous other causes of pancreatitis listed in Box 1.[1] These include drugs, viral and other infections, trauma, pancreatic tumors, autoimmune disease and metabolic causes (hypercalcemia, hyperlipidemia). Pancreatitis is also associated with Type I and Type V hyperlipoproteinemias. Hypertriglyceridemia may be the underlying mechanism in these patients. Rarely, autoimmune disease can cause or be associated with pancreatitis. In spite of an elaborate work-up, 7–10% of patients have idiopathic pancreatitis, where the cause is undetermined.

Box 2: Important critical illnesses and problems in the ICU that predispose to acute pancreatitis

- Major upper abdominal surgery
- Shock of any etiology
- Cardiopulmonary bypass
- Repair of abdominal aortic aneurysm
- Kidney/liver transplantation

Patients in the ICU with acute pancreatitis, fall into two groups—

1. Those who were in reasonably good health, and who are now stricken with the disease and require intensive care. These patients are admitted primarily for acute severe pancreatitis.
2. Those who are already seriously ill in the ICU with a critical illness, and in whom pancreatitis develops as a further complication. The list of critical illnesses in the ICU that form a background to a complicating pancreatitis continues to grow, and is shown in Box 2.

The reason why seriously ill patients with diverse critical illnesses should develop the unrelated and potentially lethal complication of acute pancreatitis is poorly understood. Multifactorial causes are probably responsible.[1] Review of possible mechanisms of acute pancreatitis in critically ill patients suggests that hypoperfusion injury plays an important pathogenetic role. Warshaw and O'Hara[2] go so far as to suggest that shock from any cause is a risk factor for the development of acute pancreatitis. The mechanisms that relate hypoperfusion states to release of activated pancreatic enzymes, and to pancreatic inflammation, are not known.

PATHOPHYSIOLOGY[3-5]

The pancreas secretes a number of digestive enzymes, which are secreted as inactive proenzymes or zymogens. When activated enzymes come in contact with tissues outside their usual milieu, they have the potential to produce inflammation, necrosis and cellular death. This is normally prevented by the storage of inactive pancreatic zymogens and enzyme activators in separate cytosol granules. Once the integrity of this protective compartmentalization is lost, autodigestion due to enzymatic activation occurs, initiating a self-perpetuating inflammatory reaction. Activated enzymes, which include proteases such as trypsin, chymotrypsin and elastase, can in turn activate proenzymes in the inflammatory and complement cascades. Lipase produces fat necrosis and liberates phospholipid remnants. Inflammation and necrosis is not confined to the pancreatic and peripancreatic area, but can occur in various organ systems, leading to multiple organ dysfunction and death.

Sepsis frequently complicates necrotizing pancreatitis. Systemic toxicity is related to the release of several mediators, including arachidonic acid metabolites, interleukin-1 and other cytokines.

CLINICAL FEATURES AND DIAGNOSTIC EVALUATION[1,4,5]

Clinical assessment is initially directed toward establishing a diagnosis and determining the severity and prognosis of acute pancreatitis. Further diagnostic evaluation is then necessary to identify the presence of pancreatic necrosis and pancreatic and peripancreatic suppuration. The timing and nature of surgical intervention in some of these patients is indeed a matter of fine judgment based on clinical features, results of diagnostic tests, and experience.

Abdominal pain and vomiting are invariably present. Unlike the pain of a perforated peptic ulcer, the severity of which is maximal almost from the start, the pain of acute pancreatitis often builds up to a crescendo over a matter of hours. The pain is classically initially felt in the upper abdomen. It is however often poorly localized, and may be felt all over the abdomen, as also in the back. Rarely, it is experienced more in the back than the abdomen. Low grade fever is often present. Abdominal distension and tenderness on palpation are present, but guarding and rigidity denoting peritonitis, are late in developing and may be absent to start with. Abdominal findings in any case, do not necessarily indicate the severity of the retroperitoneal inflammatory process. Localized ileus may cause gastric dilatation which worsens vomiting. Localized effect of inflammation on the distal transverse colon leads to distension of the loop of the transverse colon with the "colon cut off" sign on X-ray of the abdomen. In fulminant cases when retroperitoneal inflammation extends beyond the pancreas, erythema around the flanks may occur. Ecchymosis of the flanks (Grey-Turner's sign), and of the umbilicus (Cullen's sign), have been described, but are rarely observed. These signs reflect bleeding into the pancreatic bed or retroperitoneal space.

All patients with severe pancreatitis show circulatory changes of hypovolemia, characterized by tachycardia, hypotension, cold peripheries and a falling urine output. Hypovolemia is due to transudation of fluid into the retroperitoneal space, peripancreatic and extrapancreatic tissues, to sequestration of fluid in the ileum and to ascites. In fact, the diagnosis of acute pancreatitis should be always considered in any patient with abdominal pain and a compromised circulation.

Peripancreatic fluid collections occur in up to 50% of patients. Pseudocysts are better defined collections of fluid within the lesser sac, and occur in 10–15% of patients. Pseudocysts can compress the stomach, duodenum and rarely the bile duct. Pseudocysts can leak into the peritoneal cavity, or track into the retroperitoneal space, pleural cavity or even rarely into the pericardial space.

Necrosis of a part of the inflamed pancreas is termed acute necrotizing pancreatitis (Fig. 1). If volume replacement has been adequate, necrotizing pancreatitis is characterized by clinical features of the systemic inflammatory response syndrome and is associated with a hyperdynamic circulation, tachycardia, tachypnea, hypotension and fever.

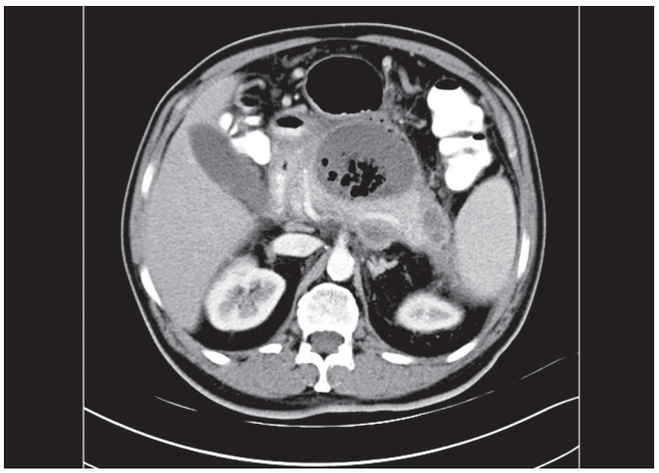

Fig. 1: Acute necrotizing pancreatitis

Pulmonary complications are an intrinsic feature of almost every patient with severe necrotizing pancreatitis. Tachypnea is invariably present. Hypoxia may occur without significant changes in an X-ray of the chest. Raised diaphragms, basal atelectasis are commonly observed. Pleural effusions (usually left sided) are frequent; the pleural fluid is an exudate with high amylase content.

Diagnosis

The diagnosis of acute pancreatitis requires two of the following three features—

1. Abdominal pain consistent with acute pancreatitis.
2. Serum amylase or lipase activity at least three times greater than the upper limit of normal.
3. Characteristic findings on contrast enhanced high resolution computed tomography (HRCT) or trans-abdominal sonography.

If abdominal pain suggests pancreatitis, but amylase and/or lipase levels are not significantly elevated, an HRCT of the abdomen is necessary to confirm the diagnosis. If however abdominal pain consistent with acute pancreatitis is associated with a very significant rise in pancreatic enzymes, an HRCT of the abdomen is not usually required in the emergency department or on admission to the ICU. This investigation then can be done after a few days and will provide more information than when done on admission.

COMPLICATIONS[6,7]

Complications may be local (within the abdomen), or systemic [taking the form of the multiple organ dysfunction syndrome (MODS)]. One should consider complications to be really a progressive evolution of the pathology and natural history of fulminating pancreatitis.

Local Complications

i. Local fluid collections have been already commented upon.
ii. Erosion of mesenteric vessels can lead to massive colonic bleed, to haematemesis, or to severe melaena. Haemorrhage into the pancreas, pancreatic duct or pancreatic bed can also occur (Hemosuccus pancreaticum). Portal vein thrombosis is commonly observed.
iii. Gastric outlet obstruction or biliary obstruction may occur.
iv. Pancreatico-enteric or pancreatico-colonic fistulas may occur.
v. Necrotizing pancreatitis is associated with infection in the necrotic area in about one-third of patients with necrosis, leading to increasing sepsis. Suppuration within the pancreas can lead to a localized abscess (walled off necrosis). Suppuration can also involve the peripancreatic area. Local fluid collections can also suppurate.
vi. The abdominal compartment syndrome may occur with disastrous consequences if increased intra-abdominal pressure is not relieved.

Systemic Complications

Multiple Organ Dysfunction Syndrome[7]

This is the most dreaded and frequent complication of severe necrotizing pancreatitis, particularly if the necrotic areas are infected. All organs can be involved. ARDS occurs in more than 20% of patients and is associated with a mortality of over 60%. Oliguric renal failure is associated with a mortality greater than 50%. Liver cell dysfunction is often observed. Disseminated intravascular coagulopathy has a grim prognosis. Metabolic complications include hyperlipidaemia, hyperglycaemia, hypocalcaemia and metabolic acidosis. Rarely coma results from a pancreatic encephalopathy.

In critically ill patients already under intensive care, the sudden added complication of acute pancreatitis may go unrecognized for a length of time. Abdominal pain and vomiting may not be severe enough to draw attention to the nature of the problem. The patient may develop non-specific features of fever, leukocytosis, haemodynamic instability, and hypotension necessitating increased fluid requirements. Yet, the classic major abdominal signs may be still absent. A quick deterioration in an already ill individual is observed. Diagnosis is possible only if there is a high index of suspicion.

Severe pancreatitis may be clinically difficult to distinguish from perforation, bowel obstruction, bowel infarction, and a leaking abdominal aortic aneurysm. Each one of these pathologies, except acute pancreatitis, requires immediate surgical intervention. The importance of a correct diagnosis can therefore never be overstressed.

LABORATORY INVESTIGATIONS[1,8]

Elevated serum amylase and lipase levels are found in a number of patients, but these tests lack both good sensitivity and specificity. A normal serum amylase does not exclude

Table 1: Ranson's early objective prognostic signs used for estimating risk of death or major complications in acute pancreatitis

On admission	*During first 48 hours*
Age >55	Hematocrit fall >10 percentage points
WBC >16000/mm^3	BUN rise >5 mg/100 mL
Blood sugar >200 mg/100 mL	Serum calcium <8 mg/100 mL
Serum LDH >350 IU/L	PaO_2 <60 mm Hg
SGOT >250 U/dL	Base Deficit >4 mEq/L
	Estimated fluid sequestration >6 L

Abbreviations: WBC, white blood cells; LDH, lactate dehydrogenase; SGOT, serum glutamic oxaloacetic transaminase; BUN, blood urea nitrogen.
Source: Ranson JH, Rifkind KM, Turner JW. Prognostic signs and non-operative peritoneal lavage in acute pancreatitis. Surg Gynecol Obstet (now called J of Am College of Surgeon). 1976;143(2):209-19.

acute pancreatitis, and enzyme elevation is often also observed in a perforated ulcer, postoperative states, bowel obstruction and infarction, renal insufficiency and ruptured ectopic pregnancy. Serum amylase levels greater than 1,000 Somogyi units are however most frequently observed only in acute pancreatitis. The measurements of isoenzymes of amylase lend some further specificity to elevated amylase levels, but the sensitivity is not what it should be. Amylase levels in blood may fall to normal within a few days after pancreatitis. Serum lipase levels remain elevated for 7–10 days; lipase activity is perhaps more sensitive and specific compared to amylase activity. Elevated lipase levels have been reported in bowel obstruction and cholecystitis.

Patients with gallstone pancreatitis have generally much higher aspartate aminotransferase (AST), alanine aminotransferase (ALT) and alkaline phosphatase levels, compared to pancreatitis due to other etiologies.

Other routine blood and biochemical tests are done as for any patient with a serious illness; none of these are diagnostic. A low serum calcium level is often observed. Arterial pH for determining metabolic acidosis and arterial blood gases should always be estimated.

Patients presenting with suspected acute pancreatitis should undergo routine abdominal and chest X-rays, which help in differentiating pancreatitis from intestinal obstruction and perforation. Pleural effusions in a patient with severe abdominal pain should suggest pancreatitis. Pancreatitis may also be suggested by localized jejunal or colonic ileus, a widened duodenal C loop, associated radio-opaque gallstones, free fluid within the abdomen, and gas in the pancreatic bed, suggestive of a pancreatic or peripancreatic abscess.

IMAGING STUDIES

Imaging the pancreas by ultrasound[9] and CT scan studies[10] are far more sensitive diagnostic tests than the serial estimation of enzyme levels in blood. Demonstration of an enlarged pancreas by imaging techniques confirms a diagnosis. Imaging abnormalities, even in mild cases, often persist for 1 week so that this modality is useful for the retrospective diagnosis of acute pancreatitis. Both ultrasound and CT imaging should be used, as they are complimentary to each other. The presence of bowel gas or obesity interferes with the examination of the retroperitoneum by ultrasonography. Subtle changes in tissue density denoting necrosis, hemorrhage and suppuration are not easily defined by this imaging technique. However, valuable information about the biliary tree can be obtained, and ultrasonography has more sensitivity than the CT scan in picking up stones obstructing the biliary tree. CT scanning is invaluable for a study of the retroperitoneal space. Its crucial value lies in the recognition and follow-up of local complications of acute pancreatitis. It thus identifies pancreatic necrosis, hemorrhage and pancreatic and peri-pancreatic suppuration with precision.[10] It is also superior to ultrasonography in identifying high density fluid collections in the transverse mesocolon, small bowel mesentery, pararenal, perirenal, renal and paracolic spaces (see Section Imaging in the Critical Care Unit).

SEVERITY OF DISEASE

It is important for the critical care physician not only to establish a diagnosis of acute pancreatitis but also to assess its severity. Ranson's criteria[11] have been used since 1976 to assess the severity and prognosis of a patient who presents with, and is admitted for acute pancreatitis. These criteria are difficult to evaluate in a patient who is already critically ill and who then develops pancreatitis as an added complication. Many of Ranson's criteria are directed towards the systemic effects of the disease. In patients who are critically ill to start with, many of these criteria may already be present prior to the onset of pancreatitis. They are therefore of little value in assessing the prognosis and severity of the disease under the circumstances stated above. Table 1 lists Ranson's diagnostic criteria.

The acute physiology and chronic health evaluation II (APACHE II) scoring system has also been used to assess the severity and prognosis of acute pancreatitis.[12] Increased APACHE II scores correlate with increased risk of inhospital mortality, but lack sensitivity in determining acute severe pancreatitis.

Current severity indices are based on clinical and imaging findings. The severity is determined by severe persistent pain, organ failure lasting more than 48 hours. Renal failure and respiratory failure indicate severe disease.

A new bedside scoring system, the bedside index for severity in acute pancreatitis (BISAP)[12,13] (Box 3) identifies patients at a high risk of death and is probably as good as the more detailed scoring systems devised to assess disease severity.[14] The BISAP system assigns one point for each of the following signs within 24 hours of presentation.

Blood urea nitrogen (BUN) greater than 25 mg/dL, impaired mental state, systemic inflammatory response syndrome (SIRS), age greater than 60 years and pleural effusion.

Box 3: Individual components of the BISAP scoring system

BUN >25 mg/dL
Impaired mental status (Glasgow Coma Scale Score <15)
SIRS; SIRS is defined as two or more of the following—
1. Temperature of <36°C or >38°C
2. Respiratory rate >20 breaths/min or $PaCO_2$ <32 mm Hg
3. Pulse >90 beats/min
4. WBC <4,000 or >12,000 cells/mm^3 or >10% immature bands
Age >60 years
Pleural effusion detected on imaging

Abbreviations: BUN, blood urea nitrogen; SIRS, systemic inflammatory response syndrome; WBC, white blood cells.

Table 2: Severity grading based on CT

Grade of acute pancreatitis based on non-contrast CT findings	Points (A)
A. Normal pancreas	0
B. Pancreatic enlargement	1
C. Pancreatic or peripancreatic fat inflammation	2
D. Single peripancreatic fluid collection	3
E. Two or more fluid collections and/or retroperitoneal air	4
Degree of pancreatic necrosis based on contrast CT findings	**Points (B)**
A. No pancreatic necrosis	0
B. Up to 30% of the gland	2
C. 30%-50% of the gland	4
D. >50% of the gland	6
CT severity index (CTSI)	**A + B**
Mild pancreatitis	0–2
Moderate pancreatitis	3–6
Severe pancreatitis	7–10

A BISAP score greater than 3 denotes severe disease with an increased risk of complications.

The above score is to be calculated within 24 hours. A score of one is given to each of the above criteria if present. As mentioned earlier, a score greater than 3 calculated within 24 hours of presentation denotes severe disease with increased risk of complications.

The CT severity index (CTSI) is another scoring system (Table 2). It is based on CT grading (A-E) and percent of necrosis.[10,14]

The scoring systems described above in our opinion are either cumbersome or fail to take into account the changing clinical features with the evolution of the disease. The difficulties with these scoring systems led to a revised classification adopted at the recent Atlanta International Symposium held in 2012. This revised Atlanta Classification classifies fluid collections in acute pancreatitis as also the degree or severity of acute pancreatitis.[10]

Table 3: Revised Atlanta classification of fluid collections in acute pancreatitis[10]

<4 Weeks after onset	
Type of pancreatitis	*Fluid collection*
IEP	APFC • Sterile • Infected
Necrotizing pancreatitis	ANC Parenchymal necrosis alone • Sterile • Infected Peripancreatic necrosis alone • Sterile • Infected Pancreatic and Peripancreatic necrosis alone • Sterile • Infected
≥4 Weeks after onset	
Type of pancreatitis	*Fluid collection*
IEP	Pancreatic pseudocyst • Sterile • Infected
Necrotizing pancreatitis	WON • Sterile • Infected

Abbreviations: IEP, interstitial edematous pancreatitis; ANC, acute necrotic collection; APFC, acute peripancreatic fluid collection; WON, walled-off necrosis.

CRITICAL APPRECIATION OF SEVERITY GRADING OF ACUTE PANCREATITIS

The different severity scoring systems in acute pancreatitis appear to me as an organized attempt by various scientific bodies to confuse the reader! Ranson's early objective prognostic signs estimating risk of death or major complications in acute pancreatitis , as also the bedside index for severity in acute pancreatitis (BISAP) may not be very accurate but atleast can be lauded for their simplicity. No classification of acute pancreatitis can be perfect but the most recent revised Atlanta classification given below is commendable both for its simplicity, its brevity and its holistic approach to a difficult problem.

The revised current (2012) Atlanta classification[15] of acute pancreatitis suggests that the disease has two phases, early and late.

To start with, it defined three types of acute pancreatitis, interstitial edematous pancreatitis, necrotizing pancreatitis and infected pancreatic necrosis (Table 3). Severity is classified as mild, moderate and severe (Box 4).

Mild acute pancreatitis is the most common form; it exhibits neither organ failure nor any local or systemic complications; and usually responds within the first week.

Box 4: Grades of severity of acute pancreatitis according to the Revised Atlanta Classification[10]

Grades of severity

- Mild acute pancreatitis—
  - No organ failure
  - No local or systemic complications
- Moderately severe acute pancreatitis—
  - Organ failure that resolves within 48 h (transient organ failure) and/or
  - Local or systemic complications without persistent organ failure
- Severe acute pancreatitis—
  - Persistent organ failure (>48 hour)—
    - » Single organ failure
    - » Multiple organ failure

Abbreviations: BUN, blood urea nitrogen; SIRS, systemic inflammatory response syndrome; WBC, white blood cells.

Moderately severe acute pancreatitis is defined by the presence of transient (<48 hours) organ failure, local complications, or exacerbation of comorbid disease.

Severe acute pancreatitis is characterized by persistent organ failure, that is organ failure lasting more than 48 hours. Three organ systems should be assessed to define organ failure, respiratory, cardiovascular and renal. Organ failure is defined as a score of 2 or more for one of these organ systems using the Marshall Scoring System.[15]

Local complications are peripancreatic fluid collections, pancreatic and peripancreatic necrosis (sterile or infected), pseudocyst and walled off necrosis (sterile or infected).

The current classification also gave a standard template for reporting CT images.

IDENTIFICATION OF LOCAL PANCREATIC COMPLICATIONS

In a patient who progressively deteriorates, or who after a phase of significant improvement lasting from 8-10 days, again starts to deteriorate, pancreatic complications should always be suspected. These fortunately can be proven by the CT appearance of increasing pancreatic necrosis complicated often by infection of the necrotic area. CT guided percutaneous needle aspiration of areas of pancreatic necrosis or of pancreatic and parapancreatic fluid collections has been the standard recommended approach for the presence or absence of infection in these necrotic areas. Microscopic examination with Gram stain and culture of aspirated material for aerobic and anaerobic organisms should be done.[16,17] At least 30–40% of necrotic collections are found to be infected. Gram-negative infections particularly due to *E. coli*, *Klebsiella* and *P. aeruginosa* are most frequent. However, a wide variety of Gram-positive and Gram-negative organisms, both aerobic and anaerobic, and occasionally fungi have been isolated on culture.

Currently, particularly in specialized centers, CT guided diagnostic aspiration is infrequently performed. This is because of the dictum (elaborated upon later) that any operative interference in acute pancreatitis as far as possible is best avoided for at least 4 weeks after the onset of the disease. If after this period, operative interference through minimally invasive techniques is felt to be necessary, tissue for culture can be effectively taken at that point in time. Perhaps the only advantage of an earlier CT guided biopsy in a patient suspected to have an infected pancreatic or peripancreatic necrosis is to help identify an organism which necessitates a change in antibiotic or antifungal therapy

EVALUATION OF OTHER ORGAN SYSTEMS

Acute necrotizing pancreatitis is an important cause of MODS. Each organ system therefore needs careful evaluation and daily follow-up both through clinical examination and relevant laboratory tests. Involvement of the respiratory system is part and parcel of the features of severe pancreatitis. Hypoxic respiratory failure may occur without ARDS. A CT scan of the lower chest often shows presence of pulmonary involvement which has been undetected on a chest X-ray.

The evolution of ARDS is characterized by an increasing alveolar-arterial gradient, bilateral pulmonary shadows and an increasing right to left shunt within the lungs.

Renal function, liver function, metabolic abnormalities, arterial pH and blood gas changes, central nervous system (CNS) function and alteration in the coagulation profile need careful evaluation.

The numerous possible complications of fulminant pancreatitis are given in Box 5.

MANAGEMENT[1,6]

Management requires the presence of a team consisting of the critical care physician, an interventional gastroenterologist, a surgeon experienced in pancreatic surgery and a radiologist. Other specialities may need to be involved. However, management should be coordinated by a single individual who looks at the overall problem in its entirety and not solely on individual disordered organ systems.

Management includes—

- Careful monitoring of the patient.
- Relief of pain.
- Correction of hemodynamic defects, chiefly correction of volume depletion and electrolyte abnormalities. It is essential to maintain adequate oxygen transport and tissue perfusion to important organ systems during the period of acute illness, and during resolution of the inflammatory process within the pancreas.
- Correction of metabolic abnormalities.
- Control of pancreatic enzyme secretion as far as possible.
- Support to all other organ systems, particularly the respiratory and renal systems.
- Nutritional support.

Box 5: Complications of acute (fulminant) pancreatitis

A. Local—
- Pancreatic/peripancreatic suppuration and necrosis
- Pancreatic abscess
- Pseudocyst formation
- Portal vein and other venous thrombosis
- Gastric outlet obstruction and/or biliary obstruction
- Enteric fistulae
- Catastrophic GI bleeds or bleeding into retroperitoneal tissues due to pancreatic/peripancreatic inflammation destroying vessel walls, or causing erosion of splenic or other large vessels

B. Systemic—
- Multiple organ dysfunction and failure
- Respiratory - Pleural effusion, V/Q abnormalities, acute lung injury
- Renal dysfunction
- Hepatic dysfunction
- Metabolic acidosis
- Electrolyte abnormalities
- Coagulopathy
- CNS—Pancreatic encephalopathy

Abbreviations: GI, gastrointestinal; V/Q, ventilation/perfusion; CNS, central nervous system.

- Use of antibiotics.
- Treatment of local complications arising from acute pancreatitis.

Ongoing evaluation of the patient requires close cooperation between the physician and a surgeon experienced in the surgical management of abdominal complications. The decision regarding the timing and nature of the surgical intervention is based not only on the clinical features, biochemical investigations, and CT appearances, but also on clinical experience and judgment.

Careful Monitoring of the Patient

In critically ill patients, full hemodynamic monitoring is of great value, and should include heart rate, arterial blood pressure, ECG, central venous pressure, and hourly urine output. In patients with large volume deficits, or in those who are hemodynamically unstable, or have sepsis or pulmonary complications, a Swan-Ganz catheter may be necessary to measure and monitor pulmonary capillary wedge pressure, cardiac index, vascular resistances and oxygen derived variables.

Frequent examination of the complete blood count (CBC), blood chemistry, serum electrolytes and arterial blood gases are necessary to detect complications, to evaluate the function of various organ systems, and to judge the adequacy of treatment.

Serial ultrasounds and CT scans are of great importance in evaluating retroperitoneal complications.

Relief of Pain

Pain can be excruciating in the early phase. Pethidine 25 mg intravenously or 100 mg intramuscularly is preferred to morphine, as the latter can contract the sphincter of Oddi, and can theoretically worsen the pancreatitis. Buprenorphine 150 µg diluted in 10–20 mL of N saline and given slowly 8 hourly via an epidural catheter, is also effective in relieving pancreatic pain. When severe pain persists in spite of the above analgesics, epidural anaesthesia prompts quick relief, allows the patient to breathe far more comfortably and reduces the incidence of basal atelectasis so frequently observed in these patients.

Fluid and Electrolyte Restitution and Correction of Hemodynamic Defects

Volume replacement is of crucial importance. *Acute fulminant pancreatitis is in effect a massive retroperitoneal burn with an ongoing loss of fluid into the retroperitoneum, peritoneal cavity, and into the gut.* Volume requirements vary. In severe cases it may be more than 8–10 L within a period of 24 hours. The adequacy of fluid replacement in severe cases should be judged clinically, by monitoring the central venous pressure and in complicated problems the pulmonary capillary wedge pressure. The latter should be kept between 12–15 mm Hg. Fluids used for volume replacement include both colloids (IV albumin) and isotonic crystalloids. The use of the pulmonary artery catheter has its inherent risks and should be reserved for special problems as in elderly patients, patients with myocardial dysfunction and patients who manifest pulmonary congestion early during fluid replacement therapy.

It is essential to remember that *though early fluid resuscitation is important, over-vigorous replenishment of fluid predisposes to ARDS and may thereby increase the mortality in the disease.*

Potassium replacement is also invariably necessary. Blood transfusions may be necessary to counter retroperitoneal hemorrhage produced by proteolytic enzyme extravasation. Hypoalbuminemia when present, should be treated by intravenous infusions of albumin. Successful fluid resuscitation should result in warm peripheries, a good pulse volume, a normal arterial blood pressure, a good urine output and an improved mixed venous oxygen tension (PvO_2) or an improved saturation of blood in the superior vena cava.

If the patient is still hypotensive in spite of adequate fluid replacement [as judged by the central venous pressure (CVP) and pulmonary capillary wedge pressure (PCWP)], inotropic and/or vasopressor suport is mandatory. Dopamine 10–15 µg/kg per minute in a slow intravenous infusion, offers good cardiovascular support. Dobutamine may be preferred to dopamine in patients who are already vasoconstricted. Both these drugs can be used for inotropic support. Norepinephrine at 5-20µg/kg per minute may also need to given as vasopressor support. It is important to optimize oxygen delivery or transport, in the hope that perfusion improves, and oxygen uptake and oxygen utilization by tissues are increased.

Evaluation of organ perfusion is difficult. Perfusion of tissues may be inadequate even in the presence of a normal arterial blood pressure. A low PvO_2 (<35 mm Hg), and/or the presence of lactic acid acidosis, are additional pointers to hypoperfusion.

Correction of Metabolic Abnormalities

Metabolic acidosis, hyperglycemia, hypokalemia, hyperkalemia, hypocalcemia and hypomagnesemia must be recognized and treated. Restoration of fluid volume, arterial blood pressure and perfusion, generally suffice to correct the metabolic acidosis.

Control of Pancreatic Enzyme Secretion

There is no definite way of reducing pancreatic enzyme secretion in acute pancreatitis. Nasogastric suction is advisable in severe cases; it is absolutely indicated in the presence of ileus and continuous vomiting. It decreases the risk of aspiration, and may perhaps help in reducing pancreatic secretions. A H_2-antagonist or proton pump inhibitor is used intravenously to help reduce gastric acid secretion. This decreases the chances of bleeding from acute erosions, and may perhaps also help to reduce pancreatic secretions. Somatostatin in an intravenous bolus dose of 500 µg, followed by an infusion of 250 µg over 4 hours, has also been shown to suppress pancreatic secretion. However, its high cost precludes its use for many patients in our part of the world. Octreotide in a dose of 50 µg three times daily subcutaneously can be used in place of somatostatin to help reduce pancreatic secretions.

Support to Other Organ Systems

Acute pancreatitis is an important cause of multiorgan failure. Support to all failing organs is necessary.

Cardiorespiratory Support

Patients who are severely tachypnoeic with a respiratory rate greater than 35/minute, or who have a PaO_2 less than 60 mm Hg in spite of getting oxygen at 6-8 L/minute through nasal prongs or a face mask, need to be intubated and kept on ventilator support. Mechanical ventilation ensures a high PaO_2 and maximum oxygen saturation of arterial blood. The evolution of acute lung injury and ARDS requires expert ventilatory care till such time as the complication resolves. *Increased alveolar-arterial oxygen gradients with a low PaO_2 may occur in pancreatitis, without necessarily progressing to ARDS*. Support to the cardiovascular system has already been detailed earlier.

Renal Support

Renal function may deteriorate despite adequate haemodynamic resuscitation. In patients with increasing azotaemia, temporary haemodialysis or haemofiltration should be carried out till renal function returns. Recovery following a complicating acute tubular necrosis is possible with good critical care.

Correction of metabolic abnormalities and maximal support to all organ systems, such as the liver and hematological systems is mandatory.

Nutritional Support[18]

All oral feeds or nutrients are stopped in severe pancreatitis as pancreatic exocrine secretion is stimulated by intragastric and intraduodenal stimuli. The first priority is the restitution of fluid and electrolyte loss and restoration of hemodynamic stability. Once this is achieved patients are started on nutritional support. The recent trend is to use total enteral nutrition (TEN) through a naso-jejunal tube. It has been shown that early use of the gut maintains mucosal integrity and prevents translocation of intestinal bacteria into the pancreatic bed, thereby reducing the incidence of pancreatic infection, an important cause of morbidity and mortality in this disease.

Ideally the patient should be maintained in a positive nitrogen balance, though this may at times prove impossibly difficult. A total caloric intake of 25–30 kcal/kg should suffice. Proteins should supply 1–1.25 g/kg and 50–60% of the nutrient mixture should consist of carbohydrate. Hyperglycemia should be controlled by insulin so that blood sugar levels are not greater than 150 mg/dL. In patients fed enterally, a low fat diet, with fats constituting less than 20% of total calories is preferable as this minimizes pancreatic stimulation. Elemental diets that contain fat in the form of medium chain triglycerides should be used to minimize pancreatic stimulation.

Enteral nutrition may be impossible in the presence of fulminating disease associated with vomiting, distension, ileus, peritonitis and severe sepsis. In these patients nutritional support with caloric intake outlined above should be given by total parenteral nutrition. Intravenous lipid emulsions are not harmful in patients with severe pancreatitis. Nosocomial sepsis through central catheter-related infections are a grave potential danger in patients on parenteral nutrition.

Vitamins, minerals, calcium, magnesium, antioxidants also need to be given for nutritional support.

Criteria for starting oral feeds are—(i) sharp reduction or absence of abdominal pain; (ii) reduction of amylase and lipase to near normal levels; (iii) absence of complications like pancreatic fistulas and (iv) resolution of ileus with return of bowel sounds.

Antibiotics

The early stage of acute pancreatitis does not warrant the use of antibiotics. Fever at this stage is due to the systemic inflammatory response syndrome. The fever generally settles down or is low-grade after a week. If fever and clinical features return, the possibility of pancreatic necrosis and supervening infection should prompt the empiric use of antibiotics. Imipenem and meropenem are antibiotics with a good penetration into pancreatic tissue and are often used in combination with metronidazole. If the possibility of an associated fungal infection is entertained (depending on risk

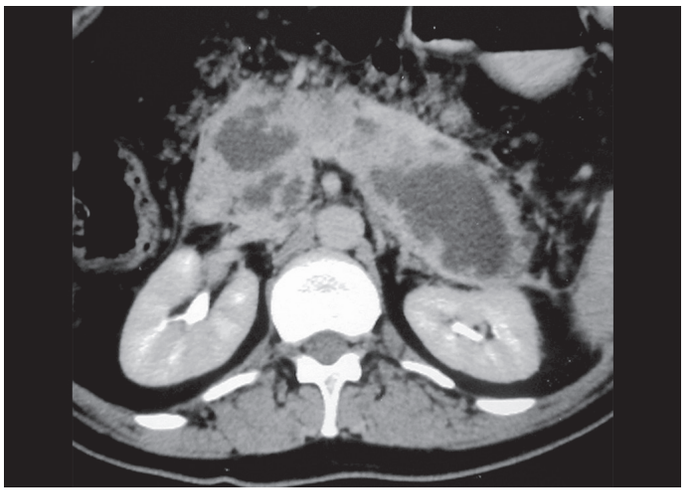

Fig. 2: Pancreatic necrosis: CT scan reveals multiple areas of necrosis in the head and body of the pancreas representing pancreatic necrosis

factors) in a given patient, antifungals may also need to be used empirically

Critical Care Management of Complications of Pancreatitis[14]

The complications that should be anticipated are—(i) pancreatic necrosis; (ii) infected necrosis, pancreatic abscess and peripancreatic suppuration; (iii) pseudocyst formation. Other complications include (iv) enteric fistulae and (v) catastrophic bleeds.

Pancreatic Necrosis

Patchy devitalization with necrosis of the pancreatic gland occurs from within a few days to a few weeks of the onset of acute inflammation. The clinical picture is one of persistent low grade fever, abdominal pain and leukocytosis. The diagnosis is made on a CT scan which shows local areas of nonenhancement. It may be impossible to determine whether the necrotic area is infected or not. A CT-guided needle aspiration with microbiological examination of the aspirate is the only method to determine whether the necrotic area is infected. The growth of aerobic and/or anaerobic organisms signifies infection. A negative culture however, does not always exclude the presence of infection in a necrotic area. Only 30–40% of patients with pancreatic necrosis get infected. Surgery should not be done if the patient has only a low grade fever, the CT findings are not suggestive of an infected necrosis or abscess, and if a CT guided aspiration of the necrotic is sterile (Fig. 2) (see later discussion on surgery).

Infected Pancreatic and Peripancreatic Necrosis, Pancreatic Abscess

Contamination of the necrotic pancreas by bacteria (presumably from the transverse colon) leads to infected pancreatic necrosis. Liquefaction of the necrotic areas produces an abscess which can be generally made out on a CT scan. CT-guided needle aspiration is positive for bacteria on Gram stain and/or a culture. The clinical course in patients with retroperitoneal sepsis can be rapidly downhill, with spiking fever, leukocytosis, tachycardia and tachypnea.

Surgical Intervention in Infected Pancreatic and/or Peripancreatic Necrosis The mortality in patients from infected pancreatic necrosis is 15–40%.[19] Death in the majority of these patients is due to fulminant sepsis with progressive multiple organ dysfunction syndrome. Surgery in fulminant necrotizing pancreatitis should be reserved only for pancreatic sepsis. However, early endoscopic retrograde cholangiopancreatography (ERCP) within 48–72 hours of the onset followed by laproscopic cholecystectomy should be performed in patients with suspected biliary calculi with or without cholangitis. ERCP along with a sphincterotomy is indicated if there is persistent hyperbilirubinemia of greater than 3 mg/dL, or a suspicion of cholangiolitic abscesses as judged by fever with chills and hyperbilirubinemia. MRCP imaging usually helps to detect an impacted stone in the bile duct.

Currently, experience of several surgeons in the field of pancreatic surgery has led to the following guidelines for surgical intervention in necrotizing pancreatitis.[20]

A. When should the surgeon intervene?

1. Surgical intervention should be reserved for infected pancreatic and/or peripancreatic necrosis.
2. Surgical intervention if thought necessary should be delayed for at least 4 weeks after the onset of acute pancreatitis. Earlier surgical intervention (i.e. within the first few weeks) is associated with a forbiddingly high mortality. One reason for this is because poorly organized necrosis (present in the early weeks of the disease) is more difficult to manage by any method than partially liquefied and walled off necrosis generally present after 4 weeks of the disease). However, prolonging surgical intervention when indicated well after 4 weeks may worsen sepsis beyond the point of no return.

   Rarely, earlier intervention (earlier than 4 weeks) is required in patients showing sharp clinical deterioration with rapidly progressive multiorgan failure in spite of maximal medical support, especially in those with obstruction of a viscus. The mortality in these patients is however extremely high.
3. Specific scenarios, such as the abdominal compartment syndrome or a perforated viscus, require urgent intervention but not necrosectomy.

B. What form should surgical intervention take?

The traditional approach has been open surgical necrosectomy. The current trend is to avoid open surgery and resort to minimally invasive techniques provided the necessary expertise is available.

Percutaneous catheter drainage, endoscopic, laparoscopic and rigid videoscopic methods are the accepted minimally invasive approaches for treating infected necrosis.

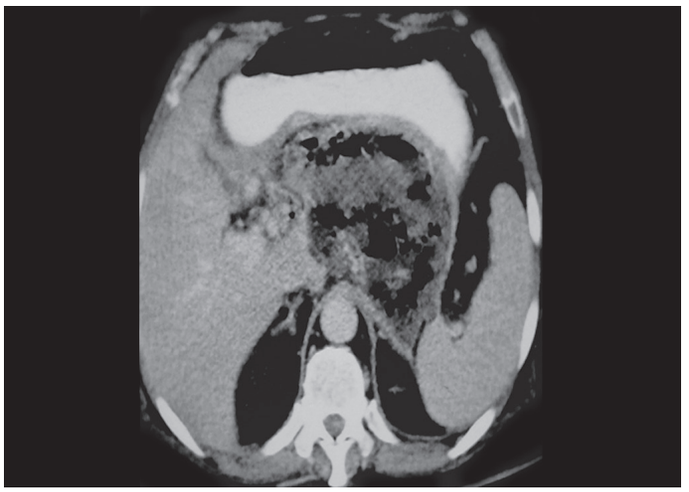

Fig. 3: Pancreatic sepsis: CT scan shows large lesser sac fluid collections with evidence of air within representing pancreatic sepsis

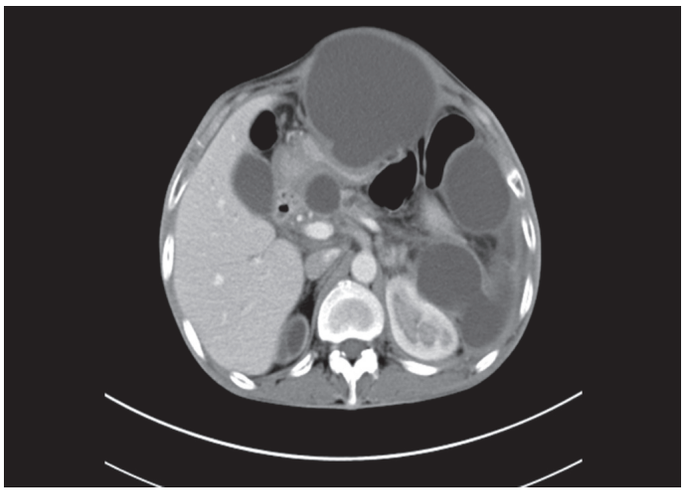

Fig. 4: Pancreatic pseudocyst: CT scan shows multiple well-defined homogenous fluid density lesions in the abdomen representing pseudocysts

The Step-up approach involves percutaneous catheter drainage followed by the minimally invasive approaches for necrosectomy mentioned above. Some patients may recover with just percutaneous drainage and may not require any further surgical intervention. Open surgical necrosectomy should remain an option only in a few selected patients. In a multicenter randomized controlled trial , the short-term and long-term results following the step-up approach has been shown to be superior to immediate open surgery in patients with infected necrosis.[21] However, no single approach is optimal for all patients. The approach is often multimodal and needs to be tailored to the requirement of an individual patient.

Critical care with maximal support is vital in all patients undergoing surgical intervention (Fig. 3).

Pancreatic Pseudocyst[14]

Fluid collections within and around the lesser sac are easily picked up by ultrasound and CT examinations of the abdomen. When sufficiently large, these collections can be palpated per abdomen. Diagnosis of a pancreatic pseudocyst does not necessitate treatment unless the cyst is infected, bleeds or ruptures into the peritoneal cavity or bowel. Repeated percutaneous aspirations of the pseudocyst may however be necessary. Definitive surgery, even for a large pseudocyst, should be delayed preferably for at least six weeks, by which time the patient is stable, and the cyst wall is thick enough to allow anastomosis between the cyst and the gut (Fig. 4).

Enteric Fistula

These occur during the phase of severe retroperitoneal inflammation associated with fulminant pancreatitis. The retroperitoneal inflammation can cause thrombosis of vessels supplying the gut; the middle colic vessels supplying the transverse colon are particularly vulnerable. Necrosis of the colonic wall leads to colonic fistula. Gastric, duodenal and small bowel perforation and fistulae can also occur. Awareness of a possibility of enteric fistulae as a major hazard of acute pancreatitis allows a quicker diagnosis and planned surgical treatment.

Catastrophic Bleeding

Severe bleeding occurs when pancreatic and peripancreatic inflammation destroys vessel walls within the retroperitoneal space or causes erosion of the splenic or other large vessels. Surgical control of bleeding may be virtually impossible in the midst of inflamed distorted tissue planes. Embolization of the vessels employing angiographic techniques to identify the bleeding vessels is the treatment of choice. Ischemic necrosis of the transverse colon can also cause bleeds into the large bowel.

CHAPTER 56

Acute Gastrointestinal Bleeding

INTRODUCTION

Gastrointestinal (GI) bleeds can occur from any part of the GI tract. Till recently, GI hemorrhage was classified into upper GI bleeds if the bleeding was proximal to the ligament of Treitz and lower GI bleed if the source of bleed was distal to the ligament of Treitz. The development of new strategic therapies has now led to proposals for a new classification. Bleeding originating from the small bowel is considered a separate entity[1,2] and the term lower GI hemorrhage is confined to bleeding from the cecum, colon and/or rectum.

Gastrointestinal bleeding is, therefore, best classified as under—

- Upper GI bleeding—source of bleeding proximal to the ligament of Treitz.
- Small bowel bleeding.
- Lower GI bleeding—source from cecum, colon and/or rectum.

EPIDEMIOLOGY

Upper GI bleeding is about five times more frequent than lower GI bleeding.[2] In the West, GI hemorrhage is more common in the elderly; the reported incidence in this population is as high as 500 cases per 100,000 people per year. The epidemiology in India and other developing countries is not well-established. Demographic trends in India as in the West also show a rising number of elderly patients in the general population. It is therefore likely that both in India and the West, the incidence of GI hemorrhage will steadily rise in the years to come.

Upper GI bleeds, in general, are more severe than lower GI bleeds and more likely to result in shock.[1] Epidemiological studies in the West have shown that despite improvement in management and therapeutic strategies, mortality has remained constant over the last 60 years.[3,4] The persistence of mortality is related to an elderly population, which has many associated comorbidities.[5,6] The high death rate is believed to be independent of GI bleeding, mortality being related to other factors.

UPPER GASTROINTESTINAL BLEEDING

General Considerations

Upper GI bleeds are a frequent cause of emergency admission to hospitals. Upper GI bleeding means bleeding from the esophagus, stomach or duodenum, arising from above the ligament of Treitz. Occasionally, blood arising from the nose, oropharynx, larynx or lungs is swallowed and either vomited as hematemesis or passed through the rectum as maelena. A careful examination and relevant investigations should distinguish such spurious GI bleeds.

Not all patients with GI bleeds require critical care. In at least 75–80% of patients, bleeding stops spontaneously and does not recur. However, about 20% of patients do not stop bleeding, or have a recurrent bleed. It is indeed difficult to predict which patient will continue to bleed or will have a recurrent hemorrhage. Intensive care is indicated in all severe bleeds, bleeds that continue or recur, bleeds in patients with cirrhosis of the liver, in elderly patients, in patients with serious background diseases, for example, ischemic heart disease, or renal failure.

Major Causes of Upper Gastrointestinal Bleed[1-3]

More than 70% of upper GI bleeds are due to acid-peptic disease—duodenal or gastric ulcer, gastric or duodenal erosions, stress ulcers or reflux esophagitis. About 15% of

Box 1: Important causes of upper gastrointestinal bleeds commonly encountered in the intensive care unit

- Acid-peptic disease—duodenal and gastric ulcers, erosions, stress ulcers, reflux esophagitis
- Portal hypertension—esophageal or gastric varices, gastropathy
- Mallory-Weiss tear
- Vascular abnormalities in the upper gastrointestinal tract, e.g. Osler-Weber-Rendu disease
- Carcinoma of stomach/esophagus
- Rarely acute pancreatitis, blood dyscrasias, or coagulation defects

upper GI bleeds are due to esophageal or gastric varices or a gastropathy caused by portal hypertension. The remaining 10–15% of bleeds are due to various etiologies. These include the Mallory-Weiss syndrome, cancer of the esophagus or stomach, vascular anomalies of the upper GI tract (e.g. Osler-Weber-Rendu disease). Acute pancreatitis may occasionally present as an acute severe GI bleed. Rarely a blood dyscrasia or a coagulation defect may present as a GI bleed.

The important causes of an upper GI bleed are listed in Box 1.

Clinical Manifestations

Bleeding from the upper GI tract, from a lesion at or above the ligament of Treitz manifests in one or more of the following ways—

- Hematemesis, which is the vomiting of fresh blood or of altered coffee ground blood.
- Maelena, which is the passage of altered blood in the form of tarry black stools. It must, however, be stressed that, in massive upper GI bleeds, maroon or bright red blood may be passed from the rectum, mimicking a bleed from the small bowel (usually ileum) or colon. Fresh blood from the rectum due to an upper GI bleed is, however, invariably associated with shock and hemodynamic instability.
- The presence of fresh blood or altered blood in the nasogastric aspirate. This may be observed—(1) when an upper GI bleed complicates a separate critical illness for which the patient is under intensive care; (2) when a patient is admitted for shock related to a GI bleed, but which, till the time of admission, has not resulted in hematemesis or maelena.
- Major bleeding in rare instances may not be easily evident, particularly in older patients. Syncope, dizzy spells, unstable angina, undue breathlessness on exertion and increasing pallor may be the initial outward manifestations of a bleed. Confusion and focal neurological signs suggesting transient ischemic attacks may occur in those with cerebrovascular disease. Rectal examination in these old patients may reveal the presence of maelena.

The manifestations of blood loss in upper GI bleeds depend on the degree and rapidity of blood loss. Hypovolemic and hemorrhagic shock have been discussed at length in the Section Clinical Shock Syndromes.

Clinical Approach to an Upper Gastrointestinal Bleed

The fundamental clinical approach should consider the following features—

- Determine the severity of the bleed and assess its effect on the hemodynamics of the circulation, and immediately initiate resuscitation by fluid replacement and transfusions in patients with moderate to severe blood loss.
- Identify high-risk patients.
- Determine the cause of the bleed by appropriate investigations and diagnostic steps. It is of interest that diagnostic procedures and therapeutic strategies are often simultaneously performed in the management of GI bleeds.

Assessment of Severity of Bleed

This has been discussed in the Section Clinical Shock Syndromes. As has been emphasized earlier, changes in pulse rate, blood pressure, skin temperature, urine output, arterial pH are all of help in estimating the degree of blood loss. Some assessment of the severity of the hemorrhage can also be made by examination of the vomitus, nasogastric aspirate and the degree of maelena. Passage of fresh blood from the rectum in an upper GI bleed always signals a massive bleed. Continuous aspiration of bright red blood through the nasogastric tube is ominous, as it signifies fresh brisk arterial bleeding.

Laboratory investigations in an acute bleed do not necessarily help, as the hematocrit and the hemoglobin may not show a significant change for over 12–24 hours.

Identification of High-Risk Patients

It is important to identify high-risk patients as soon as possible. Management in these patients should be as per a planned protocol if morbidity and mortality are to be reduced. The following factors are indicators of poor prognosis in upper GI bleeds—

- Increased age—patients over 60 years of age are at greater risk, particularly in severe bleeds or recurrent bleeds.
- The presence of shock (in particular, a systolic BP <90 mm Hg) and the necessity for multiple transfusions.
- Variceal bleeding in a cirrhotic patient—the poorer the liver function, the worse the prognosis (see Chapter Critical Care in Acute Hepatic Failure).
- The presence of a continuing bright red nasogastric aspirate, or the passage of fresh blood via the rectum.
- Bleeding from a large (>2.5 cm) gastric or duodenal ulcer.
- Hematocrit less than 30%.
- Recurrent bleeding during the same admission.
- The presence of a coagulopathy.
- The need for emergency surgery.

The factors indicating poor prognosis are listed in Box 2.

Determining the Cause of the Bleed

Hematemesis always indicates an upper GI bleed. So does the presence of fresh or altered blood in the nasogastric aspirate

Box 2: Factors indicating poor prognosis in upper gastrointestinal bleeding

- Increased age (>60)
- Presence of shock (systolic BP <90 mm Hg) and necessity for multiple transfusions
- Severe variceal bleeding in a cirrhotic patient
- Recurrent bleeding in presence of bright red nasogastric aspirate, or passage of fresh blood via rectum
- Bleeding from a large (2.5 cm) gastric or duodenal ulcer
- Hematocrit <30%
- Recurrent bleeding during the same admission
- Presence of a coagulopathy
- Need for emergency surgery

in a patient who only has maelena. Maelena in the absence of hematemesis or blood in the nasogastric aspirate suggests a bleed from a lesion in the small bowel, cecum or ascending colon. Though fresh blood is most often seen in a bleed from the large bowel or a fresh bleed from the lower ileum, it can also occur with a massive upper GI bleed. In the latter instance, hemodynamic instability is always present. The presence of hyperactive bowel sounds and a disproportionate rise in blood urea suggests an upper GI lesion. In any case, an upper GI endoscopy should prove or disprove the presence of a lesion in the esophagus, stomach or duodenum responsible for a bleed.

History and physical examination may occasionally suggest the specific disease. In a patient, who is in shock, the history should be brief and quick because of the need for emergency resuscitation. A complete history should be obtained after the patient has been stabilized. History should include the prior use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs), or the use of anticoagulants or antiplatelet drugs. A history suggestive of peptic ulcer disease prior to the present episode of bleeding may point to a correct diagnosis. A history of violent retching and vomiting prior to hematemesis suggests a Mallory-Weiss syndrome. A history of chronic alcoholism may suggest liver cirrhosis. The medical history should include past episodes of GI bleeding and their causes (if ascertained).

Clinical examination should be thorough and not just confined to the examination of the abdomen. The abdomen should be carefully palpated for tenderness, guarding, rigidity, palpable masses and percussed for the absence or presence of free fluid; auscultation of bowel sounds should never be omitted. It is important to determine the circulatory state and to look out for background comorbid disease involving other major organ systems of the body. Relevant blood and other investigations should be promptly sent for. These have been listed in the section on Management.

Management

Major upper GI bleeds are best managed jointly by an intensivist, physicians (the team should include a GI specialist), an endoscopist and a surgical team. Obviously such bleeds require intensive care. Indications for transfer to critical care in a patient admitted to the wards for a GI bleed have been mentioned earlier.

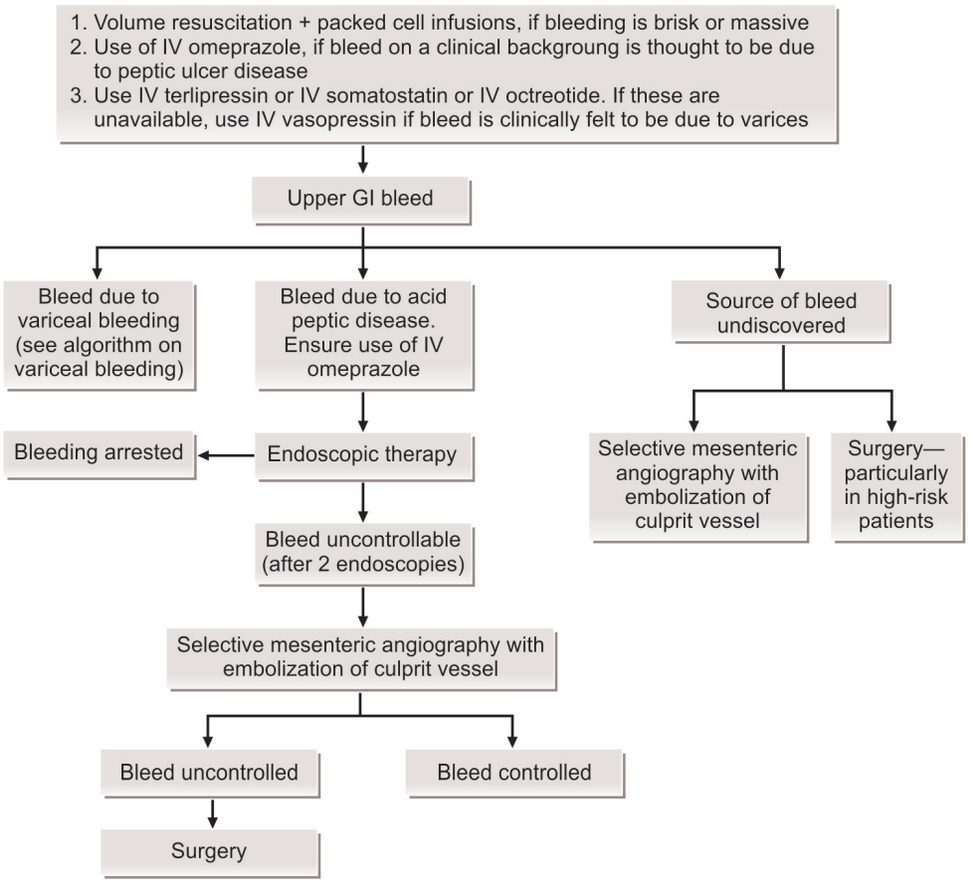
On admission, blood is withdrawn for grouping and cross-matching, as also for routine baseline hematological and biochemical parameters. A large bore catheter is inserted into a peripheral vein, and volume replacement by infusion of crystalloids (and if need be, also by colloids) started (see Chapter Hypovolemic and Hemorrhagic Shock). Investigations should include a blood count, hematocrit, platelet count, and a basic coagulation profile—clotting time, prothrombin time, partial thromboplastin time. It should always include full liver function tests including serum proteins and serum albumin concentration; serum electrolytes, blood urea, and creatinine should also be estimated. Arterial blood gas analysis is done as a baseline study and an electrocardiogram (ECG) tracing obtained. A serum amylase should always be done, as, in rare instances, acute pancreatitis may present with a severe upper GI bleed. An X-ray of the abdomen in the standing posture (if this is possible) is a routine investigation. Continuous ECG monitoring is advised, particularly in older patients, in those with a history of cardiac disease, and in those whose ECG tracing is abnormal. A Foley's catheter is inserted in patients with severe bleeds so that an hourly urine output chart is maintained. Intake/output charts are mandatory.

A central venous line is also promptly secured and connected to a pressure monitor. It is generally not necessary to monitor the left ventricular filling pressures except in those receiving massive transfusions and in older patients with known severe left ventricular disease or dysfunction. In the above high-risk group of patients, a Swan-Ganz catheter is inserted so that infusions of fluids and blood are carefully monitored to prevent pulmonary edema.

A nasogastric tube should be passed expeditiously, immediately after a peripheral vein has been secured and volume replacement started. The stomach is aspirated; the contents with regard to their nature and quantity are noted. A half hourly or one hourly chart of aspirated contents is maintained. Gastric lavage is performed through the wide bore nasogastric tube. We prefer to use iced saline to which adrenaline or noradrenaline has been added. Cold tap water probably does just as well; in fact, the current trend is to use cold tap water for lavage instead of ice cold saline. Frequent aspiration following lavage is important not only to note the degree of continuing bleed, but also to prevent aspiration into the lungs, and to allow a good view for endoscopy. At times, blood gets clotted within the stomach, and cannot be aspirated even through a very wide bore tube. Intravenous metoclopramide or IV erythromycin can help to induce gastric emptying and clear the stomach of clots and blood, so as to allow a better and more effective endoscopic view.

Meanwhile, volume replacement should be rapid and its effects should be apparent by a stable blood pressure, improved urine output and improved tissue perfusion. To replace the loss of Hb, or in a massive bleed, urgent blood

Flowchart 1: Flowchart showing management of an upper gastrointestinal bleed



1. Volume resuscitation + packed cell infusions, if bleeding is brisk or massive
2. Use of IV omeprazole, if bleed on a clinical backgroung is thought to be due to peptic ulcer disease
3. Use IV terlipressin or IV somatostatin or IV octreotide. If these are unavailable, use IV vasopressin if bleed is clinically felt to be due to varices
Upper GI bleed
Bleed due to variceal bleeding (see algorithm on variceal bleeding)
Bleed due to acid peptic disease. Ensure use of IV omeprazole
Source of bleed undiscovered
Bleeding arrested
Endoscopic therapy
Selective mesenteric angiography with embolization of culprit vessel
Surgery—particularly in high-risk patients
Bleed uncontrollable (after 2 endoscopies)
Selective mesenteric angiography with embolization of culprit vessel
Bleed uncontrolled
Bleed controlled
Surgery

transfusions are indicated. In cases where there is no time for grouping and cross-matching, O Rh-negative blood is transfused. It is preferable to give packed-cell infusions instead of whole blood whenever these are available. Over-transfusions carry the immediate risk of pulmonary edema. One unit of fresh frozen plasma should be preferably administered for every 3 units of packed red cells. The details of volume replacement have been dealt with in the Chapter Hypovolemic and Hemorrhagic Shock.

Patients with cirrhosis of the liver and patients on warfarin will have a raised INR and will need adequate infusions of fresh frozen plasma to correct these coagulopathies. Patients receiving aspirin or clopidogrel may require platelet infusions to counter platelet dysfunction. GI bleeds occurring in renal failure and uremia may respond to the administration of IV desmopressin (0.3 µg/kg), a vasopressin analogue that promotes von Willebrand factor release from endothelial cells.[7,8]

Once adequate restitution of volume and blood has been instituted and the patient is hemodynamically stable, an upper GI endoscopy should be performed. Esophagogastroduodenoscopy provides a diagnosis in more than 90% of patients scoped within 24 hours of a bleed. If this procedure is delayed for more than 48 hours, the diagnostic sensitivity drops to 33%. Endoscopy not only is essential in providing a diagnosis as the cause of the bleed, but it also provides therapeutic options. In fact, diagnostic and therapeutic procedures can be achieved at the same time. Endoscopy is not completely without risk. The complication rate is about 0.9% with an incidence of one death in 700 examinations in the acutely bleeding patient.[9] When aspiration of stomach contents is a major risk, the procedure should be done under anesthesia, after electively intubating the patient with an endotracheal tube. Continuous ECG monitoring and monitoring of oxygen saturation is imperative during the procedure.

In patients who have been bleeding and continue to bleed actively on admission, endoscopy may not be able to offer a diagnosis because of presence of large clots and fresh blood within the stomach cavity. In these patients, a selective mesenteric angiography helps to determine the vessel that is bleeding. Once an arterial source of bleeding is clearly identified on selective mesenteric angiography, the culprit vessel is embolized. The success rate (to stop bleeding) is close to 90%. Ischemic complications are rare in the upper GI tract because of the presence of many collaterals in contrast to the comparative poverty of collaterals in the lower GI tract.

The prognosis is indeed grim if selective mesenteric angiography fails to identify the bleeding vessel and the patient continues to bleed. Surgery is then the only option, but unquestionably carries a very high mortality. The therapeutic procedures (which often go hand in hand with diagnostic procedures) are discussed at greater length in the section of the Management of Specific Disorders.

Important Specific Causes of Upper Gastrointestinal Bleed

Peptic Ulcer Disease

Peptic ulcer disease is the commonest cause of an upper GI bleed. Acid peptic disease, besides gastric and duodenal ulcers, also includes gastric and duodenal erosions, stress ulcers and reflux esophagitis. The use of NSAIDs and *H. pylori* infections are important etiological factors. Severe PUD bleeding is most often due to an ulcer on the posterior wall of the duodenum eroding the gastroduodenal artery. The bleeding may stop spontaneously in the majority of patients but about 20% or more may continue to bleed. This is one condition where early use of a proton pump inhibitor (PPI) suitably increases intragastric pH and helps to arrest bleeding so that endoscopic therapeutic procedures may not be necessary.[10] PPI have been shown to be more effective than H_2 receptor antagonists or somatostatins.[11,12]

Once the diagnosis of a bleed due to PUD has been made on endoscopy, omeprazole is administered as an 80 mg IV bolus, followed by an 8 mg/hour continuous infusion for 72 hours followed by 40 mg twice daily, morning and evening for 2 weeks. These large doses of PPI have been shown to decrease the incidence of recurrent bleeding,[12-15] decrease the need for surgery and prevent the development of shock with an associated increase in morbidity and mortality. Prompt endoscopy is essential and as mentioned in the previous section, should be performed early (Flowchart 1).

Endoscopic Measures to Arrest Bleeding in Peptic Ulcer Disease

Local measures through the endoscope to stop bleeding include local injection of epinephrine, thermocoagulation and use of a bipolar probe, argon laser coagulation and application of endoscopic clips. When used alone or in combination, these methods successfully control bleeding in 90% of cases.[16] Epinephrine is injected locally in a dilution of 1:10,000; it arrests bleeding through direct vasoconstriction, through tamponade of the bleeding site if a large enough volume has been injected and through inducing increased platelet aggregation.[17,18] Rebleeding can, however, occur in 20% of patients.[13] A Cochrane database review suggested that the addition of an alternative modality to epinephrine injection, reduced further bleeding from 18.5% to 10.4%, the need for emergency surgery from 10.8% to 7.5% and mortality from 5% to 2.5% in high-risk ulcers.

Thermal coagulation is more effective in preventing rebleeding and the need for surgery but is associated with a very small risk (1%) of perforation.[19] Hemoclips are also very effective when applied endoscopically but require special expertise.

Even after endoscopic procedures have been successful in arresting bleeding, bleeding recurs in about 20% of patients with a significant increase in morbidity and mortality.

Elmunzer et al.[16] reported on the following predictive factors for rebleeding—hemodynamic instability, large ulcer (>2 cm), a posterior duodenal or lesser curvature ulcer and multiple comorbidities. The Forrest Classification has also been found to be useful in predicting rebleeding.[20] Forrest I lesions are those that are actively bleeding. Forrest II has stigmata of recent bleeding. Forrest IIa lesions are those where a nonbleeding ulcer is visible; Forrest III are lesions showing the presence of an adherent clot. Forrest III lesions show no signs of active bleeding. Forrest I and II have a high incidence of rebleeding and nearly all have a rebleeding rate of between 40% and 50% and are associated with a mortality of 11%. Endoscopic treatment is recommended for all Forrest I and IIa lesions. The treatment of Forrest III lesions is not well-defined. Most endoscopists are hesitant to remove an adherent clot for fear of rebleeding. Administration of PPIs helps to stabilize the clot and perhaps reduces the chance of rebleeding (Table 1).

Table 1: Risk factors for continued bleeding or rebleeding from peptic ulcer

Endoscopic finding	*Proportion that continues to bleed or rebleed (%)*
Arterial bleeding	90
Nonbleeding visible vessel	40–45
Adherence clot	10–25
Oozing	<20
Flat pigment spot	<10
Clean ulcer base	<5

Angiography

If bleeding fails to stop and continues to recur in spite of one or more endoscopic attempts, angiography is advised. Angiography is also promptly advised if endoscopy fails to diagnose the site of bleed or if the stomach is so filled with blood and clots that visibility through the endoscope is very poor. If a bleeding site cannot be identified through angiography, blind embolization should not be done. However, if endoscopy had identified the site of bleed, embolization of suspected vessels/vessel is often as effective as targeted embolization.[21-23] If rebleeding takes place after the first embolization, a second

embolization may be effective, the combined success rate being 95%.[21] An important complication of an angiographic procedure is acute renal failure, particularly if excessive amount of dye has been used, or in patients with a background of renal disease. Volume depletion caused by severe bleeds accentuates the nephrotoxic effect of the dye. Ischemia to the upper GI tract is rare after angiographic embolization because of the plentitude of collateral vessels in this area of the gut. Duodenal ischemia may, however, occur and should be treated conservatively with PPI.

Surgery

A small minority of patients require surgical intervention to control bleeding. It is indicated if endoscopic and/or angiographic embolization has failed to control the bleed. These patients are usually quite ill and have a higher mortality, the mortality rate after failed embolization being as high as 80%. The older the patient, the sooner must a surgery be decided upon if endoscopic and angiographic measures have failed. Recurrence of a bleed at the same admission uncontrolled by endoscopy is also an indication for surgery. The need for more than 8 units of blood in 24 hours in the presence of active bleeding is again an indication for surgery. Finally, massive bleeds with the patient remaining well-nigh pulseless with severe hypotension is in our unit an indication for emergency surgery as there is no time for any nonsurgical therapeutic procedures. Well-nigh moribund patients have come alive if the surgeon in a matter of minutes has identified and clamped the spurting artery at the base of a large peptic ulcer.

The surgical procedure of choice is oversewing of the bleeding vessels, if possible, combined with a vagotomy and pyloroplasty, vagotomy and antrectomy, or a highly selective vagotomy. Extensive surgery is not warranted because of the very effective acid-suppressive drugs available. In units where angiographic facilities for selective embolization are unavailable (and there are many such units in India and poor developing countries), surgery is indicated when (1) endoscopic attempts have failed to arrest bleeding; (2) when transfusion requirements are more than 8 units over 24 hours; (3) in patients with rebleeds and (4) in massive bleeds when there is no time for non-surgical modalities. The older the patient, the more important it is not to delay surgery under the above circumstances.

Bleeding Esophageal Varices

The management of this dangerous complication of cirrhosis of the liver has been dealt with in another chapter (Critical Care in Acute Hepatic Failure). Patients with portal hypertension may also bleed from a diffuse abnormality of the gastric mucosa, a condition called portal hypertensive gastropathy. Medical measures to counter acute bleeds are the same as in variceal bleeding. Prevention of future rebleeds may perhaps be helped by the use of propranolol 20 mg thrice daily and sorbitrate 5–10 mg thrice daily.

Stress Ulcers[24-26]

Single or multiple superficial gastric, duodenal or gastroduodenal ulcers often occur in critically ill patients. They can on occasions bleed profusely, and carry a significant mortality. It is important to prevent these ulcers from bleeding and, if possible, from forming. Patients at risk from these lesions include those with burns, head injury, multiple trauma, acute liver cell failure, acute renal failure, Gram-negative sepsis and disseminated intravascular coagulopathy. Patients on prolonged mechanical ventilation and those suffering from acute or fulminant illnesses (tetanus, *Plasmodium falciparum* infections) are also prone to acute mucosal erosions. Cook et al.[27] noted that bleeding from stress ulcers occurred only in patients who required mechanical ventilation or had coagulopathy. This is not our experience; bleeding from gastroduodenal erosions can occur in any critically ill patient with major organ system dysfunction.

Prophylaxis from stress ulcers is generally provided by the use of sucralfate as this counters acidity without unduly raising the pH of gastric contents. In high-risk cases, prophylaxis with PPIs or H_2 receptor antagonists is acceptable. If stress ulcers cause bleeding, IV PPIs should be used in large doses as mentioned under the specific management of PUD. PPIs increase intragastric pH more effectively than H_2 receptor antagonists and are believed to be more effective for prevention of gastroduodenal erosions caused by aspirin.[28]

In our unit, bleeding acute erosive gastroduodenitis from any cause is also treated by a continuous infusion of cold milk containing magnesium hydroxide and norepinephrine, given through the nasogastric tube. This generally stops bleeding. In critically ill patients in whom oral feeds are contraindicated, endoscopic methods to stop bleeding may prove effective. Failing this, angiographic therapy, either in the form of a vasopressin infusion into the left gastric artery, or embolization of the left gastric artery should be tried. *Every effort should be made to avoid surgery in these patients, as surgery carries a forbidding mortality.*

Mallory-Weiss Tear

Mallory-Weiss tear is most often observed along the esophagogastric junction. It is most common in young males who often give a history of severe vomiting or retching, coughing or straining, prior to the hematemesis. Mallory-Weiss tears are commonly associated with alcohol abuse, hiatus hernia and possibly with *H. pylori* infection. A correct diagnosis is easily made at endoscopy. Most tears stop bleeding spontaneously. Some may, however continue to bleed massively. If bleeding continues, band ligation or hemoclips usually arrest it.[29,30] Local injections of epinephrine also help. Thermocoagulation has also been tried but its use requires further evaluation. If these methods fail, arteriographic embolization or surgery may be necessary.

Aortoenteric Fistula

These invariably occur in patients who have an aortic graft in situ. The diagnosis should be suspected whenever a patient with an aortic prosthesis suffers an upper GI bleed.

The communication with the aorta can occur along any portion of the gut but is generally with the third part of the duodenum, so that the patient has both hematemesis and maelena, with all the hemodynamic effects of a severe bleed. Aortoenteric fistula usually occurs following graft-related sepsis. Endoscopy should be performed to exclude more proximal lesions. A CT scan shows gas in the retroperitoneal space. Aortography may fail at times to reveal the fistula. Treatment is surgical and should be performed as soon as the hemodynamic state has been improved by immediate rapid volume replacement. Endovascular repair has been reported,[31-33] but should be used as a temporary measure before definitive surgical repair. Endovascular repair remains an option in patients with a short life expectancy, as in those suffering from advanced cancer.

Dieulafoy's Lesion

A Dieulafoy's lesion is a large anomalous artery responsible for 2% of upper GI bleeds.[34] This lesion can occur anywhere along the digestive tract but is most frequently present in the fundus along the lesser curvature of the stomach. This bleeding site can be easily missed by even an experienced endoscopist, more so as it bleeds intermittently. Its appearance is that of 1–3 mm bleeding arteriole protruding through the mucous membrane. It is dealt with endoscopically by epinephrine injection, by electrocoagulation or heat coagulation, and/or clips. Occasionally, angiographic embolization is needed to stop the bleed. Mortality is close to 20%, particularly in older individuals, chiefly because of associated comorbidities.[34]

Even a moderate-sized bleed complicating a critical illness can markedly enhance its gravity, and ultimately be responsible for the patient's death. Finally, patients with upper GI bleeds who have large clots in their stomach are at a considerable risk for sepsis. Most of these patients have received large doses of antacids, and the additional presence of blood clots form an excellent medium for the overgrowth of dangerous Gram-negative organisms. We have seen Gram-negative sepsis kill these patients, even after definitive surgery has been successfully performed.

15

UPPER GI BLEEDS IN THE IMMUNOCOMPROMISED

Upper GI bleeds in the immunocompromised may be due to all the conditions listed above. In addition, immunocompromised patients may suffer a GI bleed because of infection by opportunistic organisms. Opportunistic infections involving the esophagus, stomach, duodenum and at times other parts of the GI tract include the cytomegalovirus, herpes simplex virus, fungal infections, notably candida, and rarely aspergillus and mucor. These infections can cause inflammation of the mucosa, erosions, ulcerations. They can be diagnosed through endoscopy, biopsy, with appropriate staining and histopathological study of the biopsy material. The prognosis is often grim in spite of appropriate specific treatment, death being due to uncontrollable bleeding or perforation.

BLEEDING FROM THE SMALL BOWEL

Till recently, bleeding from the small bowel was considered under the category of lower GI bleeding. It is best considered as a separate entity because of the newer diagnostic procedures and therapeutic applications used both for diagnosis and control of these bleeds.

Prakash and Zuckerman[35] in their cohort of 29 patients with small intestinal bleeds reported that bleeding from the small bowel had worse outcomes compared to bleeding from the large bowel.

The two most important causes of small bowel bleeds noted in our unit over several years are angiodysplasias which are noted in elderly patients as also in renal failure, and neoplasms of the small bowel. Neoplasms chiefly include adenocarcinoma of the bowel; rarer tumors like GIST tumors may also to bleed severely. Other lesions include ulcerations caused by aspirin and NSAIDs, inflammatory pathologies as in tuberculous ulcers, typhoid ulcers and Crohn's disease. A solitary jejunal ulcer, the etiology of which is uncertain, is a rare pathology that can cause a bleed and be difficult to detect. Small intestinal varices due to cirrhosis and portal hypertension can also cause brisk blood loss. Meckel's diverticulum is another source of small intestinal bleed, as is the presence of a Dieulafoy's lesion. Non-Hodgkin's lymphoma involving the small gut can also result in bleeding. Ischemia of the bowel, particularly superior mesenteric artery thrombosis (SMAT) or mesenteric vein thrombosis can result in the passage of fresh blood through the rectum. Patients on anticoagulants as also patients who develop coagulopathy can bleed from any site within the body including the small bowel. Investigations are the same as with bleeding from the upper GI tract. These have been listed earlier. As with upper GI bleeds, the first priority is the restoration of volume with crystalloids and colloids and transfusion of packed blood cells in all patients who are hemodynamically unstable because of severe blood loss.

Determining the Cause and Site of the Bleed

This indeed can be difficult. History is often not of much help. A past history suggestive of inflammatory bowel disease is important. Evidence of diffuse atherosclerotic disease in association with episodic abdominal pain may suggest ischemia to the bowel. Painless bleeding is seen with angiodysplasia, Meckel's diverticulum and arteriovenous anomalies. A history suggestive of small bowel obstruction should raise suspicion of a mitotic lesion.

Physical examination should, as with any bleed, determine the hemodynamic and circulatory state. Careful examination of

the abdomen for tenderness, palpable lumps, and for evidence of localized or general peritonitis is important. Examination of other organ systems to determine comorbidities should always be done.

Routine blood investigations are the same as with patients admitted for an upper GI bleed, establishing that the site of bleed in the small bowel is generally by a process of exclusion, e.g. excluding an upper GI bleed and a lower GI bleed.

1. An upper GI scopy is normal—it shows no pathology and the aspirated contents contain acid and bile. This should rule out a bleed proximal to the ligament of Treitz. We have, however, seen one patient where a bleed from the proximal jejunum regurgitated backward through the duodenum, leading to both hematemesis and maelena.
2. A colonoscopy is again normal—this can only be ascertained if a clear view is obtained and the colon is not filled with fresh or altered blood.
3. If both upper and lower scopies show no definite pathology, the bleeding is presumed to be from the small bowel. The following diagnostic tests are now set into motion. Diagnostic tests and therapeutic interventions often go hand in hand.

The protocol followed is detailed below—

- A standing plain X-ray of the abdomen followed by high resolution computed tomography of the abdomen with IV contrast + oral contrast are performed. Edema localized to a portion of the small gut, ulceration of the mucosa, strictures, or the typical cobblestoned mucosa of Crohn's can be picked up easily. An intraluminal mass within the small gut can also be evident. Edema of the wall of a localized segment of the gut with prominence of the mucosal folds is an early imaging sign of mesenteric artery thrombosis, which can be substantiated by mesenteric angiography.
- Enteroclysis (small bowel enema), a procedure in which contrast is instilled directly into the duodenum together with methyl cellulose and air allows better visualization of the lumen, mucosa and the wall of the small gut.
- Mesenteric angiography which can be highly selective reaching out to small vessels supplied by the superior mesenteric artery is in our opinion best suited to quickly identify the exact site of bleed. If found this can be promptly embolized.

Mesenteric angiography may fail if the bleed is intermittent and the procedure is performed at the time when the bleed has temporarily stopped or is negligible.

In the presence of a severe bleed with hemodynamic instability a mesenteric angiography should be the first diagnostic (cum therapeutic) procedure performed.

If a mesenteric angiography is noncontributory, the following tests can be done—

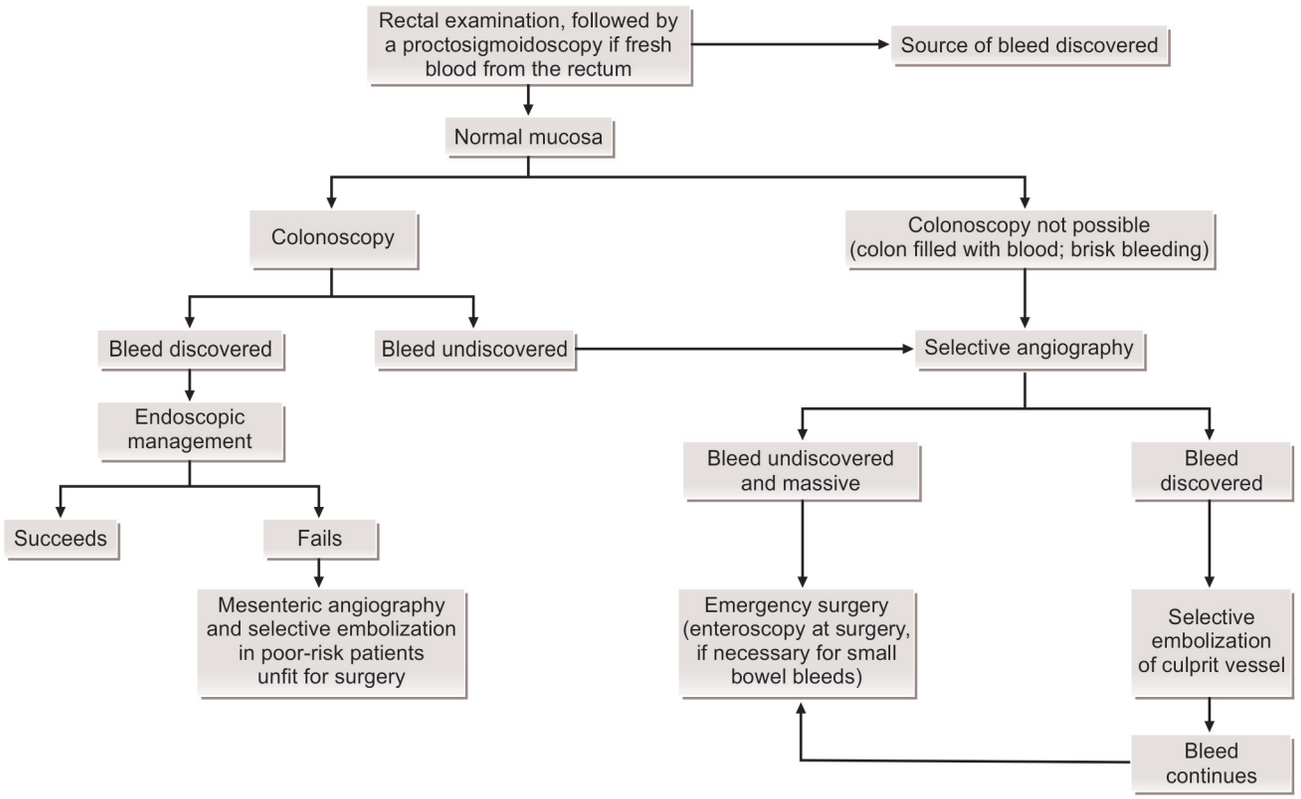
- ^{99}Tc tagged red blood cell (RBC) scan is commonly used to define the site of bleed; it, however, gives both false positive and negative results and we have rarely found this test to be useful in detecting significant small bowel bleeds.
- Push enteroscopy with a dedicated video enteroscope allows the visualization of the proximal 50–100 cm of the small bowel. This procedure can be both diagnostic and therapeutic.
- Double-balloon enteroscopy is a relatively new technique that allows complete visualization of the small bowel.[36-38] It uses a 200-cm enteroscope with two balloons, one attached to the tip of an endoscope and the other to the tip of a flexible overtube. The balloons are sequentially inflated, allowing the advance of the endoscope without looping. The enteroscope can be inserted orally or through the anus, or both, to examine the entire small bowel. This enteroscope can localize the site of bleeding, can take biopsies and also allow therapeutic interventions (adrenaline injections, thermocoagulation) to stop bleeds.
- Wireless capsule endoscopy. Capsule endoscopy is a comparatively new technique. The procedure has three components—(1) a capsule endoscope; (2) an external receiving antenna with an attached portable hard drive, and (3) a personal computer workstation for review and interpretation of images. The capsule is swallowed on a fasting stomach and the images are reviewed as the capsule finds its way down the GI tract. Adverse effects include failure of the capsule to progress through the bowel. GI obstruction or pseudo-obstruction is a contraindication to capsule endoscopy. Capsule endoscopy is reported to have a success rate of 67%[39,40] to as high as 92%.[41] The procedure does not yield reliable results during a massive bleed when the bowel is choked with blood. Unfortunately, this is just the situation where determining the site of bleed is of crucial importance. We have not found the use of capsule endoscopy helpful in situations which are urgent and where it really matters.

Our critical care and GI unit have no experience with enteroscopes. Therefore, when confronted with a severe life-threatening GI bleed not identified by an upper GI scopy or a colonoscopy, we promptly opt without further delay for a mesenteric or celiac artery angiography. If the bleeding site is determined, it is embolized. If there is rebleeding after a lapse of time, the site is embolized for the second time. If a situation arises where mesenteric angiography has failed to identify the site of bleed, we promptly opt for an emergency laparotomy. An intraoperative enteroscopy (performed through a colonoscope) is the best means for evaluating the small bowel. As yet, we have always managed to identify the site of bleed in all difficult problems by this method. Once identified, the site of bleed can be dealt with appropriately.

LOWER GASTROINTESTINAL BLEEDING

Patients with lower GI bleeding present with hematochezia or blood per rectum. It is important to note that very brisk bleeding from the upper GI tract may also present with hematochezia; these patients (as mentioned earlier), however, are always hemodynamically unstable and are invariably hypotensive.

Flowchart 2: Algorithm for bleed from small bowel or large bowel—patient presenting with fresh blood per rectum or maelena. Upper gastrointestinal excluded by an upper GI scopy



Rectal examination, followed by a proctosigmoidoscopy if fresh blood from the rectum
Source of bleed discovered
Normal mucosa
Colonoscopy
Colonoscopy not possible (colon filled with blood; brisk bleeding)
Bleed discovered
Bleed undiscovered
Selective angiography
Endoscopic management
Bleed undiscovered and massive
Bleed discovered
Succeeds
Fails
Mesenteric angiography and selective embolization in poor-risk patients unfit for surgery
Emergency surgery (enteroscopy at surgery, if necessary for small bowel bleeds)
Selective embolization of culprit vessel
Bleed continues

Note: If after colonoscopy or mesenteric arteriography, the bleed is undiscovered, a push enteroscopy or wireless capsule enteroscopy may be tried to determine the source of the bleed, provided the bleed is not massive and life-threatening and the necessary expertise is available. Push enteroscopy can be combined with therapeutic endoscopy.

Occasionally, bleeding from the right colon may present as maelena because of a longer transit time. Common, important causes of bleeding from the lower GI tract include colonic diverticulosis, angiodysplasia, inflammatory bowel disease, amebic ulcerations of the large bowel and neoplasms.

Investigations are as with bleeding from any site, and have been detailed in the section on upper GI bleeding. The importance of quick restoration of body fluids and transfusions of packed RBCs in severe bleeds must commence immediately to restore hemodynamic stability.

As with GI bleeds described earlier in this chapter, the first diagnostic modality for determining the site of the bleed is through endoscopy—colonoscopy for lower GI bleeds. If this is unrewarding, a mesenteric angiography is done. Diagnostic and therapeutic procedures run hand in hand as with the management of upper GI bleeds and bleeds arising from the small bowel (Flowchart 2). Specific diseases causing lower GI bleed will now be discussed.

Colonic Diverticulosis

Diverticulosis is common, so that bleeding from diverticular disease should be diagnosed only if active bleeding is observed to originate from diverticuli at colonoscopy. Bleeding from diverticuli in the right colon is also fairly frequent. Hence the futility of doing a left hemicolectomy in the hope of stopping bleeding in a patient with diverticular disease when the exact site of diverticular bleeding has not been identified. Bleeding in some of these patients can be massive so that colonoscopy is non-informative. Arteriography may demonstrate the bleed in these instances. The reported success rate with superselective embolization exceeds 85% and the incidence of clinically significant colonic ischemia is low (<5%).[42] If colonoscopy can identify the site of bleeding, control over the bleeding site can, at times, be achieved by the local injection of epinephrine or vasopressin. However, selective embolization offers better long-lasting results and is of obvious advantage in poor risk patients. If bleeding from the colon persists, and the patient is stable and is a good surgical risk, surgical resection of the bleeding site is often recommended. It is, however, critical to identify the bleeding site before surgery. In a retrospective review, blind resection of a "suspected" segment of the colon carries a high mortality. If colonic bleeding is profuse and the site through diagnostic procedures cannot be identified, a subtotal rather than a segmental colectomy is recommended.[43]

Angiodysplasia[37-39]

Arteriovenous malformations become increasingly common with age. The lesions are focal, submucosal and most often present in the cecum. Multiple lesions occur in less than 25%

of patients. Lesions are also often found in the ascending colon and may occur in other parts of the gut, including the small bowel. Angiodysplasia can cause a steady constant ooze of blood, which over a period of time in an elderly patient may prove life-threatening. The lesions are frequently visualized through a colonoscope and can be treated endoscopically by injecting adrenaline, by heat, or by electrocoagulation of bleeding points. It is recommended that for actively bleeding angiodysplasias, treatment should start at the periphery of the lesion so as to tackle the feeding vessels and then go to the actively bleeding area. Endoscopic treatment however carries some hazard because of the thinness of the wall of the cecum and ascending colon. As the lesion is focal, it is also amenable to treatment by arterial embolization at angiography. Continuing massive bleeding, unarrested by colonoscopic procedures or by embolization, requires surgery. Since these lesions chiefly involve the right colon, a right hemicolectomy is indicated.

Ischemic Bowel Disease[44]

Ischemic colitis can cause recurrent pain, diarrhea and bleeding per rectum. At times, the clinical picture resembles ulcerative colitis. Old age, diffuse atherosclerotic disease and atrial fibrillation are important background factors in ischemic colitis. Younger patients with diabetes, connective tissues disease, sickle cell disease and pancreatitis are also at risk. Ischemia in older patients is often precipitated by hypotension from any cause. Colonoscopy shows purplish discoloration of segments of the bowel, with focal areas of mucosal ulceration. Barium contrast studies may reveal thumb-printing of the colonic wall. Mesenteric angiography may show arterial or venous occlusion.

Management is conservative. It should ensure that the patient is not volume-depleted. The cardiac state should be improved, and the ventricular rate slowed appropriately if there is an atrial fibrillation. Fulminant disease leads to necrosis of the colonic wall, and will require surgical resection. These patients invariably have serious background disease; multiple organ failure is a common complication. The mortality in severe ischemic colitis necessitating surgery is often close to 50%.

Inflammatory Bowel Disease

The two inflammatory bowel diseases that occasionally cause massive colonic bleeds are ulcerative colitis and Crohn's disease.

Severe life-threatening continuous bleeding may necessitate emergency colectomy. Ten percent of emergency colectomies performed for the management of complications of ulcerative colitis are because of massive colonic bleed.

Massive bleeding (1%) in patients with Crohn's disease also needs emergency surgery.

Medical treatment should undoubtedly be initiated first. Endoscopy can occasionally be both diagnostic and rarely therapeutic. Angiography may also play a role in both diagnosis and therapy. Massive bleed in severe ulcerative pancolitis is, however, generalized and invariably needs subtotal colectomy and ileostomy.[45] If surgery is contemplated in massive bleeding from Crohn's disease, the site of bleed should be identified as most of these bleeds originate from lesions within the small bowel. Limited resections should be done in these patients.

Neoplasia

Massive bleeds from neoplasms as in patients with non-Hodgkin's lymphoma are uncommon. Colonic polyps can occasionally bleed spontaneously or more often after resection. Major bleeding after resection of a polyp is invariably arterial. It can be treated endoscopically with injection of epinephrine or thermocoagulation. If this is ineffective, superselective angiography with embolization of the culprit vessel is invariably successful.

Rectal Bleeding

Severe rectal bleeding is rare but can occur. It accounts for only 2% of lower GI bleeding. Hemorrhoids are the most frequent cause; severe bleeding is noticed in patients with portal hypertension, and in patients receiving anticoagulants, aspirin or clopidogrel.

Bleeding piles may, at times, hide a more proximal lesion in the proximal colon. A colonoscopy should therefore, always be done. At the same time, it should be noted that the rectal bleeding from hemorrhoids may occasionally be so profuse that blood not only leaks out but extends inward and fills the colon. At colonoscopy, a doubt arises whether there is a proximal colonic lesion (because of blood in the colon) even though there is none.

A solitary rectal ulcer is another possible cause of rectal bleeding in elderly persons. These elderly patients are often bedridden, debilitated with many comorbidities. Bleeding can be life-threatening and therapeutic approaches include endoscopic thermocoagulation, placement of vascular clips and transanal sutures.[46] An important cause of profuse rectal bleeding is from radiation-induced proctitis following treatment of prostate cancer. Radiation results in endarteritic occlusion of vessels, which is followed by the formation of multiple telangiectatic vessels that are prone to bleed. Bleeding can occur within months or even some years after radiation.

Finally, in critically ill people who are constipated with hard stools filling the colon, stercoral ulcers can be the source of severe bleeding. Pressure over devitalized colonic mucosa, poor mucosal and submucosal blood supply are the contributing factors. After careful evacuation of the bowel, injection of adrenaline and/or thermocoagulation through a colonoscope generally helps to reduce or arrest bleeding.

ACUTE ISCHEMIC INJURY TO THE SMALL BOWEL

Acute ischemic injury to the small bowel is termed acute mesenteric ischemia (AMI). It is most often due to superior mesenteric artery embolism (SMAE), superior mesenteric

artery thrombosis (SMAT) and nonocclusive mesenteric ischemia (NOMI). The latter is observed in low flow states as in shock from any cause or from prolonged hypotension.

Venous forms of AMI result from superior mesenteric venous thrombosis (SMVT).

The end results of small bowel ischemia vary from mild alteration in bowel function to marked deprivation of blood supply causing transmural necrosis, perforation and gangrene.

Acute Mesenteric Ischemia: General Features

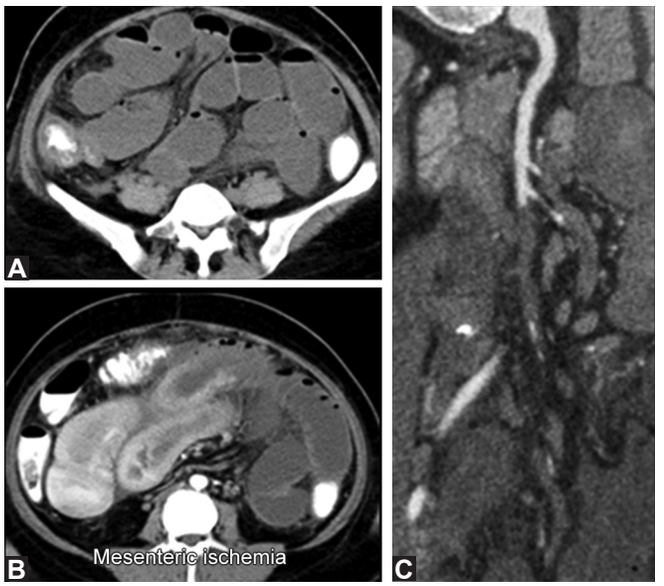
Clinical Presentation

Sudden severe abdominal pain is the first symptom of a block within the superior mesenteric artery. The presence of sudden severe abdominal pain together with a comparatively nonrigid, in fact, normal, feel to the abdomen occurring in a middle-aged or elderly individual should suggest the diagnosis. The diagnosis becomes even more likely if there is associated bleeding per rectum occurring around the time of abdominal pain or soon after it.

If the condition in the early stage is unrecognized, there is now increasing guarding, rigidity of the abdomen and absent bowel sounds. Free fluid may be detected clinically and on ultrasound. These are all features of peritonitis caused by perforation of the necrotic bowel and/or following gangrene of the small bowel following deprivation of its blood supply.

Laboratory Findings and Radiological Study

- Leukocytosis generally over 15,000/cm^3 is invariably present.
- There is a rise in serum lactate levels and around 50% have metabolic acidosis. Rise in serum amylase may offer a wrong diagnosis of pancreatitis. A rise in D-dimer has also been reported.[47]
- Blood culture may be positive as a result of bacterial translocation across the ischemic bowel.
- Plain X-ray of the abdomen is normal (other than ileus) in the standing position. However, an early sign on a high resolution CT scan of the abdomen is thickening of the ischemic bowel wall with significant edema of the mucosal folds. This involves only that segment of the small bowel which is deprived of blood. A contrast CT often shows a clear block in the superior mesenteric artery due to a thrombus. Lack of opacification of the mesenteric vein after injection of contrast is indicative of a clot in the superior mesenteric vein.
- Mesenteric angiography is the mainstay of diagnosis in both occlusive and nonocclusive form of AMI. This allows an early diagnosis, which is important for survival. Angiography has a sensitivity of 75–100% and a specificity of 100%. It also differentiates between occlusive and nonocclusive AMI in most patients. Finally, mesenteric angiography allows treatment by infusion of vasodilator or thrombolytic agents, which can be used at the same time as the diagnostic procedure and which have been shown to improve outcome (Figs 1A to C).



Figs 1A to C: Mesenteric ischemia: (A) CT scan reveals dilated small bowel loops due to ileus; (B) Distal small bowel loops reveal hyperdensity in the wall of small bowel loops as a result of hemorrhage; (C) CT angiography reveals a thrombus in the superior mesenteric artery

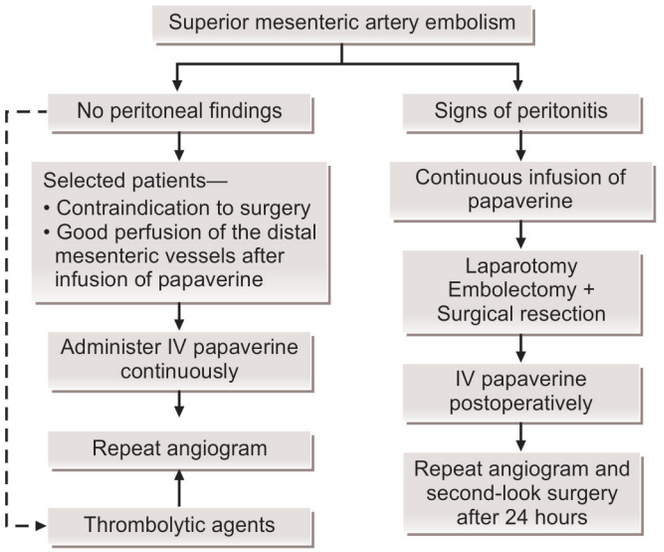
Superior Mesenteric Artery Embolism

Superior mesenteric artery embolism occurs in 50% of patients with AMI. Emboli are generally present at the origin of the superior mesenteric artery or just distal to it. At times, smaller emboli may lodge into distal branches of the superior mesenteric artery.

Treatment

- Volume resuscitation, correction of hypotension, control of congestive heart failure and/or arrhythmias should be promptly achieved.
- In the absence of peritoneal signs, infusion of a vasodilator, such as papaverine administered through the angiography catheter as a continuous drip of 30–60 mg/hour helps to produce vasodilatation of the vasoconstricted, obstructed and non-obstructed branches of the superior mesenteric artery. Relief of mesenteric vasoconstriction is important in the management of AMI from mesenteric emboli. Thrombolytic agents—streptokinase, urokinase, recombinant tissue plasminogen activator have been used with variable success in selected patients.[48,49]
- If signs of peritonitis are present, there is a unanimous agreement that a laparotomy is mandatory with the intent to restore blood flow and resect the necrotic or gangrenous bowel. Blood flow is restored by an embolectomy or arterial bypass. The surgical advice is to resect only the necrotic bowel. If a part of the bowel has questionable viability, it is left alone and a "relook" exploration, also called "second look", is performed 24 hours later. Algorithm for the management of superior mesenteric artery emboli is given in Flowchart 3.

Flowchart 3: Management of superior mesenteric artery embolism



Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia is reported to occur in 20–90% of AMIs and result from severe mesenteric vasoconstriction following poor perfusion consequent to shock or hypotension. It is often missed in the intensive care unit and then carries a formidable mortality of 70–90%. It can also occur following large volume shifts as after hemodialysis and in patients with heart failure and arrhythmias. Angiography is the only way to make a diagnosis. Once identified papaverine infusion should be started to relieve vasoconstriction and prevent further ischemia. There is a significant reduction in mortality from 0% to 50% following prompt diagnosis and treatment.[50,51] The infusion is continued and angiography repeated daily until there is no clinical or imaging evidence of persistent vasoconstriction.

Acute Superior Mesenteric Artery Thrombosis

Acute SMAT necessitates immediate surgical intervention with emergency surgical revascularization. Thrombolytic therapy, percutaneous angioplasty and the use of intravascular stents have been attempted. There are often technical problems encountered during the stenting procedure. Restenosis is an important complication.

Acute SMAT generally results from atherosclerotic disease of the superior mesenteric artery, which invariably is just one feature of generalized atherosclerotic vascular disease. Even so, procoagulant factors may be contributory and should always be looked out for, particularly in younger individuals.

Acute Superior Mesenteric Venous Thrombosis

Mesenteric venous thrombosis is comparatively infrequent occurring in 5–10% of patients with acute intestinal ischemia. Symptoms are often nonspecific and diagnosis difficult. Abdominal pain is an important feature occurring in over 90% of patients. It is often not severe and the patient may seek medical attention several days after the onset of pain. Nausea, vomiting and altered bowel habits may be present. CT may demonstrate a central lucency in the superior mesenteric vein, thickening of the bowel wall or dilated collaterals in a thickened mesentery. Angiography demonstrates a thrombosis in the superior mesenteric vein.

If there are signs of peritonitis, an emergency laparotomy is performed with resection of the involved bowel. Mesenteric venous thrombectomy also has a role in the surgical treatment. A "second look" operation needs to be done after 24 hours. Anticoagulation should be carried out routinely following surgery as anticoagulation reduces both recurrence and mortality to a significant extent.

Patients without peritoneal signs are treated with heparin followed by warfarin for a period of 6 months.

It is important to investigate for a procoagulant state in all forms of AMI, particularly in patients with SMAT and in those with SMVT.

CHAPTER 57

Hemorrhagic Disorders

GENERAL CONSIDERATIONS

Bleeding and hemorrhagic disorders are frequently observed in an intensive care unit (ICU). They are almost invariably acquired and are due to underlying disease, or are iatrogenically induced, most frequently by drugs. Rarely a congenital defect in the bleeding or clotting mechanism is uncovered for the first time in a patient admitted for an acute problem unrelated to this defect. Equally rarely, a patient with a congenital disturbance in his clotting mechanism may be admitted for the critical care of an acute severe bleed. A past history of bleeding and relevant investigations are necessary to determine the exact nature of the congenital defect. This chapter briefly outlines the inherited defects in platelet function and in coagulation that can cause severe bleeding. It also discusses at greater length the acquired disorders of platelets and acquired coagulation disorders, which are far more frequently encountered in critical care units when compared to inherited disorders.

Hemorrhagic disorders in the ICU are due to one or more of the following: (i) thrombocytopenia; (ii) a qualitative defect in the platelets; (iii) damage to capillary endothelial cells and (iv) coagulation defects.

There are some diseases, particularly renal failure, sepsis and multiple organ failure, which cause or are associated with two or more of the above defects. An awareness of the nature of acquired disorders in bleeding and clotting mechanisms, peculiar to important common critical illnesses, is of great importance in management. This is because in poor developing countries, very few centers have facilities for doing detailed coagulation profiles or studies on platelet function. Even when these facilities are available, there is a lag of precious time between the sampling of the blood and the actual results of the analysis. Treatment in severely bleeding patients is therefore empiric. It is however always wise to collect blood for a proper analysis of hemorrhagic disorders, before starting such empiric treatment. Results of such analysis may then help to suitably modify treatment.

CLINICAL APPROACH

History

A good history is all-important, particularly with reference to spontaneous bleeding in the past or to excessive bleeding, following an injury or surgery. Rarely a background suggesting a possible congenital defect in bleeding or clotting, or an acquired one as in immune thrombocytopenic purpura, will be uncovered. Previous coagulation profiles and platelet counts done in the course of an acute illness are also of help in comparing values. A meticulous history regarding intake of drugs is invaluable, as drug-induced disturbances are an extremely important cause of thrombocytopenia in an intensive care setting. Aspirin, non-steroidal anti-inflammatory drugs, the newer synthetic penicillins, ticlopidine, clopidogrel, platelet glycoprotein IIb-IIIa inhibitors, and antihistaminics are amongst the more frequently used drugs responsible for either thrombocytopenia or a qualitative defect in platelet function.

Coagulation defects may be congenital or acquired. Congenital defects, when marked, are generally evident from the history of frequent bleeds since childhood. Acquired coagulation defects are far more frequently encountered in an ICU than congenital defects. As detailed later, acquired coagulation defects occur against a background of severe liver or renal dysfunction, or following consumption of coagulation factors, or in Vitamin K deficiency, or rarely due to circulating

inhibitors of coagulation. A detailed history coupled with a careful physical examination should help uncover most of the background diseases known to produce acquired coagulation defects that result in a bleeding disorder.

Though drugs frequently affect platelets, they very rarely alter coagulation factors qualitatively or quantitatively. There are however several cephalosporins which diminish the production of Vitamin K-dependent coagulation factors. These include cefoperazone, cefamandole and the monolactams. Patients on oral anticoagulants (e.g. warfarin) or on heparin have as expected, an altered coagulation profile. It is worth remembering that, in rare instances, catastrophic bleeding can occur in a patient on warfarin, even when the alteration in the coagulation profile [i.e. the prothrombin time (PT)] is within the therapeutic range. Ten percent of these patients may bleed, and in 1–2% of these cases, the bleeding may be intracranial with catastrophic results.

Physical Examination

Physical examination should have four important objectives—

1. To determine clinically or on relevant tests, the nature of the background disease or critical illness. This suggests the cause and nature of the associated hemorrhagic disorder, which results from the disease.
2. To carefully inspect the site of bleeding or hemorrhage. Petechiae, bleeding from catheters or drains, and bleeding from the gastrointestinal tract, urinary tract and mucous membranes is more commonly observed with thrombocytopenia or a qualitative defect in platelet function. Defects in coagulation factors can also cause bleeding from these sites, but are also associated with deep soft tissue bleeds, retroperitoneal hemorrhage, hemarthrosis or bleeds into internal organs.
3. When bleeding occurs from one local site, e.g. the GI or the urinary tract, it is important to clearly exclude an anatomic cause for the bleed, even in patients with thrombocytopenia or a clotting defect. Not uncommonly, a local pathology and a hemostatic disorder may both be contributory to such a bleed.
4. Inherited disorders of platelets or of coagulation are comparatively rare in the ICU. A good family history, absence of background disease known to cause platelet and coagulation abnormalities, and detailed laboratory hematological investigations generally provide an accurate diagnosis.

Laboratory Tests

Basic screening tests to determine the cause of bleeding include a routine blood count, a platelet count, PT and activated partial thromboplastin time (aPTT). A template bleeding time (BT) was in the past generally included as a screening test to assess qualitative platelet dysfunction. It is now not performed as it was an inadequate predictor of bleeding and platelet function. Now, platelet function is assessed by automated tests, the one most frequently used being the platelet function analyzer. This automated test assesses platelet function with greater sensitivity and reproducibility. Currently, it is felt that even this test lacks enough sensitivity and specificity to test platelet function in qualitative platelet disorders.[1]

Table 1: Interpretation of prothrombin time (PT) and activated partial thromboplastin time (aPTT) in bleeding disorders

PT	*aPTT*	*Interpretation*
Prolonged	Normal	Liver disease Factor VII deficiency/defect Vitamin K deficiency
Normal	Prolonged	Hemophilia A, B, C Lupus anticoagulant Antiphospholipid antibody
Prolonged	Prolonged	Advanced liver disease, vitamin K deficiency, warfarin therapy, disseminated intravascular coagulation, fibrinogen deficiency/defect, factor II, V or X deficiency or defect
Normal	Normal	Thrombocytopenia, platelet dysfunction, α_2 antiplasmin deficiency, factor XIII deficiency

There is much that can be inferred from a *CBC*, *platelet count*, *PT*, and *aPTT*, as is evident from Table 1.

Further Tests to Assess Bleeding[2]

Thrombin Test

Many units do this test routinely for assessing a bleeding disorder. The thrombin test measures the conversion of fibrinogen into fibrin. This test is prolonged if the patient is on heparin or there is a direct thrombin inhibitor in the test system and in patients with advanced severe liver disease. The thrombin test is also positive in the presence of fibrinolysis, fibrinogen degradation products.

Test for an Inhibitor of a Coagulation Factor in the Presence of a Prolonged PT and aPTT[2]

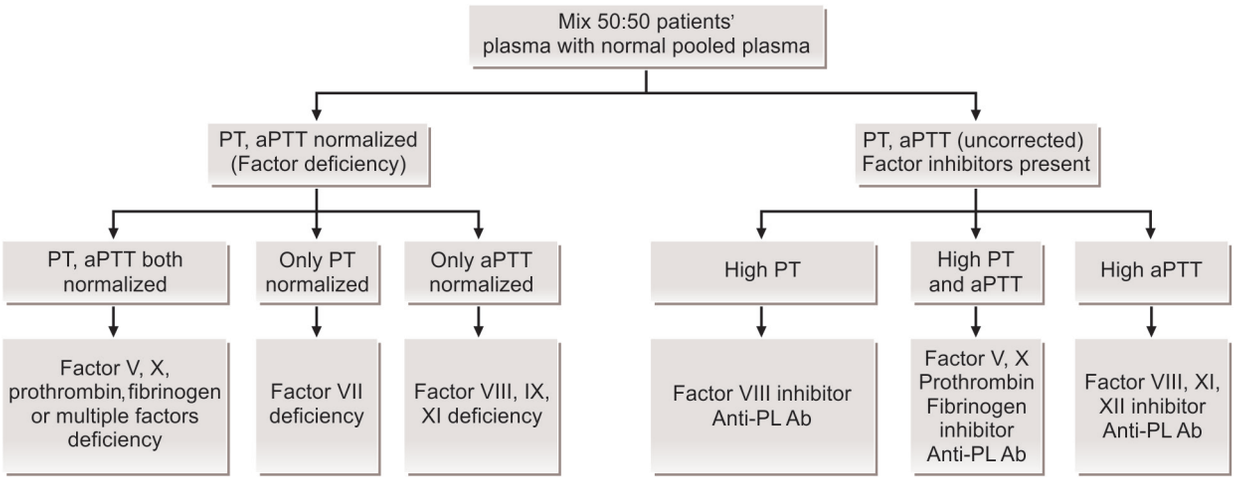
The patient's plasma is mixed with equal quantities of pooled normal plasma. The PT and aPTT are tested immediately and after 2 hours. Flowchart 1 explains the interpretation of this test.

Qualitative Platelet Defect

In the presence of normal platelet count and a Hb of at least 10 g/dL, the automatic platelet analyzer helps to detect platelet dysfunction. Special tests such as the platelet aggregation test may, however, need to be done to determine with certainty the presence and nature of platelet dysfunction.

Quantitative estimation of all coagulation factors can also be done in well-equipped specialist laboratories.

Flowchart 1: Tests to determine coagulation factor deficiency and presence of inhibitors of coagulation factors



Mix 50:50 patients' plasma with normal pooled plasma
PT, aPTT normalized (Factor deficiency)
PT, aPTT (uncorrected) Factor inhibitors present
PT, aPTT both normalized
Only PT normalized
Only aPTT normalized
High PT
High PT and aPTT
High aPTT
Factor V, X, prothrombin, fibrinogen or multiple factors deficiency
Factor VII deficiency
Factor VIII, IX, XI deficiency
Factor VIII inhibitor Anti-PL Ab
Factor V, X Prothrombin Fibrinogen inhibitor Anti-PL Ab
Factor VIII, XI, XII inhibitor Anti-PL Ab

Abbreviations: PT, prothrombin time; aPTT, activated partial thromboplastin time; Anti-PL Ab, antiphospholipid antibody.

Principles in Management

The intensivist must determine whether the hemorrhagic disorder is related to a qualitative or quantitative defect in platelets or to a coagulation disorder. Not uncommonly thrombocytopenia and/or platelet dysfunction coexist with a coagulopathy. Bleeding due to thrombocytopenia or platelet dysfunction should be treated with platelet infusions. Bleeding due to a coagulopathy should be treated by transfusion of coagulation factors through fresh frozen plasma (FFP) and/or cryoprecipitate. The nature of the coagulation defect is invariably suggested by the background disease responsible for the overall clinical problem in a given individual. Besides the routine laboratory tests stated above, a blood sample should be collected and sent to a reference laboratory for a study on qualitative platelet functions and for coagulation factor assays, if there is a detectable abnormality in the screening tests. *Treatment of the underlying disease responsible for the hemorrhagic disorder is imperative.*

Patients with bleeding or clotting disorders should not be given intramuscular injections. Blood loss should be roughly estimated and replaced. CBC and packed cell volume (PCV) should be done at necessary intervals to estimate the degree of blood loss. It may take 12–24 hours or even more, for the full effect of blood loss to manifest by a fall in the Hb or PCV, in a critically ill patient. Clinical evaluation of blood loss is therefore of prime importance.

The subsequent sections of this chapter now deal with platelet dysfunction (inherited and acquired), thrombocytopenia, and with inherited and acquired coagulation disorders.

INHERITED PLATELET DYSFUNCTION[3]

Platelets are essential for normal hemostasis. Defects in platelet adhesion, aggregation, secretion or procoagulant activity can lead to impaired hemostasis, which results in bleeding. Inherited platelet dysfunction is extremely rare, follows autosomal recessive inheritance patterns, and results in varying degrees of bleeding in neonates or in childhood. These defects are associated with a prolonged BT or absent platelet aggregation in response to platelet agonists like ristocytin, ADP, adrenaline and collagen. The coagulation profile is normal.

Bleeding associated with prolonged BT can occur with von Willebrand's disease.[4] Inherited platelet dysfunction needs to be distinguished from acquired dysfunction. Platelet aggregation studies help distinguish these two conditions. Bleeding occurring for the first time in an adult is extremely unlikely to be related to inherited platelet dysfunction.

Treatment for bleeding is the infusion of normal platelets.

ACQUIRED PLATELET DYSFUNCTION[5]

Various conditions can lead to defects in platelet adhesion, aggregation, secretion or procoagulant function without causing a significant fall in the platelet count. The most important of these are drugs. Aspirin inactivates cyclo-oxygenase and thereby prevents the production of thromboxane A_2 which mediates both platelet secretion and aggregation. Most individuals on aspirin will have a slightly prolonged BT but serious clinical bleeding is rare unless there are other hemostatic defects. However, it is always wise to stop aspirin for 5–7 days before major surgery and also before cataract surgery. Ticlopidine and clopidogrel selectively affect platelet aggregation, increase BT and may induce significant mucosal bleeds. Platelet glycoprotein IIb/IIIa inhibitors are increasingly used particularly at and after angioplasty in the management of ischemic heart disease. The use of these inhibitors is often combined with the use of anticoagulants and can at times cause catastrophic bleeding. We have seen two deaths from intracranial hemorrhage following the combined use of platelet glycoprotein inhibitors and heparin.

Acquired platelet dysfunction is common in renal failure as judged by prolonged BT (as judged by the automated plasma analyzer) and by defects in platelet aggregation.

Box 1: Important causes of qualitative platelet defects

- Associated background disease—
  - Uremia, liver cell failure
  - Myeloproliferative disorders, acute leukemia
  - Dysproteinemias
- Cardiopulmonary bypass
- Drugs—
  - Aspirin, non-steroidal anti-inflammatory drugs
  - Dipyridamole
  - Ticlopidine, clopidogrel, prasugrel
  - Platelet glycoprotein IIb/IIIa inhibitors
  - Dextrans
  - Antihistaminics, furosemide, propranolol
  - Ethanol

Remarkably enough, the risk of bleeding does not necessarily correlate with the degree of disturbance in platelet function. The exact biochemical nature of platelet dysfunction in renal failure or hepatic disease remains unknown.

Cardiopulmonary bypass induces both platelet dysfunction and thrombocytopenia. These disturbances rectify themselves within a few hours after surgery. Transient coagulation disorders also occur in the immediate postoperative period. Bleeding therefore is accentuated not only by platelet dysfunction and thrombocytopenia, but by coagulation defects and perhaps by incomplete hemostasis.

Myeloproliferative disorders, myelodysplastic syndromes, acute leukemias may result in the production of intrinsically defective platelets. Multiple myeloma, Waldenstrom's macroglobinemia are associated with the production of abnormal immunoglobulins, which can also interfere with platelet function. Important causes of acquired qualitative platelet dysfunction are listed in Box 1.

Clinical Features

The clinical features are characterized chiefly by mucosal bleeding or post-traumatic or surgical bleeding. The total platelet count is within normal limits and the coagulation profile is normal. The BT is raised. In vitro platelet aggregation studies require both experience and expertise for reliable results. They should be resorted to only in special cases with unexplained increase in BT or in patients with obscure bleeding with a normal BT and a normal coagulation profile.

Treatment

Drug-induced platelet dysfunction is treated by withdrawal of the offending drug. Desmopressin (0.3 μg/kg intravenously) is useful in the management of bleeding due to platelet dysfunction observed in uremia, liver disease and following cardiopulmonary bypass. Aprotinin, a plasmin inhibitor, is also often used to combat postoperative bleeding after cardiopulmonary bypass surgery.

Renal failure is one of the commonest causes of platelet dysfunction, and is an important cause of active serious bleeding in an ICU setting. Uremia produces a qualitative defect in platelet function, and also affects platelet adhesiveness to the capillary endothelium, by causing a defect in von Willebrand's factor. Transfused platelets may be lifesaving in severe bleeds (particularly when the bleed occurs into organ systems) in uremic patients. Cryoprecipitate (10 U)[6] and desmopressin (DDAVP) (0.3 μg/kg)[1] can both cause release of von Willebrand's factor into the circulation, and are also used to arrest the bleeding in uremia. The BT generally decreases within 1–2 hours after infusion of cryoprecipitate, and within 1–4 hours after desmopressin use. Estrogens in high doses (0.6 mg/kg per day for 5–7 days) also reduce the BT in uremic patients.[6] Bleeding in renal failure is often due to both platelet dysfunction and defects in clotting factors. The latter need to be replaced by the infusion of FFP or of appropriate coagulation factors. The bleeding tendency in patients with renal failure is decreased and more easily controlled in patients on regular dialysis and with the use of erythropoietin.

Platelet infusions should be used to counter severe bleeding due to platelet dysfunction, whatever the etiology, or for planned surgery. Drugs (in particular, aspirin) known to cause platelet dysfunction should be scrupulously avoided and the underlying disease known to cause defects in platelet function should be treated as best as possible.

THROMBOCYTOPENIA

Thrombocytopenia, i.e. a fall in the platelet count, results from decreased production of platelets in the marrow, destruction or utilization of circulating platelets or sequestration of platelets within the spleen. Important causes of thrombocytopenia are listed in Box 2. Decreased production by the marrow invariably affects all hematopoietic cells so that anemia and leukopenia are associated with thrombocytopenia. Decreased production is classically observed in extensive metastatic disease involving the marrow, lymphoproliferative diseases, myelofibrosis, myelodysplastic syndromes, aplastic anemia, and B_{12} or folic acid deficiency. Chemotherapy, exposure to radiation, drugs, and fungal, protozoal and viral sepsis can also suppress platelet production.

Increased destruction or utilization can either be mechanical or immunological. Important mechanical causes include cardiopulmonary bypass, disseminated intravascular coagulopathy (DIC), abnormal heart valves and vasculitis. Immunological destruction may result from drugs, multiple transfusions, autoimmune disease (e.g. systemic lupus erythematosus). Immune thrombocytopenic purpura is characterized by an immunological destruction of platelets occurring as an isolated disorder. Mechanical destruction of platelets is often associated with hemolytic anemia and with red blood cell (RBC) fragmentation in the peripheral smear.

Sequestration of platelets can occur in many conditions causing splenomegaly and hypersplenism. The classical example of thrombocytopenia due to hypersplenism is seen in cirrhosis of the liver with portal hypertension

Box 2: Causes of thrombocytopenia

A. *Decreased production*—
1. Marrow infiltration or replacement—
   - » Metastatic carcinoma, myelofibrosis, lymphoma, leukemia, aplasia
2. Toxic exposure—
   - » Chemotherapy, radiation, alcohol, chemicals
3. Drugs—
   - » Thiazide diuretics
4. B_{12}, folate deficiency
5. Myelodysplasia
6. Infections—
   - » Bacterial, fungal, viral, protozoal sepsis

B. *Increased destruction or utilization*—
1. Mechanical—
   - » Disseminated intravascular coagulopathy
   - » Abnormal heart valves
   - » Cardiopulmonary bypass
   - » Thrombotic thrombocytopenic purpura
   - » Hemolytic uremic syndrome
   - » Vasculitis
2. Immunological—
   - » Autoimmune thrombocytopenia
   - » Systemic lupus erythematosus, antiphospholipid syndrome
   - » Drug-induced, e.g. quinine, quinidine
   - » Chronic lymphatic leukemia, Hodgkin's lymphoma
   - » HELLP syndrome
3. Bacterial, viral, fungal and protozoal sepsis
4. Massive transfusions
5. Sequestration—hypersplenism

and splenomegaly. Anemia and leukopenia may be associated with thrombocytopenia in many patients with hypersplenism.

Clinical Features

Thrombocytopenia can cause bleeding, and the bleeding is generally from mucocutaneous surfaces. Epistaxis, bleeding gums and hematuria may occur. Petechiae are generally observed only when thrombocytopenia is marked. Spontaneous bruising is seen but soft-tissue hematomas (common in coagulation disorders) are rare in thrombocytopenia. Hemarthrosis does not occur. Severe thrombocytopenia can cause bleeding within organ systems, the most dreaded being an intracerebral bleed. Bleeding from surgical wounds, or during or immediately after surgery, is an important feature of thrombocytopenic purpura.

The risk of bleeding is, to an extent, unpredictable and depends on (1) the degree of thrombocytopenia, (2) the presence or absence of any qualitative defects in platelets, (3) the presence or absence of an associated coagulation disorder and (4) the presence or absence of associated mucosal lesions, vascular injury or trauma.

Platelet counts greater than 100,000/mm^3 do not cause bleeding. In fact surgery is safe with thrombocytopenia of this degree provided the platelets are qualitatively normal and there is no coagulation defect.

Platelet counts over 50,000/mm^3 do not cause bleeding problems, though it would be wise to avoid major surgery till the count is close to 100,000/mm^3.

Platelet counts between 30,000/mm^3 and 50,000/mm^3 generally do not cause increase in bleeding except after trauma or surgery.

When the count ranges between 20,000/mm^3 and 30,000/mm^3, the risk of spontaneous mucocutaneous bleeding increases; epistaxis, menorrhagia, hematuria and bleeding from the mouth and gums can occur.

Platelet counts below 20,000/mm^3 and particularly below 10,000/mm^3 are dangerous, can lead to severe life-threatening GI bleeds and spontaneous bleeds into viscera (e.g. intracranial hemorrhage).

Diagnosis depends on the presence of a prolonged BT, thrombocytopenia of a sufficient degree, mucocutaneous bleeding and/or petechiae, absence of other hemostatic defects and the presence of a background or associated disease known to cause thrombocytopenia.

A complete blood count and examination of the peripheral smear are important. Isolated thrombocytopenia is mostly due to an immunological cause but may occur in acute alcoholic intoxication and in hypersplenism. The presence of both nucleated RBCs and immature white blood cells in association with thrombocytopenia suggests bone marrow infiltration. Fragmented RBCs in the peripheral blood point to intravascular trauma to cells as seen with mechanical prosthetic valves, thrombotic thrombocytopenic purpura and HELLP (hemolysis, elevated liver enzymes and low platelet count) syndrome. Palpable purpuric lesions are often observed in vasculitis. Macrocytosis and pancytopenia are observed in B_{12} deficiency, particularly in strict vegetarians, whose B_{12} intake is very poor. Bone marrow aspiration and biopsy will help uncover important diseases that reduce production of platelets.

A coagulation disorder should be excluded by doing basic tests such as PT and the partial thromboplastin time (PTT). Disseminated intravascular coagulopathy is associated with an increase in both PT and PTT as also a thrombocytopenia. Other severe coagulation disorders are associated with an abnormal coagulation profile and a normal platelet count.

von Willebrand's disease or a qualitative defect in platelet function should be considered when mucosal bleeding is associated with a prolonged BT but with no thrombocytopenia.

Treatment

The principles of treatment are as follows—

- ❑ To diagnose and treat the critical illness responsible for the platelet disorder. Thus, steroids are used in idiopathic thrombocytopenic purpura or for SLE; myeloproliferative diseases responsible for thrombocytopenia merit specific treatment.

- To omit drugs which may be primarily responsible for, or which could accentuate an existing qualitative or quantitative defect in platelets.
- To replace platelets with platelet infusions.

The mere occurrence of thrombocytopenia does not merit platelet infusions. Patients do not usually bleed unless platelet counts are less than 20,000–30,000/mm^3. Platelet counts between 50,000/mm^3 and 80,000/mm^3 are generally safe for minor invasive ICU procedures, e.g. inserting or changing central lines. If surgery is necessary for a critically ill patient in the ICU, platelet levels between 80,000/mm^3 and 100,000/mm^3 are considered safe. These levels should be maintained during the surgical procedure and for 48 hours after surgery; the same levels should also be maintained during episodes of active bleeding.[7]

Platelet infusions can increase the platelet count in thrombocytopenia. Ordinarily, the infusion of one unit of platelets in an adult should produce a rise in the platelet count by 5,000–10,000/mm^3. If this increase is not observed, single-donor pheresis platelets or group-specific platelets may be given. Intravenous IgG (1 g/kg for 3–5 days) may also be given,[7] though it is effective in less than 50% of cases. Platelet infusions should preferably be given only when thrombocytopenia causes bleeding or when surgery is planned in a thrombocytopenic patient. Platelet transfusions should also be given prophylactically, particularly in critically ill individuals, whose platelet counts are less than 10,000/mm^3.

Platelet transfusions are not generally indicated in idiopathic thrombocytopenic purpura, which is treated with corticosteroids (60–80 mg prednisolone daily) and intravenous IgG. However, platelet infusions may need to be given initially to counter a life-threatening bleed in these patients. Platelet transfusions should as far as possible be avoided, and may, in fact, be harmful in thrombotic thrombocytopenic purpura, hemolytic uremic syndrome and heparin-induced thrombocytopenia.

Very occasionally heparin, which is used very frequently as an anticoagulant in the ICU, can cause thrombocytopenia, and can result in venous and even arterial thrombi. This is due to heparin-induced platelet aggregation. Thrombocytopenia (<50,000/mm^3) necessitates withdrawal of the drug, and oral anticoagulation should be substituted for heparin.

Platelet replacement by infusions has one major drawback. The half-life of platelets is short, so that within a day or two, fresh replacements are necessary. Antibodies to transfused platelets soon develop, and besides causing untoward reactions, further reduce the life-span of the transfused platelets.

INHERITED COAGULATION DISORDERS[4,8,9]

Inherited coagulation disorders are uncommon and rarely met with in a critical care unit. The pattern of inheritance is dominant or recessive, or autosomal or X-linked; rarely it results from a new mutation of a gene. In the latter instance, the family history is noncontributory to the diagnosis. A personal history often reveals previous episodes of bleeding except when the inherited defect is mild or there has been no previous challenge to hemostasis (e.g. trauma or surgery). Inherited coagulation disorders can involve any one of the several coagulation factors responsible for blood clotting. The three commonest and most important of these disorders are von Willebrand's disease, hemophilia A and hemophilia B.

von Willebrand's disease[4] results from the deficiency of von Willebrand's factor due to an inherited autosomal dominant defect in its production. This factor is essential for platelet aggregation and also serves as a carrier for procoagulant factor VIII. The disease therefore affects both platelet function and coagulation. Severe defects can cause serious bleeding similar to that observed in patients with hemophilia A.

Hemophilia A is the commonest of inherited coagulation defects and is believed to occur in 1 in 5,000 men. It is due to inheritance of an X-linked autosomal recessive mutation in the factor VIII gene that results in a mild (>5% activity), moderate (1–5% activity) or severe (<1% activity) deficiency in the production of this factor. Hemophilia is a disease of males, the female serving as the carrier. Very rarely, it may occur in females from the inheritance of two abnormal X chromosomes—one from the affected father and one from a carrier mother.

Hemophilia B results from the inheritance of an X-linked autosomal recessive mutation in the factor IX gene which results in a diminished production of factor IX. It exactly resembles hemophilia A; however, a severe deficiency of factor IX occurs only in 50% of cases. Hemophilia B is ten times less common than hemophilia A, occurring in about 1 in 50,000 men.

Inherited deficiencies of other coagulation factors are autosomal and generally recessive in nature. They are extremely rare and are observed in consanguineous marriages. Bleeding disturbances are usually not as severe as in hemophilia A and B, and, as mentioned earlier, are very rarely met with in critical care units.

Clinical Features

A careful personal history and a family history will suggest the nature of the coagulation disorder as also its pattern of inheritance.

Bleeding can occur spontaneously but it often occurs or is reported after dental extraction, trauma or surgery. In von Willebrand's disease, platelet function is also affected, so that easy bruising often occurs. In hemophilia, spontaneous bleeding from the nose, the GI tract, the urinary tract and, most importantly, into joints (hemarthrosis) is common. In patients in whom factor VIII is grossly deficient, exsanguinating hemorrhages can occur spontaneously into soft-tissues, retroperitoneally, and into various organ systems. Intracranial hemorrhage is catastrophic and generally fatal.

Laboratory Tests

Deficiency of factors II, V, VII, VIII, IX, X, XI, XII and XIII can be determined by special techniques. The diagnosis

Table 2: Principles for factor replacement in inherited coagulation disorders

Factor deficiency	*Hemostatic requirement (%)*	*Source*	*Dose*	*Interval between doses*
Factor VIII	25–30	Purified factor VIII Recombinant factor VIII	10–15 units/kg—minor bleeds 30–40 units/kg—major bleeds 10–15 units/kg—minor bleeds 40–50 units/kg—major bleeds	12 hours
Factor IX	20–30	Purified factor IX Recombinant factor IX	10–20 units/kg 100 units/kg, then 7.5 units/kg/hour	24 hours
Factor II	20–40	Fresh frozen plasma (FFP) Purified prothrombin complex concentrate (PCC)	15 mL/kg, then 5–10 mL/kg 20 units/kg, then 10 units/kg	24 hours
Factor V	15–25	FFP	20 mL/kg, then 10 mL/kg	12–24 hours
Factor VII	10–20	FFP Recombinant factor VII Purified PCC	20 mL/kg, then 10 mL/kg 60–100 µg/kg 30 units/kg, then 10 units/kg	4–6 hours
Factor X	10–20	FFP Purified PCC	15–20 mL/kg 10 units/kg	24 hours
Factor XI	10–20	FFP	15–20 mL/kg	12–24 hours
Factor XIII	3–5	FFP	5 mL/kg	1–2 weeks
Fibrinogen		Cryoprecipitate	1–2 bags/10 kg	48 hours
von Willebrand's factor	25–50	Desmopressin Cryoprecipitate	0.3 µg/kg/30 minutes 30 units/kg	24–48 hours 12 hourly for a day, then every 24 hours

of von Willebrand's disease is made on the basis of a low von Willebrand's factor antigen, an abnormal ristocetin cofactor activity and a factor VIII activity, which is generally reduced. Quantitative defects in von Willebrand's factor can be distinguished from qualitative defects by special techniques.

Differential Diagnosis

Bleeding from inherited coagulation disorders must be distinguished from bleeding caused by acquired coagulation disorders. The differentiation is evident from the history and the presence of background disease in patients with acquired coagulation defects.

It is to be remembered that abnormal coagulation tests are not always associated with bleeding. Thus, a positive lupus anticoagulant test is associated with thrombotic rather than bleeding phenomena.

Mild coagulation defects may be associated with minimally prolonged or normal coagulation tests and may result in bleeding only in the event of vascular injury.

Bleeding in the presence of normal coagulation tests suggests thrombocytopenia, or a qualitative defect in platelets, an underlying vascular defect (if there is bleeding from a single source), vasculitis, excessive fibrinolysis or factor XIII deficiency.

In patients with inherited coagulation defects, the frequent infusions of a deficient factor may induce antibodies to this factor so that subsequent infusion of this factor may not be as effective as before. Antibodies or inhibitors to factor VIII in hemophilia A can cause problems in the management of this serious disorder.

Management

Factor replacement Patients with inherited coagulation disorders need replacement of the appropriate deficient factor either when they bleed or in preparation for surgery as also in the postsurgical period (Table 2).

Surgical procedures in these patients should be performed only in centers with good laboratory facilities and good blood banks. Intramuscular injections and aspirin are avoided in patients with coagulation defects. Patients who develop inhibitors to the deficient factor can cause problems in management. The problem is usually circumvented by using larger volumes of the deficient factor as replacement therapy or by using products that bypass the factor inhibitor, e.g. activated prothrombin complex concentrate with factor VIII inhibitor bypassing activity, recombinant factor VIIa or porcine factor VIII in patients who develop inhibitors to factor VIII in hemophilia A. Plasmapheresis is at times resorted to in order to reduce the circulating inhibitory factor.

Adjuvant factors Adjuvant factors of help are desmopressin, antifibrinolytic agents (aminocaproic acid) and topical agents such as fibrin glue, and collagen preparations applied to local sites of bleeding.

Desmopressin (0.3 µg/kg intravenously over 15–30 minutes) raises both von Willebrand's factor and factor VIII to 2–5 times the prevailing level within 30 minutes. It is useful to arrest bleeding in von Willebrand's disease

and in patients with mild factor VIII deficiency. The use of desmopressin may obviate the need for factor replacement in mild bleeding episodes and may reduce the quantity of factor replacement in patients with moderate and severe bleeding episodes. It is to be noted that severe hemophilics or patients with a qualitative defect in von Willebrand's factor will not respond to desmopressin and will need factor replacement therapy.

Some units use antifibrinolytic agents as adjuncts to factor replacement therapy to control severe bleeding in inherited coagulation disorders. Contraindications to their use are the occurrence of intravascular coagulopathy or the use of prothrombin-activated complex. The dose of aminocaproic acid for the control of active bleeding is 1 g/hour till bleeding is controlled (maximum 24 g), followed by a maintenance dose of 6 g intravenously or orally every 6 hours for 7–10 days. Tranexamic acid is an antifibrinolytic agent given in a dose of 10 mg/kg intravenously or 25 mg/kg orally three to four times a day, one day before surgery or during bleeding. It should be continued for 2–7 days.

ACQUIRED COAGULATION DEFECTS

Coagulation defects in critically ill patients in the ICU are most frequently observed in liver disease, renal disease, sepsis, DIC and following massive transfusions. They may also be observed with Vitamin K deficiency. Oral anticoagulants like uniwarfarin are given in a dose sufficient to produce a controlled coagulation defect. As mentioned earlier, severe and even catastrophic bleeding can occur even when the altered clotting mechanism is within the therapeutic range. Very rarely inhibitors against various coagulation factors may develop, and lead to a serious bleeding diathesis.

From the overall clinical point of view, acquired coagulation disorders or defects are invariably characterized by deficiency of multiple factors, and are also frequently associated with thrombocytopenia and/or a qualitative defect in platelet dysfunction. The clinical features are varied and often dominated by the background disease; an abnormal coagulopathy is just one manifestation of this underlying disease process.

Clinical Diagnosis

A good clinical history, physical examination and basic laboratory screening tests to determine the coagulation profile generally suffice to help diagnose the nature of the coagulation defect.

The clinical features are characterized by bleeding, the presence of background disease known to cause an acquired coagulation defect and the laboratory evidence of a coagulation disorder.

Bleeding can be spontaneous, or excessive bleeding may result from surgical procedures. A disruption of vascular or mucosal integrity can lead to profuse bleeding. This is particularly observed in cirrhotics with varices due to portal hypertension or those with one or more mucosal ulcers in the GI tract. These patients bleed profusely into the gut and present with exsanguinating hematemesis or melena.

Spontaneous bleeding may occur from the mucosa at various sites, can result in bruising of the skin, soft-tissue hematomas, retroperitoneal hematomas, and hematomas or bleeds into organ systems. However, petechiae so often seen in severe thrombocytopenia or platelet dysfunction do not generally occur in patients with acquired coagulation defects.

Disseminated intravascular coagulopathy is one condition in which bleeding may be associated clinically with intravascular thrombosis in various organ systems.

A brief resumé of the nature of clotting defects found in the clinical conditions mentioned earlier is given below.

Liver Disease[10,11]

Multiple coagulation abnormalities are invariably present in patients with advanced liver cell dysfunction. The liver synthesizes all coagulation factors except factor VIII and von Willebrand's factor. It also synthesizes other regulatory proteins including α_1 antiplasmin, protein C, protein S and antithrombin III. The liver is responsible for the clearance of activated clotting factors, and the degradation products of fibrin and fibrinogen. Liver dysfunction prevents Vitamin K from being effective in the synthesis of Vitamin K-dependent clotting factors resulting in a functional Vitamin K deficiency. There is also impaired fibrin polymerization due to increased fibrin degradation products and accelerated fibrinolysis. Finally, thrombocytopenia or a qualitative defect in platelet function may be associated with the coagulation abnormalities described above.

Bleeding in severe liver disease is therefore multifactorial and is invariably due to a deficiency of several coagulation factors. The PT is elevated; it is a sensitive index of liver cell function. Later the aPTT is also prolonged due to low levels of factors IX and X. Patients with severe liver disease cannot utilize Vitamin K; the PT therefore remains high and unchanged after Vitamin K therapy. The decreased levels of protein C and a decreased clearance of activated clotting factors predispose to the development of DIC. The accelerated fibrinolysis, and the associated thrombocytopenia and platelet dysfunction can contribute strongly to bleeding in some patients.

Treatment of severe bleeding in liver disease may be individualized according to the deficiency of one or more factors, as evinced from a study of the coagulation profile. This may not be possible if an elegant sophisticated laboratory back-up is unavailable. In any case, acute bleeding necessitates urgent replacement of clotting factors. This is best achieved by infusion of FFP. Six to ten units of FFP may have to be infused to raise the clotting factors to a level that arrests the hemorrhage. The short half-life of clotting factors necessitates frequent use of FFP, which may easily precipitate a fluid overload in critically ill patients. When patients cannot tolerate the large volume of FFP necessary to stop the bleed, exchange transfusions with replacement by FFP may be life-saving. Continuous arteriovenous hemofiltration is an

alternative method of reducing fluid overload in such patients. An infusion of cryoprecipitate (8–10 units) becomes necessary when the fibrinogen level falls close to or below 100 mg/dL.

Platelet transfusions may also be necessary because of quantitative or possible severe qualitative defects observed in liver cell dysfunction. Thrombocytopenia in chronic liver cell disease is however often due to hypersplenism. In these patients platelet infusions do not produce the expected increase in the platelet count.

Factor IX concentrates (activated prothrombin complex concentrates), which are rich in Vitamin K-dependent factors, can be selectively used to counter hemorrhage in acute hepatocellular failure. The main advantage is a reduced volume load. The disadvantages are the risk of blood borne viral infections and of thrombotic complications including DIC.

Prophylactic infusions of FFP or of selective clotting factors found to be deficient in patients with liver disease, may need to be given before any emergency or elective major surgery.

Renal Disease[6]

Uremia in renal failure very frequently produces platelet dysfunction and a deficiency of clotting factors. Management of platelet dysfunction has been outlined earlier. Clotting factors are replaced by FFP, or by selective replacement of one or more deficient factors. Hemodialysis improves bleeding tendencies in renal failure. In the presence of acute bleeding requiring emergency infusions of large volumes of FFP and of packed RBCs, a continuous arteriovenous hemofiltration is necessary to avoid fluid overload.

Disseminated Intravascular Coagulopathy[12-16]

Disseminated intravascular coagulopathy occurs as a result of abnormal activation of coagulation and clotting factors because of vascular injury, release of precoagulant factors into the blood or both. This leads to consumption of coagulation factors (consumption coagulopathy), and of platelets, and is accompanied secondarily by increased fibrinolysis. A generalized bleeding tendency results with bleeding from the mucosa, puncture sites and surgical wounds. The clinical spectrum ranges from small thrombi in multiple organ systems that can result in organ dysfunction on the one hand, to profuse bleeding on the other. Evidence of both thrombi and active bleeding may be present. The presence of small thrombi in the microcirculation leads to tissue hypoxia. Widespread thrombi together with bleeding produce the features of purpura fulminans, with skin necrosis and gangrene of fingers and toes, or even of distal portions of the extremities. Multiple organ dysfunction chiefly involves the kidneys, liver, lungs, skin and the central nervous system.

There are numerous causes of DIC. The most important cause is bacterial sepsis, and in tropical countries, fulminant *Plasmodium falciparum* infections. Other fulminant infections can also produce a DIC. The next most common cause observed by us in our setting is the presence of obstetric complications—in particular eclampsia, retained dead fetus and abruptio placenta. In Southern India, and in other snake-infested regions of the world, viper bites are an important cause of DIC. Severe burns, crush injuries, trauma, malignancies and acute leukemias are other conditions causing DIC. A consumption coagulopathy should always be suspected whenever there is bleeding or evidence of thrombotic episodes or both, in the clinical conditions given in Box 3.

Box 3: Important background diseases causing disseminated intravascular coagulopathy in the ICU

- Infections: bacterial, fungal, viral, protozoal, e.g. *P. falciparum* infection
- Obstetric complications: ectopic pregnancy, abruptio placenta, retained dead fetus, septic abortion, amniotic fluid embolism
- Massive trauma, crush injuries
- Burns
- Snake bite
- Neoplasms, acute leukemias
- Vascular disorders, presence of prosthetic devices, giant hemangiomas, aortic aneurysm
- Miscellaneous causes, e.g. acute lung injury, acute pancreatitis, blood transfusions, hyperthermia, hypothermia, severe hypotension, hypoxia

The laboratory diagnosis of DIC is not always easy. In low-grade DIC, the synthesis of coagulation factors and platelet production keep pace with the increased consumption. Screening coagulation studies may be normal in these patients. The only laboratory abnormality may be a rise in the fibrin degradation products.

In the more severe form of DIC that is generally observed in an ICU setting, bleeding is invariably present. The patients show a prolonged PT and PTT, thrombocytopenia, hypofibrinogenemia and increased fibrin degradation products. None of these tests are sensitive or specific enough to conclusively establish a diagnosis of DIC. Coagulation defects in severe liver disease may at times be impossibly difficult to differentiate from those in DIC. The factor VIII levels are generally not significantly diminished in liver cell failure, but are severely decreased in DIC. Also, the presence of circulating fibrin monomers as judged by a positive protamine sulfate test or the presence of cross-linked fibrin as judged from a positive D-dimer test generally points to DIC.

Schistocytes (fragmented RBCs) may be found in patients with DIC. When present, DIC should be distinguished from microangiopathic hemolytic anemia. The latter condition is observed in thrombotic thrombocytopenic purpura, hemolytic uremic syndrome and the HELLP syndrome. Microangiopathic hemolytic anemia is however characterized by hemolytic anemia, fragmented RBCs in the blood smear, thrombocytopenia, without alteration of the coagulation profile. It can therefore be distinguished from DIC.

In the final analysis, it is the clinical background which prompts the diagnosis of DIC in a critically ill, bleeding patient, who has an elevated PT, a reduced platelet count and an increase in the serum levels of fibrin degradation products.

Management

Disseminated intravascular coagulopathy is a manifestation of a serious underlying disorder, and management should always be primarily directed towards the disease. Sepsis needs to be countered by appropriate antibiotics, and surgical drainage or intervention should be promptly instituted whenever indicated.

Serious bleeding is countered by fresh blood transfusions and by transfusions of FFP in sufficient quantity so as to decrease the PT to within 2–3 seconds of normal. Cryoprecipitate may be infused to maintain fibrinogen levels above 100 mg/dL and platelet concentrates given to raise the platelet count to greater than 50,000/mm^3. Unfortunately, as stated earlier, both platelets and clotting factors have a short half-life, so that the effects of these infusions are very transient. We have never used heparin in DIC. Its use in lower doses has been advocated in purpura fulminans, in DIC complicating acute leukemia and in patients with low-grade DIC due to solid tumors manifesting as small widespread thrombi in various organs of the body. Secondary fibrinolysis invariably accompanies DIC. Antifibrinolytic agents are generally contraindicated because of the risk of inducing widespread thrombosis. Some units however persist with the use of epsilon-aminocaproic acid in patients with severe fibrinolysis and with no evidence of thrombotic complications.

It should be noted that massive external or internal bleeding can cause a consumption of clotting factors and mimic DIC. In this situation, though the consumption and depletion of clotting factors and platelets may result in a serious increase in bleeding tendency and a rise in the fibrin degradation products, formation of thrombi in the microvasculature of various organ systems does not occur.

Primary fibrinolysis is a very rare bleeding disorder and results in a rapid dissolution of fibrin clots, destruction of fibrinogen and consumption of plasminogen and its inactivators. It has to be distinguished from DIC. Primary fibrinolysis is not associated with intravascular thrombi nor with thrombocytopenia.

15

Massive Transfusions[17]

Patients receiving large volumes of blood in the form of packed RBCs or stored whole blood will develop thrombocytopenia and a deficiency of labile clotting factors. Platelet infusions must be given to these patients to maintain a platelet count close to 100,000/mm^3, and FFP is infused to counter Factors V, VIII, and other clotting factor deficiencies. If necessary, cryoprecipitate should also be infused to maintain fibrinogen levels above 100 mg/dL. Usually, 1 unit of FFP is given after every 4 units of packed RBCs, and 4–6 units of platelets after every 10 units of packed RBCs. If the patient continues to bleed in spite of adequate replacement, other causes for bleeding should be sought. Local pathologies in the gut, notably stress ulcers, are often responsible for severe GI bleeding. Bleeding in patients, who have sustained severe traumatic injuries or who have been in shock due to poor tissue perfusion, could be due to a DIC.

Vitamin K Deficiency

Vitamin K is necessary for the synthesis of a number of clotting factors—Factors II (prothrombin), VII, IX, X and Proteins C and S. This vitamin is present in green vegetables, and is also synthesized by bacteria in the intestinal lumen. Vitamin K deficiency occurs in seriously ill patients, particularly when they are on broad-spectrum antibiotics. Obstructive jaundice can also lead to vitamin K deficiency. Malabsorption from any cause does the same. Patients on oral anticoagulants (like warfarin) have an induced vitamin K deficiency, as these anticoagulants inhibit its metabolism in the liver. Aspirin in high doses as well as certain cephalosporins are known to induce a deficiency of vitamin K-dependent coagulation factors; this can be reversed by administration of vitamin K.

Vitamin K deficiency results in a deficiency of all vitamin K-dependent clotting factors. Factor VII is depleted first because it has the shortest half-life. This leads to an increase in the PT. Factors IX and X are depleted next, causing an increase in the activated PTT. If the patient's liver function is normal, vitamin K_1 given as an intravenous infusion over 10–15 minutes will normalize the PT in 6–24 hours and the PTT in 24–48 hours. Parenteral vitamin K_1 reverses the effects of oral anticoagulants like warfarin, in the same period of time. If correction of PT does not occur within 24–48 hours, liver functions are invariably deranged. In severe bleeding resulting from vitamin K deficiency, FFP should be administered in addition to vitamin K to help increase the levels of depleted clotting factors.

DRUGS

- *Warfarin* is the most frequently used anticoagulant. It should be monitored by doing the PT at periodic intervals, the international normalized ratio (INR) being kept between 2 and 3. Rarely serious bleeding can occur even when the PT is within the therapeutic range. If the INR exceeds normal but is below 5 and the patient does not bleed, it is best to withhold the drug till INR falls in the therapeutic range and then restart a titrated dose of the drug. If the INR is between 5 and 9, and there is no bleeding, the drug is withheld, and if there is a serious risk for a possible bleed, 1 mg vitamin K is given intravenously or 5 mg given orally and repeated if necessary, after 24 hours. If the INR is greater than 9, 2.5 mg vitamin K is given IV repeated, if necessary, after 12–24 hours. If there is a serious bleed after the use of warfarin, with prolongation of the INR, IV 10 mg vitamin K is given over 10 minutes. FFP, prothrombin complex concentrate or factor VIIa will enable prompt reversal of the anticoagulant effect.

Table 3: Laboratory findings in acquired coagulation disorders

	DIC	*Liver disease*	*Kidney disease*	*Vitamin K deficiency*	*Inhibitors*	*Primary fibrinolysis*
PT prolonged	+	+	+	+	+	
PTT prolonged	+	+	+	+	+	
TT prolonged	+	+				+
FDP elevated	+	+			+	+
D-dimer present	+	+				
Protein C/S diminished	+	+		+		
Antithrombin III diminished	+	+				
Fibrinogen diminished	+	+				+
Associated thrombocytopenia	+	+				
Red blood cells	Schistocytes present	Target cells, macrocytes present	Schistocytes present			

Inhibitor screen: Mix with normal plasma. If no correction—inhibitor present
If correction—factor deficient
The coagulation profile in severe liver disease is very similar to that in DIC; however, in liver disease, the factor VIII levels are not significantly reduced, while in DIC, they are severely reduced.

- *Heparin*, low molecular weight heparin and fondaparinux are anticoagulants which need to be monitored (aPTT and factor Xa). *Bleeding is countered by the administration of IV FFP. Bleeding due to unfractionated heparin can be countered by the use of IV protamine and infusion of FFPs. Bleeding following the use of low molecular weight heparin can be only partially countered by IV protamine. Recombinant factor VII (rVIIA) should be given in patients with severe bleeding. There is no antidote to bleeding caused by Factor XA inhibitors like fondaparinux. Severe life-threatening bleeds should be countered by the infusion of rVIIA.*
- Direct thrombin inhibitors include *argatroban, lepirudin* and *bivalirudin*. There is no antidote for bleeding caused by these drugs. Fortunately, they have a short half-life, so that bleeding spontaneously stops with time. *Cryoprecipitate, antifibrinolytics and desmopressin acetate should be administered for life-threatening bleeds (see Table 6 in Chapter Pulmonary Embolism).*
- Superwarfarins are present in rat poison, which is occasionally taken with suicidal intent. The bleeding is severe and persistent as the raised PT remains very high for days or weeks.

CIRCULATING INHIBITORS TO COAGULATION FACTORS

Circulating inhibitors pose significant problems in the management of bleeding disorders. As with the treatment of hemophilia A, management consists of using high doses of the particular deficient coagulant factor or using factors that bypass the factor that is being inhibited (use of activated prothrombin complex or recombinant factor VIIa). The titer of the inhibitor factor can be reduced by plasmapheresis or by immunosuppression. In patients with multiple myeloma, the abnormal myeloma protein prevents fibrin polymerization. Chemotherapy against myeloma can rectify this abnormality; plasmapheresis is useful as a temporary measure.

Table 3 gives important laboratory findings in acquired coagulation disorders.

CHAPTER 58

Transfusion (Blood Product) Therapy

INTRODUCTION

Whole blood or blood products are of extreme therapeutic value in critical care units. However, despite all care and attention in the collection, preparation and storage of blood products, there is an inherent risk in the administration of these products. The benefits in appropriate clinical settings invariably outweigh the risks. Even so, the hazards of transfusions should always be borne in mind, so that blood products are only transfused when absolutely indicated.

This chapter gives the blood components available for transfusion, indications for use and their therapeutic effects. It then goes on to briefly describe complications of transfusion, including the risk of transmitted infection, and various transfusion reactions encountered in clinical practice.

BLOOD PRODUCTS[1,2]

The text below outlines the blood products available and indications for their use (Table 1).

Red Blood Cells[1-4]

Red blood cell concentrates are prepared by removing most of the plasma from a unit of whole blood. This is the blood product of choice when increase in the oxygen carrying capacity of blood is desired, as in an anemic patient. Each unit contains 200–225 mL of red cells, and should raise the hematocrit by 3%. In a bleeding patient, who is given packed RBCs, volume replacement should be supplemented by infusion of colloids or crystalloids. Besides acute blood loss, RBC transfusions are indicated in severe anemia. The decision to transfuse cells is based not only on the hematocrit or Hb value, but also on the clinical state of the patient.

In the intensive care unit, anemia is an important frequently encountered problem and can be due to several causes. In the critically ill patient, adequate tissue oxygenation is of vital importance. Oxygen delivery and oxygen consumption by tissues can be impaired if there is a reduced cardiac output (a fall in O_2 delivery), decreased red cell mass (lowered Hb) and a decrease in the circulating volume caused by RBC loss or reduction. Besides overt or occult blood loss, anemia in this setting could be due to other causes, which include hemolysis, inability to utilize iron, impaired haemopoiesis in the marrow and decreased erythropoietin production.

Infusion of packed RBCs increases the oxygen carrying capacity of blood and increases oxygen delivery to the tissues. This is all to the good in critically ill anemic patients, but the question that arises is at what level of Hb does one transfuse a critically ill patient.

There exists a considerable variability in transfusion parameters and in spite of guidelines from different centers, the treatment of anemia in critically ill ICU patients is not yet well-defined. One view advocates RBC transfusions if the Hb is less than 10 g/dL; another more "restrictive" approach is to transfuse only when Hb is less than 7 g/dL, keeping the Hb between 7 g/dL and 9 g/dL. The latter view suggests that Hb values between 7 g/dL and 9 g/dL are well tolerated by critically ill patients. Admittedly there is evidence to support the "restrictive" approach. In a large multicenter randomized trial, patients transfused at an Hb threshold of 10 g/dL had a higher mortality than those transfused at an Hb threshold of 7 g/dL.[5] Advocates of a restrictive transfusion strategy[6] maintain that trying to achieve a normal or near normal Hb concentration does not improve mortality in critically ill patients and may be associated with increased risk of infection and increased morbidity and mortality. The exception to the

Table 1: Commonly available blood products and main indications for their use

Blood product	*Main indications*
Red blood cells (RBCs)	Restoration of oxygen carrying capacity
Whole blood	Restoration of oxygen carrying capacity + restoration of blood volume
Leukocyte-poor red cells	Restoration of oxygen carrying capacity, prevention of febrile transfusion reactions
Frozen/Deglycerolized red cells	Used in patients who are extremely sensitive to plasma, e.g. those with congenital absence or marked deficiency of immunoglobulin A (IgA).
Platelets	Actively bleeding patient with thrombocytopenia, thrombocytopenic patient undergoing surgery, prophylactically in patients with platelet count less than 10,000/mm^3
Leukocytes	In patients having neutropenia with sepsis; hardly ever used. The granulocyte-stimulating factor is more effective
Fresh frozen plasma (FFP)	Replacement of multiple coagulation factor deficiencies, e.g. in patients with uremia, liver disorders, disseminated intravascular coagulation (DIC), and following multiple blood transfusions
Cryoprecipitate	Hemophilia A, von Willebrand's disease, Hypofibrinogenemia
Specific clotting factors— • Factor VIII concentrate • Prothrombin complex concentrate	 Hemophilia A Deficiency of factor II, VII, IX or X
Factor VIIa	Bleeding in hemophilia A + exsanguinating life-threatening bleeding from other causes
Other blood products— • Human albumin • Intravenous (IV) immunoglobulin	 Expansion of plasma volume as in burns, to increase serum albumin levels in patients with hypoalbuminemia In patients with immune thrombocytopenic purpura (ITP), or congenital deficiency of immunoglobulin

above restrictive policy is with regard to patients who have an acute coronary syndrome. In these patients the, Hb should be close to 10 g/dL. On the other hand, those advocating a more "liberal" transfusion policy stress on the possible dangerous effects associated with an increasing oxygen debt.[7]

Though many critical care units follow the "restrictive approach" to blood transfusions in critically ill patients, it is important to consider each patient's requirements individually rather than apply a blanket rule based on the statistical analysis of randomized controlled trials involving large population groups. It is important to remember that the heart and brain are extremely vulnerable to the lack of oxygen. Elderly people with a history of myocardial infarction, patients with documented multivessel coronary disease, those with a history of a stroke in the recent past or a history of recurrent transient ischemic attacks perhaps deserve a less "restricted" policy toward transfusion of RBCs. It is impossible in a critically ill elderly individual to assess the state of the coronary arteries or the cerebral vessels. An electrocardiography (ECG) is certainly no guide to the presence or absence of coronary artery disease. In all the above situations, it may perhaps be wise (notwithstanding the absence of "evidence") to keep the Hb close to 10 g/dL.

It should be noted that any condition that impairs the ability of the patient to increase stroke volume, cardiac output and intravascular volume will result in poor tolerance of acute blood loss or severe anemia. Patients with ischemic heart disease or poor pump function may be unable to maintain satisfactory tissue perfusion to the myocardium and to other vital organs after blood loss and may need more urgent yet carefully administered packed RBC transfusions. Patients with respiratory disease and a PaO_2 less than 55 mm Hg require urgent replacement of blood loss as the lowered PaO_2 coupled with a low Hb produce a sharp fall in the O_2 content of blood. Patients with chronic liver disease are tipped into liver cell failure with even a minor blood loss in the GI tract, and often need prompt transfusions to replace the blood lost. In all the above conditions, each patient should be judged individually, and, if thought appropriate, the restrictive approach may need to be a trifle relaxed. Yet it needs to be pointed out that a Hb greater than 10 g/dL is of no advantage and can perhaps even do more harm than good.

In the acutely bleeding patient, who runs a risk of dying due to exsanguination within a short time, un-crossmatched O-negative red cells may be transfused till properly typed and cross-matched blood is available. It needs to be stressed that infusions of packed RBCs are not the right choice to augment blood volume at a quicker rate. The use of crystalloids, colloids or whole blood is preferable for this purpose (see Chapter Hypovolemic and Hemorrhagic Shock).

Whole Blood

Whole blood contains both RBCs and plasma. Transfusion of whole blood increases both the oxygen carrying capacity of blood, as also the volume. Whole blood is to be preferred in the severely bleeding patient, and, when transfused, it should

be ABO identical with that of the patient. The use of whole blood in a patient, who is not bleeding profusely, exposes the patient unnecessarily to plasma, and prevents donor blood from being processed into other blood components. Platelets and clotting factors, particularly factors V and VII, are not adequate in whole blood.

Gamma-irradiated Blood

The application of external beam radiation to a unit of blood produces gamma-radiated blood. This allows for destruction of donor T lymphocytes for the prevention of graft versus host disease in patients who have undergone stem cell transplant and in severely immunocompromised patients.

Cytomegalovirus Antibody Negative Blood

Cytomegalovirus (CMV) antibody negative blood is used in patients (e.g. transplant recipients) who are CMV negative and are therefore at high risk if transfused with CMV positive blood. Leukocyte reduction is also an effective method to reduce risk of CMV infection.

Leukocyte-poor Red Cells

This product is prepared in a manner that eliminates most leukocytes and platelets, but retains at least 80% of the RBCs. The leukocyte count is less than 5×10^8 per unit. The method of preparation of leukocyte-poor red cells is by centrifugation and washing, or by more elaborate filtration methods. Filters and filtration methods, if available, are now more frequently used in well-equipped blood banks. Leukocyte-poor red cells are valuable in patients who have recurrent febrile reactions after transfusion of the usual packed RBCs. Such reactions are believed to be caused by sensitization to human leukocyte antigen (HLA) present in donor leukocytes, as also to other surface antigens on leukocytes and platelets in donor blood. Such sensitization is common in patients receiving multiple blood transfusions. The advantage of leukocyte and platelet-free RBCs is twofold: (1) it reduces the incidence of HLA alloimmunization caused by blood products and (2) it reduces (but does not completely eliminate) the risk of transmission of CMV from the donor to the recipient.

Frozen/Deglycerolized Red Cells

Red cells can be frozen and stored if glycerol is used as an intracellular cryoprecipitant. When they need to be used, the red cells are thawed, and the glycerol removed by extensive washing, a process that removes all plasma, leukocytes and platelets. This product is used for patients who are known to be extremely sensitive to plasma, as in those who have a congenital absence or marked deficiency of IgA. Ordinary packed cells or whole blood transfusions can cause almost life-threatening reactions in IgA-deficient patients. Frozen/deglycerolized RBCs are difficult to obtain, extremely expensive to prepare and store, and have no additional advantage for routine use.

Platelet Transfusions[1,2,8]

Platelet transfusions can control bleeding in patients with severe thrombocytopenia or in those with qualitative defects in platelet function. One unit of blood ordinarily yields platelets sufficient to raise the platelet count by about 10,000/mm^3 per square meter of body surface area. This amounts to a rise of 5,000–7,000 platelets/mm^3 in a 70 kg adult. Ordinarily, 6–8 units of platelets are administered to produce a significant rise in the platelet count. It is necessary to do a platelet count 1 hour and 24 hours after transfusion, so that the effectiveness of the transfusion in raising the platelet count can be estimated. Antibodies to platelets from alloimmunization can lead to rapid destruction of transfused platelets. Fever, sepsis, drugs, liver cell dysfunction, uremia and hypersplenism probably shorten even further the life-span of transfused platelets.

The indications for platelet transfusions, which have been briefly touched upon earlier, are recapitulated below—

- The actively bleeding patient with thrombocytopenia. A platelet count of 50,000/mm^3 in these patients generally ensures hemostasis unless there is a co-existing qualitative defect in platelet function.
- Usually, spontaneous bleeding does not occur until the platelet count falls below 5,000–10,000/mm^3. Prophylactic platelet transfusions are generally given in patients undergoing chemotherapy or hematopoietic stem cell transplant if the platelet count is less than 10,000/mm^3 even in the absence of bleeding.
- For elective or emergency surgery or high-risk procedures in patients with thrombocytopenia, platelet infusions are necessary to raise the platelet count to greater than or equal to 100,000/mm^3. This level should be maintained for at least 48 hours after surgery.
- For the majority of invasive procedures performed in the ICU (insertions of central lines, pleural or peritoneal tap, etc.), a platelet count of 30,000–50,000 is adequate.
- Alloimmunization to platelet antigens often results in poor survival of transfused platelets, and a poor response is inevitable. HLA-matching can improve platelet survival in 70% of alloimmunized patients. Obtaining HLA-matched platelets is difficult because of the heterogenicity of HLA antigens, and requires technicians and doctors with experience and expertise.
- Platelets are of no use in the treatment of bleeding due to idiopathic thrombocytopenic purpura, a condition in which there is autoimmunization to platelet antigens. These patients need specific treatment with corticosteroids. It is remarkable how counts as low as 5,000–10,000/mm^3 are tolerated without active bleeding in these patients. This is perhaps related to the production of young "extra sticky" platelets by the bone marrow. These platelets are very effective in securing hemostasis during their short period of survival.
- Desmopressin administered intravenously increases the level of von Willebrand's factor; this improves platelet function in uremia and following cardiopulmonary bypass.

- Platelet counts less than 50,000/μL are associated with increased rate of microvascular bleeding in the massively transfused patient. Therefore, platelet transfusions have been advocated with replacement of blood volume to avoid dilutional thrombocythemia.
- A qualitative defect in platelet function can induce bleeding even when the platelet count appears adequate. Platelet transfusions are indicated in these patients. Platelet function abnormalities are observed after use of certain drugs, in sepsis, trauma, malignancy, in obstetric complications, hepatic and renal disease. The use of glycoprotein IIb IIIa inhibitors in patients with ischemic heart disease leads to a qualitative defect in platelet function with bleeding as a recognized complication.
- The expected rise in the platelet count following platelet infusion is as follows—
  - One unit in a 50 kg individual will cause a rise of 9,000/μL; 6 units a rise of 54,000/μL.
  - One unit in a 70 kg individual will cause a rise of 6,000/μL; 6 units a rise of 36,000/μL, provided the spleen is normal and there are no platelet antibodies.

Fresh Frozen Plasma[1,2,8]

Fresh frozen plasma (FFP) is prepared from whole blood, and is frozen within 6 hours of collection of the donated unit. Each unit of FFP contains 250 mL plasma, all the clotting factors, and 400 mg of fibrinogen. FFP infusions are indicated to replenish deficiency of multiple clotting factors as observed in uremia, liver disease, DIC and coagulopathy following multiple blood transfusions. FFP (together with intravenous vitamin K) is also useful in reversing the coagulopathy produced by warfarin, and may be beneficial in treating thrombotic thrombocytopenic purpura and antithrombin III deficiency.

One unit of FFP increases the level of clotting factors by 3% in an adult. Excessive bleeding is controlled and generally stops when clotting factor levels are over 30% and the prothrombin time (PT) and partial thromboplastin time (PTT) are reduced to about 1.5 times normal. It is therefore not necessary to aim at restoring clotting factors to absolute normal levels. The efficacy of FFP infusions should be monitored by coagulation assays—at least of the PT and the PTT. Specific factor deficiencies may be treated by infusion of specific factors. The short half-life of clotting factors and the dangers of fluid overload need to be kept in mind.

Cryoprecipitate[1,2,8]

When FFP is thawed at 4°C, a precipitate is formed. This cryoprecipitate is separated from the supernatant plasma, re-suspended in a small volume of plasma, and then refrozen at −18°C. The cryoprecipitate can be stored for a year. Each bag or unit of cryoprecipitate (about 50 mL) contains 100–250 mg fibrinogen, 80–100 units of factor VIII, 40–70% of von Willebrand's factor concentrate, and factor XIII in a concentration 2–4 times that present in FFP.

Cryoprecipitate transfusions are indicated in bleeding due to severe hypofibrinogenemia (<100 mg/dL), in patients with deficiency of von Willebrand's factor, in hemophilia and in factor XIII deficiency. It is particularly useful in achieving hemostasis in patients with uremia or chronic liver disease with low serum fibrinogen levels and in patients with DIC.

Fibrinogen levels should be kept greater than 100 mg/dL to counter bleeding due to fibrinogen deficiency. Two to three bags of cryoprecipitate per 10 kg will raise fibrinogen concentration by about 100 mg/dL. Maintenance doses of 1 bag/15 kg body weight can be given daily till the bleeding is controlled. Bleeding due to deficiency of von Willebrand's factor stops if this factor level is increased to 50%, and the prolonged BT is corrected. Factor XIII replacement requires transfusion of 4–6 bags of cryoprecipitate every 3 weeks.

Specific Clotting Factors[1,2,8,9]

Factor VIII concentrate and factor IX (prothrombin complex) concentrate are prepared by fractionation and lyophilization of pooled plasma. Factor VIII is used in the treatment of hemophilia A. It is not used in an intensive care setting except for bleeding hemophilics requiring critical care. All current methods of preparing factor VIII inactivate the human immunodeficiency virus (HIV I), and decrease the incidence of transmission of Non-A, Non-B hepatitis. Bleeding hemophilics, who have antibodies to factor VIII, can be given porcine factor VIII concentrate, or activated prothrombin complex concentrates that bypass factor VIII in the coagulation cascade.

Factor IX concentrates contain factors II, VII, IX and X, and can be used in patients with selective deficiency of these factors.

Factor VIIa[9] is a recombinant factor and is used for bleeding complications in hemophilia with inhibitors to factor VIII, in acquired hemophilia A and B, and in factor VII deficiency. Severe exsanguinating bleeding, which is life-threatening, is another indication for infusion of factor VIIa, provided it is ascertained that there is no local cause for the bleed and the use of FFP, cryoprecipitate has been ineffective. The dose of factor VIIa in the above situation is 60 μg/kg IV; this can be repeated after 2 hours if the bleeding has not stopped. Thrombotic complications are known to occur after its use.

Other Blood Products

These are prepared by fractionation of large pools of plasma. They include intravenous immunoglobulin used to treat congenital immunoglobulin deficiency and idiopathic thrombocytopenic purpura.

Intravenous human albumin preparations are chiefly indicated in hypovolemic states (e.g. burns) to expand the volume of the vascular compartment and thereby support circulation. They are also used to increase serum albumin levels in patients with marked hypoalbuminemia. Very low serum albumin levels can lead to waterlogging of tissues and is a bad prognostic sign in a critical illness.

Table 2: Important immune-mediated acute transfusion reactions

Reaction	*Symptoms*	*Etiology*
Anaphylactic	Choking in throat, bronchial spasm, constricting chest pain, anxiety and shock	Antibodies to donor plasma proteins (severe); often anti-immunoglobulin A (IgA)
Transfusion-related acute lung injury (TRALI)	Dyspnea, tachypnea, fever, hypoxia, tachycardia and bilateral pulmonary infiltrates	Antibodies to donor leukocytes or antibodies in a donor reacting with recipient HLA or leukocyte-specific antigen
Acute hemolytic	Fever, flank pain, chest tightness, shock, hypotension, oliguria and renal shut-down	Antibodies to donor red cell antigens

TRANSFUSION REACTIONS

Transfusion reactions occur in about 5% of patients. They may be very mild and permit continuation and completion of the transfusion; occasionally they may be severe and life-threatening, necessitating immediate stoppage of the transfusion and institution of emergency measures to counter these reactions.

The important immune-mediated transfusion reactions are summarized in Table 2.

Anaphylactic Reactions

These are frightening. A choking feeling in the throat, constricting chest pain, and a state of shock quickly supervene. Overwhelming bronchial spasm may choke the patient to death within a few minutes. The transfusion should be stopped immediately. Adrenaline 0.5 mL intramuscular or intravenous is administered and is followed by 300 mg of intravenous hydrocortisone. The airway should be secured, and oxygen administered at a high flow rate. Circulatory support with volume infusions and inotropes are necessary. The blood bank should be immediately informed about the untoward reaction.

Transfusion-related Acute Lung Injury[10]

Transfusion-related acute lung injury (TRALI) is an extremely distressing complication occurring within 30 minutes to 6 hours after transfusion. It is characterized by sudden onset of dyspnea, fever, tachypnea, tachycardia, hypoxia with bilateral pulmonary infiltrates most marked in the mid and lower zones of both the lungs. Bilateral basal crackles are heard on auscultation. The condition resembles acute respiratory distress syndrome (ARDS), or volume overload, or acute left ventricular failure. It is due to non-cardiogenic pulmonary edema due to a capillary leak within the pulmonary vessels. It is believed to be an immune-mediated process due to antibodies present in the donor blood reacting with recipient HLA or leukocyte-specific antigen. Alternatively, the recipient, i.e. the patient, could have antibodies reacting against the donor leukocytes. A nonimmune mechanism has also been postulated.

The treatment is supportive. High flow oxygen is administered. In most cases TRALI is self-limiting, but mechanical ventilatory support is occasionally necessary.

Febrile Non-hemolytic Transfusion Reactions

Febrile non-hemolytic transfusion reaction (FNHTR) is a 1°C or greater rise in temperature, which cannot be explained by the patient's clinical condition. FNHTR is generally due to sensitization to the antigen on donor leukocytes. It is more common with platelet transfusion or in patients who have received multiple transfusions. Storage of cellular blood compounds may release cytokines which are responsible for this transfusion reaction. Pre-storage leukocyte depletion of RBCs and platelets by filtration may prevent this reaction. Occasionally, this transfusion reaction may be quite severe and needs to be distinguished from bacterial contamination, which is associated with rigors, higher fever and with other features of sepsis.

The transfusion should be discontinued and recipient blood as also that which has been transfused should be sent for culture.

Acute Hemolytic Reactions

Acute hemolytic reactions are almost always due to human error due to transfusion of incompatible blood. ABO incompatibilty is the most common, as anti-A, anti-B antibodies occur naturally. However, other antibodies due to prior sensitization can also cause acute hemolysis. Incompatible blood transfusions can be prevented by adhering to a strict protocol for blood collection, labeling, storage, release and the final checking of the correctness of the unit, prior to administration to the patient.

Hemolytic transfusion reactions may vary from the mild to the fulminant and fatal. Back pain, fever and chest tightness are the warning complaints in conscious patients. If the patient is undergoing surgery under general anesthesia, unexplained hypotension, tachycardia, fever and red scanty urine are observed. Recovery from anesthesia may be slow. High fever with chills, sometimes accompanied by seizures, may occur at this stage. There also may be generalized oozing from venepuncture sites due to an evolving DIC.

Acute hemolytic transfusion reactions often produce acute oliguric renal failure. Hemoglobinuria is present, and there is an increase of free hemoglobin in the blood. Cardiovascular collapse and DIC are important complications, which are due to immune complex deposition and stimulation of the coagulation cascade, resulting in a consumption coagulopathy. In severe cases, perfusion to vital organ systems

is grossly impaired, leading to tissue hypoxia and damage. The degree of damage is dose-related. For this reason, even mild febrile reactions occurring in a patient receiving a transfusion should prompt a stopping of the transfusion, checking the label and group of the blood product being used, and checking with the blood bank regarding the possibility of incompatibility. This is particularly important if the patient is being transfused for the first time, or has never exhibited transfusion reactions in the past.

Management of an acute severe hemolytic reaction requires critical care. Vital signs are monitored, and a volume load infused to maintain adequate blood pressure and renal perfusion. Furosemide 40–100 mg intravenously together with intravenous fluids and mannitol should be used to help to maintain a urine output of 100 mL/hour or more. Furosemide should be given in a continuous intravenous infusion at the rate of 20–40 mg/hour if the urine output falls. Renal function should be monitored, and baseline coagulation studies should be done and repeated at periodic intervals. If acute renal shutdown due to acute tubular necrosis occurs in spite of the above measures, treatment is as for acute renal failure. DIC may need to be treated by replacement of clotting factors and/or by infusion of cryoprecipitate. Hemodialysis may be necessary for renal support till such time as renal function returns to normal.

Delayed Hemolytic Reactions

These are mild and generally occur 1 week after transfusion. Initial crossmatching fails to detect antibodies to the donor red cell antigens. Prior sensitization by transfusion of RBC antigens not belonging to the ABO group results in a transient rise in antibodies. The titer of these antibodies wanes within a few weeks, and may not be detectable. A second transfusion with a repeat exposure to the red cell antigen provokes an anamnestic rise of the antibody to a degree sufficient to cause hemolysis.

Transmission of Infection[11]

The risk of transmitting infections through blood transfusions can never be entirely eliminated.

Bacterial contamination of RBCs and platelets during collection can have disastrous consequences. In tropical developing countries, donor blood could transmit malaria, typhoid, dengue or other infectious diseases, if the donor donates blood when infected.

Contamination with cold-loving organisms as for example, yersinia can occur. The CMV virus, other viruses, prion-causing Creutzfeldt-Jakob disease and rarely syphilis have been known to be transmitted through transfusions.

The major risk is with transmission of hepatitis B, C viruses and HIV virus I and II. However, by current technique of screening blood using polymerase chain reaction (PCR) test for hepatitis C and HIV ribonucleic acid (RNA), the estimated risk per unit of blood is as low as 1 in 2 million for HIV and hepatitis C.

Risk for viral transmission of hepatitis B is estimated 1 in 500,000. These are American figures. Risks for transmission of infection in poor developing countries must indeed be much higher.

Transfusion-related Graft versus Host Reaction

Though rare, this reaction can prove fatal. It occurs 2–30 days after transfusion and is characterized by fever, rash, diarrhea, increasing hepatic dysfunction and severe pancytopenia. This reaction occurs in patients with a marked defect in cellular immunity as is seen in lymphoproliferative disorders. Transfusions from relatives and HLA compatible donors can result in this dangerous reaction. It can be prevented by gamma radiation of cellular blood components. The reaction is due to donor lymphocytes that engraft and multiply in response to the host antigen.

CHAPTER 59

Endocrine Dysfunction

ACUTE ADRENAL CRISIS

GENERAL CONSIDERATIONS

Acute adrenal crisis or adrenocortical insufficiency is due to a severe lack or deficiency of adrenocortical hormones. It is a critical illness requiring intensive care, and is quickly fatal unless promptly recognized and treated.[1] Early diagnosis is essential, but so protean are the manifestations that delay in diagnosis is common. An awareness of the background factors against which acute adrenal crisis suddenly unfolds should make one suspect the diagnosis. Suspecting adrenal crisis is, in fact, a major step towards arriving at the correct diagnosis.

Acute adrenal insufficiency is rather infrequently encountered in patients under critical care. It does, however, occur under the following situations—

- Following sudden withdrawal of corticosteroids in a patient whose own adrenal glands have been suppressed by prolonged administration of corticosteroids. If these patients undergo stress in the form of surgery or an acute infection, they require a larger dose of corticosteroids. Sudden withdrawal of the drug can precipitate an acute crisis, which, if not promptly recognized, can prove fatal. More often than not, the drug is not administered in the intensive care unit (ICU) because the physician is unaware that the patient was on a maintenance dose of corticosteroids.
- Acute stress in a patient with latent adrenocortical insufficiency—the stress may be in the form of prolonged anesthesia and major surgery, acute infection, trauma, and occasionally following a difficult, protracted delivery in females. Relative adrenocortical insufficiency has been shown to exist in critically ill patients with severe sepsis; cortisol levels may be normal, but do not rise appropriately after adrenocorticotropic hormone (ACTH) stimulation.[2,3]
- As a complication in a patient with overt chronic adrenocortical failure—this is not as uncommon as is believed to be. A frequent cause of chronic adrenocortical insufficiency, in our part of the world, is tuberculous destruction of both the adrenal glands. In the West, autoimmune disease destroying the adrenals is far more frequent.
- Acute bilateral destruction of the adrenal glands by hemorrhage[4]—this occurs after trauma and in fulminant infections (Waterhouse-Friderichsen syndrome). Meningococcal septicemia is an important cause of the Waterhouse-Friderichsen syndrome. Adrenal hemorrhage has also been reported in pneumococcal, staphylococcal and Haemophilus influenzae infections. Pseudomonas aeruginosa infection in children is also an important cause of sepsis producing adrenal hemorrhage. Other causes of bilateral adrenal hemorrhage include anticoagulant therapy, disseminated intravascular coagulopathy and rarely acute bilateral venous thrombosis causing hemorrhagic infarcts in patients with antiphospholipid antibody syndrome.
- Acute adrenal insufficiency following bilateral adrenalectomy or following removal of a unilateral adrenocortical tumor, which has suppressed the opposite gland, does not pose problems in diagnosis.
- Very rarely, shock, peripheral circulatory failure and a collapsed state are observed following hemorrhage into

Box 1: Important causes of adrenocortical insufficiency

- Withdrawal of steroids in patients receiving corticosteroids for a long time
- Infections—tuberculosis, fulminant sepsis due to Gram-positive or Gram-negative bacteria, fungal infections, cytomegalovirus infection, HIV
- Adrenal hemorrhage—fulminant infection or use of anticoagulants, DIC, antiphospholipid antibody syndrome
- Autoimmune destruction
- Bilateral metastatic adrenal disease
- Medications—megestrol acetate (decreased secretion of ACTH); ketoconazole (decreased cortical synthesis); rifampin, phenytoin (increased metabolism of cortisol)
- Hypothalamic and pituitary disorders (secondary adrenocortical insufficiency)
- Relative adrenal insufficiency in some patients with severe sepsis

Abbreviations: HIV, human immunodeficiency virus; DIC, disseminated intravascular coagulation; ACTH, adrenocorticotropic hormone.

the pituitary (pituitary apoplexy), which causes acute adrenocortical failure.

Important causes of adrenocortical insufficiency are given in Box 1.

CLINICAL FEATURES[1,5]

The clinical features are protean, and, at times, bizarre, so that diagnosis depends on a high index of suspicion.

The onset may be explosive, and, at times, is characterized by fever, confusion, and drowsiness graduating to severe mental obtundation and even coma. In some patients, the temperature is subnormal, and severe asthenia predominates, so that the patient is unable to even turn on his own in bed. Abdominal symptoms are very frequently present. Abdominal pain may be severe, and may mimic an acute abdomen. Nausea, vomiting and diarrhea are often observed, and confuse the clinical picture. However, the most striking feature in all patients is the rapid development of peripheral failure and shock, characterized by a rapid thready pulse and progressive hypotension. The shock resembles hypovolemic shock, but is not corrected by volume replacement or the use of inotropic support; quick improvement only follows after the use of adrenocortical steroids.

In the Waterhouse-Friderichsen syndrome, the explosive onset with high fever, headache, vomiting and prostration is accompanied by purpuric skin rashes. These rashes may be confluent producing large areas of hemorrhage. Respiratory distress, cyanosis and a quickly evolving irreversible state of shock are observed with death occurring within 24–48 hours.

LABORATORY INVESTIGATIONS

- A moderate degree of hyponatremia may be present; it may be associated with hyperkalemia. Hyponatremia is most often related to an associated mineralocorticoid deficiency. These patients, however, become hyponatremic even in the presence of a positive sodium balance. This indicates inability to excrete free water due to glucocorticoid insufficiency.
- Urea, creatinine and nonprotein nitrogen levels in the blood are raised due to prerenal factors.
- Hypoglycemia is often observed. Glucocorticoids play an important role in gluconeogenesis and counter the action of insulin.
- Blood cortisol levels are very low and do not show an adequate response to the ACTH stimulation test. The ACTH stimulation test is the definitive test for adrenal hypofunction. After administration of synthetic ACTH, an adequate adrenal response shows a 10 μg rise in cortisol level over baseline at 60 minutes, or a stimulated cortisol level greater than 20 μg/dL. Values below those stated above point to adrenal hypofunction. Cortisol values greater than 20 μg before or after ACTH stimulation are compatible with normal adrenal function. The interpretation of the ACTH stimulation test should, however, take into consideration the fact that cortisol is bound to corticosteroid-binding globulin and albumin and these are often reduced in critically ill patients.

  Primary adrenocortical insufficiency should be distinguished from secondary adrenal insufficiency. The aldosterone response to ACTH stimulation are impaired in primary adrenocortical insufficiency, but preserved in secondary adrenocortical insufficiency. Also, ACTH levels in blood are raised in primary adrenocortical insufficiency and below normal in secondary adrenocortical insufficiency. The clinical features of hyperpigmentation of the mucosa and skin and the presence of hyperkalemia are characteristics of primary adrenocortical insufficiency. They do not occur in secondary adrenocortical insufficiency.
- Adrenocortical insufficiency may be associated with hypothyroidism and other hormonal deficiencies. If clinical suspicion exists, relevant tests for other hormonal deficiencies should be done.
- In the Waterhouse-Friderichsen syndrome, blood cultures are generally positive. Organisms may be seen in petechial scrapings.

DIAGNOSIS[1,2,5]

The possibility of acute adrenocortical insufficiency should always be considered when faced with any acute illness in the ICU, which is characterized by protean manifestations and peripheral circulatory failure. The background against which acute adrenal insufficiency occurs, should always be kept in mind as it affords an invaluable clue to the diagnosis. Inexplicable shock occurring after a straightforward operation (e.g. appendicectomy or herniorrhaphy), or in a patient with an ordinary infection, should always suggest the possibility of acute adrenal crisis.

An important cause of hyperpyrexia with prostration and collapse is acute adrenocortical failure. In such cases, the diagnosis is often confused with an acute infection like malaria, pneumonia, sepsis or even meningitis. Quite often an acute infection precipitates adrenocortical failure, so that the confirmed presence of the former, in no way excludes the latter.

In patients, who are drowsy or mentally obtunded, the differential diagnosis of poisoning, cerebrovascular accidents or other causes of a semiconscious state should be considered.

The occurrence of acute abdominal pain and vomiting continues to fox the most experienced of clinicians. An earlier history of asthenia, hypotension, mucosal pigmentation, and pigmentation of the exposed parts, particularly the creases of the palms, and of the skin over the knuckles should suggest the diagnosis.

The diagnosis of an acute adrenal crisis requires a high index of suspicion and is necessarily clinical. In most ICUs in our country, the diagnosis cannot be immediately confirmed by objective laboratory tests. Treatment should be immediate and vigorous. If possible, a blood sample should be collected for cortisol assay and this can be repeated after 1 hour of ACTH stimulation. The patient, however, needs to be given a glucocorticoid without awaiting results. Dexamethasone 4 mg, intravenously given as a bolus dose, does not interfere with cortisol assays. Recovery of the patient following correct treatment is probably the most reliable objective pointer to a correct diagnosis.

TREATMENT[2,5]

Treatment should be prompt. If the ACTH stimulation test has been done, dexamethasone 4 mg intravenously is administered, without awaiting the results of the test.

Use of Glucocorticoids

Hydrocortisone hemisuccinate in a dose of 100–200 mg is given intravenously 6 hourly over the first 24 hours. The drug may be given either as a continuous intravenous infusion or as a bolus IV injection. The dose of intravenously administered hydrocortisone over the next 24 hours should also be 300–400 mg. By this time, recovery is apparent, so that from the third day onward, the dose is reduced by 25–50 mg/day, and within the next 8–10 days, the patient is on a maintenance dose of 100 mg hydrocortisone daily. Once the crisis is over, the patient is put on oral prednisolone + mineralocorticoid therapy (fludrocortisone 0.05–0.1 mg/day), and IV hydrocortisone is omitted. The above is a general outline of dosage requirements in patients in an acute crisis. The dosage may need to be modified according to the patient's response. As a general rule, adrenal insufficiency is one of those rare situations where it is safer to overtreat than to undertreat. A careful watch on the side effects of corticosteroid therapy must be maintained.

An acute crisis can be prevented, if patients with underlying adrenocortical insufficiency (on a maintenance dose of corticosteroids) are given larger doses during the stress of surgery or acute infection. Empiric recommendations are 25 mg/day of hydrocortisone for mild stress, 50–75 mg/day for 2–3 days for moderate stress and 100–150 mg/day for 2–3 days for severe stress. After recovery from stress, patients are placed on a maintenance dose of 15–30 mg/day.

Restoration of Fluid and Electrolyte Balance

Dehydration and salt depletion characterize an adrenal crisis, and it is important to quickly correct these abnormalities. During the first 24 hours, the usual requirement is at least 2 liters of normal saline. The administration of fluid and electrolytes should be monitored by clinical examination, by central venous pressure measurements and by estimation of serum electrolytes. Many patients, who have not been correctly diagnosed, or diagnosed late, are often already excessively volume loaded, in an attempt to correct shock and hypotension. Further volume loading in these patients is unnecessary and may precipitate acute pulmonary edema.

Serum potassium may fall during recovery from a crisis. This is particularly likely if large doses of glucocorticoids continue to be used; potassium replacement is necessary in these patients.

Vomiting is often present and precludes oral feeds in the first 24–48 hours. Nutrition is poor in many of these patients, and this should be carefully supplemented once oral feeds are tolerated.

Dextrose Infusion

Hypoglycemia, though generally not marked, needs to be countered by an IV infusion of dextrose. One liter of 10% dextrose is infused in the first 24 hours, followed by 500 mL of the same solution in the next 24 hours. By this time, the patient is generally out of the crisis and can take glucose orally in fruit juice or other liquids.

Treatment of Precipitating Factors

It is important to identify and treat these factors. Infection, in particular, is the most important precipitating cause and needs the use of appropriate antibiotics. Fulminant infections causing bilateral adrenal hemorrhage are often fatal. They require the use of antibiotics in massive doses, chosen according to the nature of the infection, and expert overall critical care. A few patients with adrenocortical insufficiency also have other endocrinopathies, which should be identified and treated. Patients suffering from combined adrenocortical and thyroid deficiency should first receive corticosteroids to correct the cortisol deficiency and then treated with eltroxin to correct hypothyroidism. Initial correction of hypothyroidism without correcting adrenocortical insufficiency can precipitate a worsening acute adrenal crisis. The treatment of an acute adrenal crisis is summarized in Box 2.

Box2: Treatment of acute adrenal crisis

- Intravenous hydrocortisone 100 mg 6 hourly in the first 24–48 hours; this is gradually reduced over the next 5 days. Use oral prednisolone or oral hydrocortisone + a mineralocorticoid subsequently
- Restore fluid and electrolyte balance—
  - Two liters of N saline in the first 24 hours—monitor volume infusions clinically and with central venous pressure (CVP), particularly in patients who have received large volume loads prior to arriving at the correct diagnosis
  - Correct hypokalemia during recovery
- Intravenous dextrose infusions to counter hypoglycemia. One liter of 5–10% dextrose is generally necessary over 24 hours
- Diagnose and treat precipitating factors—chiefly infection

CRITICAL ILLNESS-RELATED CORTICOSTEROID INSUFFICIENCY[5]

There could be a relative deficiency of cortisol in patients with severe sepsis, septic shock and acute respiratory distress syndrome (ARDS). Recommendations for the use of corticosteroids cannot be made with definite certainty. The subject has been discussed in the Chapters Intra-Abdominal Sepsis and Acute Lung Injury and Acute Respiratory Distress Syndrome. The options on whether to use or not use steroids in suspected hypoadrenal crisis in critically ill patients are still open. If IV cosyntropin (synthetic ACTH) results in an inadequate cortisol response, hydrocortisone is indicated.

COMPLICATIONS DURING TREATMENT OF AN ADRENAL CRISIS

- Overhydration occurs when a massive volume load has been administered prior to establishing a correct diagnosis. This is generally done as a measure of desperation to reverse shock. Once a diagnosis is made in these patients, the combination of further infusions of N-saline with large doses of IV hydrocortisone can produce cerebral edema or pulmonary edema. Cerebral edema may result in seizures and unconsciousness; pulmonary edema may be fatal.
- Severe hypokalemia with increasing asthenia, flaccid muscle weakness of the limbs, abdominal distension and arrhythmias may complicate recovery from a crisis. Serum potassium levels, as explained earlier, should be carefully monitored, and, if present, hypokalemia should be corrected by administration of potassium.
- Hyperpyrexia may occur as part of an acute adrenal crisis. Rarely, it is observed during recovery following the use of IV corticosteroids and saline infusions.
- Important and frequently encountered side-effects of corticosteroid therapy include acute gastrointestinal bleeding and acute psychotic reactions.

THYROID DYSFUNCTION AND EMERGENCIES MERITING CRITICAL CARE

Life-threatening problems[1] in thyroid disease requiring critical care include the following—

1. Thyroid storm or crisis occurring in a patient with a hyperfunctioning thyroid gland.
2. Sudden atrial fibrillation with a very fast uncontrollable ventricular rate leading to acute congestive failure, occurring as a complication of hyperthyroidism.
3. Myxedema coma due to a markedly poor function of the thyroid gland.
4. Hemorrhage into one or more nodules of a nodular goiter can lead to acute compression of the trachea in the neck, and hemorrhage into a substernal goiter can lead to acute mediastinal compression, necessitating urgent surgical intervention.

The first three conditions requiring critical care are discussed in this chapter. This is followed by a brief description of the euthyroid sick syndrome, a commonly encountered abnormality in a critical care setting.

THYROID CRISIS (THYROID STORM)[1,2]

A thyroid crisis or storm is a life-threatening metabolic storm resulting from a marked increase in free thyroxine (T_4) circulating in the blood. The thyroid gland runs amuck, berserk with marked increase in its activity and its hormonal output, thereby producing an excessive metabolic rate, which the body cells cannot withstand.

The fulminant forms of thyroid crisis, which can kill a patient within 24–48 hours, usually occur following surgery on an uncontrolled hyperfunctioning thyroid gland. These are now fortunately rare since surgery on a hyperfunctioning thyroid gland is never done without prior control of thyroid activity by proper medical treatment. In present days, a crisis is most often precipitated in a patient with hyperthyroidism by an acute infection or by the stress of major surgery. Other precipitating causes include trauma, severe psychological stress, diabetic ketoacidosis, treatment of uncontrolled hyperthyroidism with radioactive iodine, or withdrawal of drugs given to control hyperthyroidism. The patient may be admitted to the ICU for a thyroid crisis. At times a patient with underlying undetected hyperthyroidism is admitted for another life-threatening problem. A crisis in this situation is precipitated by some of the factors outlined above following admission to the unit. In these critically ill patients, even if the degree of hyperthyroidism does not amount to an acute crisis, it is sufficient to add significantly to the gravity of the clinical situation. Thyrotoxicosis can also be induced in critically ill patients following the use of iodine-rich drugs—amiodarone, povidone-iodine and radiographic contrast agents.[3,4]

Box 3 lists the important precipitating factors of an acute thyroid crisis.

Box 3: Important precipitating factors of acute thyroid crisis

- Acute infection
- Stress of trauma/major surgery
- Severe psychological stress
- Diabetic ketoacidosis
- Sudden withdrawal of drugs used to control hyperthyroidism
- Treatment of uncontrolled hyperthyroidism with radioactive iodine
- Following surgery on uncontrolled hyperfunctioning thyroid gland

Clinical Features

The clinical picture is characterized by a marked increase in all the symptoms and signs encountered in thyrotoxicosis. Fever, marked restlessness, irritability and tachycardia that may be as high as 160–200 min, dominate the picture. In hot climes, hyperpyrexia with temperature greater than or equal to 106°F may be noted. Atrial fibrillation with a fast ventricular rate as also other forms of supraventricular tachycardia are common. The circulation is hyperdynamic with tachycardia, warm peripheries, bounding high volume pulse and a high pulse pressure due to elevation in the systolic reading and lowering of the diastolic pressure reading. The presence of diffuse enlargement of the thyroid gland (with an auscultatory bruit over it), exophthalmos, lid lag are classic features of Graves' disease. One or more nodules in the thyroid may be palpable in a toxic nodular goiter.

Abdominal pain and vomiting may occasionally usher a crisis. In these patients, or even otherwise, diarrhea may be a presenting feature. Patients in a crisis do not eat well and may have anorexia. This should never negate the diagnosis of severe hyperthyroidism.

In elderly patients, a thyroid crisis may just present with marked apathy, extreme weakness and unexplained fever. Diarrhea is frequent and paroxysmal disturbances in cardiac rhythm are common. Death in a thyroid crisis may be due to hyperpyrexia or cardiac failure.

Diagnosis

A thyroid crisis precipitated by surgery is often missed for an acute postoperative infection or a transfusion reaction. With a known background history of hyperthyroidism, the diagnosis of a sudden spurt in hyperthyroid activity should always be given prior consideration in a patient who develops a febrile illness, or does poorly following surgery.

Patients first seen in a crisis, who are unaware of a hyperthyroid background, may pose difficulties in diagnosis. Common errors are to mistake thyroid crisis for sepsis, heat stroke, an acute gastrointestinal infection or ischemic heart disease.

In patients presenting with hyperpyrexia, delirium and tachycardia, the differential diagnosis should include sepsis, malignant hyperthermia, neuroleptic malignant syndrome and acute mania with catatonia. The first three of these conditions could be associated with or indeed precipitate a thyroid storm.

A careful clinical examination for tell-tale features of hyperthyroidism is invariably rewarding. Atrial fibrillation with an uncontrolled fast ventricular rate, which is not slowed with digitalis, should always arouse suspicion. An extremely valuable sign that helps in the diagnosis of a thyroid crisis is the presence of an enlarged thyroid gland or the presence of one or more palpable nodules in the thyroid gland. This enlargement is often not obvious and requires careful clinical palpation. Clinical examination should also be directed towards determining the precipitating cause of a thyroid crisis.

Laboratory Investigations

The triiodothyronine (T_3) and T_4 concentrations are high, but these are not necessarily greater in a thyroid storm than in the usual thyrotoxic state. The thyroid-stimulating hormone (TSH) is low. In critically ill patients, free T_4 and TSH should be measured. *Clinical hyperthyroidism results in an increased free T_4 and a suppression of TSH to less than 0.01 μU/L.* A TSH within normal range should exclude hyperthyroidism. However, TSH may occasionally be low in about 10% patients with nonthyroid critical illness, in patients on dopamine and in patients on a high dose of glucocorticoids. Hence, though an (unsuppressed) normal TSH excludes hyperthyroidism a low TSH does not always establish the diagnosis. A normal free T_4 with a reduced TSH should prompt the intensivist to search other causes (stated above) for a low TSH. It should be noted that heparin therapy can artificially increase plasma free T_4; in heparin-treated patient, the total T_4 should be measured.

There are no other laboratory abnormalities characteristic of a thyroid storm. Hypercalcemia, hyperglycemia and a rise in alkaline phosphatase may be noted. Hyperglycemia is due to gluconeogenesis. There is decreased glucagon suppression and impaired insulin response to hyperglycemia. Electrocardiography (ECG) may show atrial fibrillation or atrial flutter with a fast ventricular rate.

Management: Prevention

Surgery on a hyperthyroid gland should never be performed until the thyrotoxic state is controlled with neomercazole or by the thiouracil group of drugs. Neomercazole (carbimazole) is stopped 8 days before planned surgery, and Lugol's iodine substituted during these 8 days in a dose of 0.1–0.3 mL thrice daily. Following the above precautions, thyroid crisis following surgery on a hyperthyroid gland is extremely rare. The awareness of the fact that all stressful situations (physical or mental) in hyperthyroid patients are potential triggering factors for a thyroid crisis, goes a long way in the prevention of this serious problem.

Treatment of Thyroid Crisis[1,2,5]

Control of the Hyperthyroid State

Use of thiouracils, carbimazole and methimazole Propylthiouracil is the drug of choice. It is given in a loading dose of 600 mg, followed by 250 mg 6 hourly. The drug is not easily available in India. Carbimazole or methimazole is available and the drug is given in a dose of 20 mg three to four times a day. All three drugs have a rapid onset of action and act by inhibiting iodide oxidation and organification by thyroid peroxidase. Propylthiouracil has the additional advantage of being able, to an extent, to inhibit the peripheral conversion of T_4 into T_3. Common side effects of antithyroid drugs are rash, urticaria, arthralgia and fever. Rarely agranulocytosis and hepatic toxicity may be observed.

Use of iodine Intravenous sodium iodide is the quickest method to control thyroid activity in a thyroid storm. Iodine acts by blocking the synthesis and release of thyroid hormones, but is safe to administer only after organification of iodine is arrested by propylthiouracil. It should, therefore, be given 1–2 hours after the first dose of propylthiouracil or carbimazole or methimazole.

Sodium iodide is given in a dose of 1 g in 500 mL dextrose over 8–12 hours. A total dose as high as 3 g may be given over the first 24 hours.

A maintenance dose of 0.5 g may then be given daily for the next 2 days. Lugol's iodine may be given orally if sodium iodide is not available for IV use. The dose is 3–5 drops (6 mg/drop) thrice daily. Potassium iodide can substitute for Lugol's iodine, and is given in a dose of 200 mg 12 hourly. Iodine is preferably stopped after 5–7 days.

Studies have shown that ipodate sodium (an iodine-containing radiocontrast agent), when given orally, has an extremely rapid onset of action, resulting in a lowering of T_3 levels within 6 hours with normal T_3 levels within 24–48 hours. The dosage is 500 mg four times a day. We have no experience with its use, but this drug, when available, has replaced Lugol's iodine and potassium iodide in the treatment of severe hyperthyroidism. Ipodate sodium should be given 1–2 hours after the first dose of propylthiouracil or carbimazole or methimazole.

Use of beta-blockers Beta-blockers are the drugs that best counter the catecholamine-dependent symptoms and signs of an acute thyroid crisis. They play a vital role in treatment as they control both the psychomotor and cardiovascular manifestations that typify a thyroid storm. Beta-blockers reduce the heart rate in patients with marked sinus tachycardia, reduce the fast ventricular rate in patients with atrial fibrillation and often succeed in restoring sinus

rhythm in patients with atrial fibrillation and supraventricular tachycardias.

Propranolol is given in a dose of 40–60 mg orally three to four times a day. Propranolol has the advantage of decreasing the conversion of T_4 into T_3. Though the drug can be given very slowly intravenously in a dose of 0.5 mg to start with, the IV use is best avoided because of the reported experience of sudden bradycardia and arrest after IV use of the drug.

A quicker beta-blocade is provided by esmolol 500 μg/kg IV followed by 50 μg/kg per minute IV. Metoprolol can also be used as an alternative to esmolol—5 mg IV repeated every 5–10 minutes to a maximum of a total dose of 15 mg IV. The oral dose of metoprolol is 50–100 mg twice daily. Atenolol can be used likewise in the same dose.

Though beta-blockers are very useful drugs (particularly in the presence of tachyarrhythmias), they should be used with great caution in patients who have congestive cardiac failure. Marked hypotension and cardiac arrest may occur following their use in these patients.

Use of adrenocortical hormones Glucocorticoids are useful to prevent adrenocortical insufficiency. The rate of utilization of adrenocortical hormones is excessive in a thyroid crisis, and it is possible that some patients may have a relative conditioned deficiency of these hormones. Hydrocortisone is given routinely in a dose of 100 mg intravenously 8 hourly till the crisis is controlled. Besides offering adrenocortical support, glucocorticosteroids are of benefit because they inhibit peripheral conversion of T_4 to T_3.

Control of Atrial Fibrillation

Atrial fibrillation with a fast ventricular rate generally does not respond satisfactorily to digitalis. Propranolol given in the manner described above is the drug of choice. Metoprolol is longer acting and may also be given intravenously in an initial dose of 5 mg given at a rate of 1–2 mg/minute, to a total dose of 10–15 mg.

In an acute hemodynamic crisis with a barely recordable blood pressure and the presence of features of cardiogenic shock, a synchronized direct current (DC) shock should be promptly administered. It generally restores sinus rhythm. Once this is achieved, a beta-blocker is used as mentioned earlier.

Digoxin (even though the response is generally unsatisfactory) and diuretics may also be used in atrial fibrillation with congestive cardiac failure. If atrial fibrillation persists, anticoagulants should be given to prevent embolic episodes.

Treatment of Hyperpyrexia

Symptomatic treatment of hyperpyrexia is necessary in a few patients; else death can result before more definitive therapy can take effect.

Control of Restlessness, Excitability and Irritability

Restlessness is controlled by the use of phenobarbitone sodium 60 mg intramuscularly or chlorpromazine hydrochloride 25–50 mg intramuscularly or the use of 5 mg diazepam IV. This can be repeated as and when necessary.

Maintenance of Fluid and Electrolyte Balance

Patients suffering a thyroid storm sweat profusely. This is even more marked in hot tropical climes. A tremendous loss of water, sodium and chloride occurs. Potassium loss is also marked because of diarrhea and a poor intake. A fluid intake well over 3 liters and, at times, exceeding 4 liters, is necessary. It is, however, worth recording that pulmonary edema is an important complication of thyroid crisis. A close monitoring of the cardiovascular status, renal function and urine output is necessary. Fluid and electrolyte replacement should be based on clinical considerations and on serum electrolyte estimations.

Since hepatic glycogen is used up quickly in a thyroid crisis, fluid replacement should include at least 1 liter of 10% dextrose. The hypermetabolic state in a thyroid crisis places an excessive demand on nutrients and vitamins necessary for proper functioning of different tissues in the body. The demand particularly for thiamine may be great. In poorly nourished individuals so commonly encountered in the tropics, an acute thiamine deficiency may arise, particularly if large quantities of dextrose are given intravenously and an adequate dose of thiamine (200–500 mg) is not supplied.

Use of Oxygen

The demand and consumption of oxygen are excessively increased in the hypermetabolic state that characterizes a crisis. The patient is given oxygen at a flow rate of 6–8 L/minute.

Note It is important to treat the underlying illness that could have triggered a thyroid storm or crisis.

The management of an acute thyroid crisis is summarized in Box 4.

HYPERTHYROIDISM CONTRIBUTING TO THE MORBIDITY OF OTHER CRITICAL ILLNESSES IN THE ICU

The commonest cause of hyperthyroidism is Graves' disease which in a florid state is easily diagnosed but may be missed in early or an evolving state. Other causes include a toxic nodular goiter and a thyroid adenoma. The above conditions are associated with an increased iodine-131 uptake by the gland. Hyperthyroidism can also be induced by the use of amiodarone, iodine-containing contrast media, or can result from acute or subacute thyroiditis. Rarely, hyperthyroidism may be due to the purposeful ingestion of thyroid hormone—factitious hyperthyroidism. All these conditions are associated with a decreased iodine-131 uptake by the gland.

Undetected hyperthyroidism in patients admitted to the ICU for other critical illnesses can pose diagnostic problems, and can add to the morbidity of the critical illness. The stress of a critical illness often increases the degree of hyperthyroidism in a patient, so that mild or latent

Box 4: Management of acute thyroid crisis

- Control of hyperthyroid state
- Propylthiouracil 250 mg 6 hourly or carbimazole 30 mg 6 hourly
- One gram sodium iodide in 500 mL dextrose, given as an IV infusion, followed by a maintenance dose of 0.5 g daily for the next 2 days. Alternatively, 3–5 drops (6 mg/drop) of Lugol's iodine are given orally thrice daily. Start iodine 1–2 hours after first dose of propylthiouracil or carbimazole
- Propranolol 40 mg qds orally or esmolol in an IV infusion (see text) or metoprolol 5 mg IV repeated every 5–10 minutes for a total of 15 mg
- Hydrocortisone 100 mg is given IV 8 hourly or dexamethasone 2 mg IV qds
- Control of atrial fibrillation and other tachyrhythms—
  - Metoprolol 5 mg IV (at the rate of 1–2 mg/min) up to a total dose of 10–15 mg
  - Propranolol 40–60 mg tds
  - Synchronized DC shock given in acute hemodynamic crisis
- Symptomatic treatment of hyperpyrexia
- Control of restlessness and irritability with phenobarbitone sodium 60 mg IM or chlorpromazine 25–50 mg IM or diazepam 5–10 mg IV repeated as and when required
- Maintenance of fluid and electrolyte balance—
  - Three to four liters of fluid infused over 24 hours after monitoring the patient's cardiovascular status and urine output
  - Correct hyponatremia, hypokalemia
  - Intravenous dextrose—at least 1 liter of 10% dextrose required in 24 hours
  - Administer 200–500 mg thiamine, particularly in poorly nourished patients
- Administer oxygen at a flow rate of 6–8 L/min
- Identify and treat precipitating factor—in particular, underlying sepsis

hyperthyroidism now becomes clearly manifest. The features of such coexisting hyperthyroidism often merge and may well be indistinguishable from the features of the critical illness for which the patient is admitted.

Hyperthyroid activity in these patients generally takes the following forms—

- Pyrexia of unknown origin, which fails to respond to antibiotics given because of a mistaken diagnosis of infection.
- An unstable hyperdynamic circulation which is generally attributed to the critical illness for which the patient was admitted, or to complicating sepsis.
- Rhythm disturbances with or without congestive cardiac failure, or the evolution and persistence of congestive cardiac failure with a fast ventricular rate.

The following points help in correct diagnosis—

- The possibility of hyperthyroidism should always be considered at any age when a patient develops atrial fibrillation, a fast ventricular rate and congestive cardiac failure, which does not promptly respond to digitalis. Most such patients are past 40 years in age and may complain of cardiac pain due to relative coronary insufficiency produced by a very rapid ventricular rate. This often makes the unwary fall into the trap of diagnosing ischemic heart disease causing atrial fibrillation and congestive heat failure. Even if the patient has proven ischemic heart disease, as viewed from the past history and ECG recordings, this does not always exclude a coexistent hyperthyroid state.
- Paroxysmal atrial fibrillation, or any form of paroxysmal supraventricular tachycardia in a patient admitted to the ICU for a serious illness, should suggest the possibility of a coexisting hyperthyroid state.
- Hyperthyroidism should always enter into the differential diagnosis of congestive heart failure of undetermined etiology. A careful examination may reward the clinician with a few tell-tale signs, as, for example, the presence of a slight stare, a lid lag, a warm moist skin and an enlarged thyroid gland.

Raised free T_4 levels with a low TSH level prove the diagnosis of a hyperthyroid state in these patients.

The importance of a correct diagnosis is obvious. Manifestations of excessive thyroid activity can only be controlled by the specific measures stated earlier. They remain uncontrolled with conventional therapy used for atrial fibrillation or for congestive heart failure. It is important to control coexisting hyperthyroidism in critically ill patients. Control reduces the metabolic demands of the critical illness and should improve the chances of recovery.

MYXEDEMA COMA[6-8]

Myxedema coma is invariably the culmination of long-standing hypothyroidism. It may occur as the terminal event in the natural history of severe myxedema. It may however also be precipitated by exposure to cold, by infection and by the unwise use of sedatives to which patients with myxedema are extremely susceptible. Other precipitating factors include trauma, surgery, stroke, hypovolemia from any cause and congestive heart failure. Box 5 lists the important precipitating factors of myxedema coma.

Diagnostic Clinical Features

The onset is gradual particularly when myxedema coma is the terminal event of long-standing progressive hypothyroidism. It may be fairly abrupt if the problem is triggered by the precipitating factors listed above. The hallmark of myxedema coma is hypothermia—the rectal temperature being often less than 80°F. This is missed as it will not be recorded by a clinical thermometer; the degree of hypothermia can be ascertained with a chemical thermometer.

Box 5: Important precipitating factors of myxedema coma

- Infection
- Exposure to cold
- Injudicious use of sedatives and narcotics
- Surgery/Trauma
- Cerebrovascular accident
- Hypovolemia due to any cause
- Congestive heart failure

The cardiovascular system on examination shows marked bradycardia. The stroke volume and cardiac output are decreased; there is an increased peripheral vascular resistance with decreased blood volume and diminished blood flow to vital organs. The heart size is often enlarged; pericardial effusion is frequently observed. Signs of congestive heart failure—engorged neck veins, enlarged liver and pitting edema are often present. The blood pressure to start with may be noncontributory in the diagnosis. Terminally hypotension is invariably observed. There may be a rise in the creatine kinase (CK) and lactic acid dehydrogenase (LDH) enzymes, so that a diagnosis of myocardial infarction can be wrongly made. The ECG shows bradycardia and low voltage; conduction defects may occur in the sinoatrial (SA) node, atrioventricular (AV) node and in the bundle branches of His.

The respiratory system shows important changes. Hypoventilation with resulting hypoxia and hypercapnia are invariably present. There appears to be a decreased response to hypercapnia, so that uncontrolled oxygen therapy can complicate the picture by inducing hypercapnic narcosis and worsening the obtunded state. There are probably a number of causes for hypoventilation in myxedema coma. The most important reason is, in all probability, a diminished central respiratory drive, followed by poor muscle power, poor tone and poor contraction of the respiratory muscles. Contributory causes may be extreme obesity and obstruction to the upper airways due to macroglossia and to edema of the oropharynx. Marked sensitivity to the effects of sedatives and tranquilizers, narcotics and anesthetic agents can trigger both coma and hypoventilation in patients with myxedema.

The other tell-tale features are all there for those who have eyes to see; it is astonishing how these features are explained away! The dry, cool, puffy skin, the myxedematous facies, the constant drowsiness and confusion that precede coma, the loss of scalp and body hair (which includes the axillary hair), the macroglossia and delayed relaxation of the ankle reflex are all present.

Constipation is a nonspecific symptom but is almost always present. Ascites is uncommon, but, if present, may lead the unwary to a wrong diagnosis. Gastric atony and ileus involving both the small and large bowel are frequently observed. Urinary retention is common because of atony of the bladder.

A normocytic, normochromic anemia is present and the white blood cell count may be decreased. Inability to raise the core temperature or to generate a leukocytosis in response to infection renders the diagnosis of a complicating infection doubly difficult.

Box 6: Clinical features and laboratory abnormalities in patients with myxedema coma

- Hypothermia (except in the presence of infection)
- Clinical features of severe myxedema—
  - Dry, cool and puffy skin
  - Typical myxedematous facies
  - Loss of scalp and body hair
  - Drowsiness/mental obtundation preceding coma
  - Macroglossia
  - Delayed ankle reflexes
  - Atonic GI tract; atonic bladder
  - Marked bradycardia; ECG changes
  - Pleural, pericardial, peritoneal effusions
- Hypoventilation; hypercapnic respiratory failure
- Hypotension in terminal stages
- Laboratory abnormalities—
  - Normocytic, normochromic anemia, decreased WBC count
  - Hyponatremia, hypoglycemia, elevated levels of CK, LDH
  - T_3, T_4 levels decreased; TSH increased
  - Arterial blood gas (ABG)—PaO_2 decreased; $PaCO_2$ increased
- Radiological abnormalities—
  - Chest X-ray—cardiomegaly, pericardial effusion
  - Ultrasound of the abdomen—ascites may be present
- Hemodynamic parameters—
  - Decreased stroke volume and cardiac output
  - Increased peripheral vascular resistance
  - Decreased blood flow to vital organs

The clinical diagnosis of myxedema coma should be proved by low T_3, low T_4, and high TSH values. These values, however, need to be no different from those observed in a patient with obvious myxedema.

The basic features necessary for a clinical diagnosis and a summary of laboratory changes in patients with myxedema coma are summarized in Box 6.

Treatment[9-11]

The principles of treatment of myxedema coma are—

- ❑ Quick replacement of thyroid hormone.
- ❑ Use of adrenocortical steroids.
- ❑ Respiratory and cardiovascular support.
- ❑ Treatment of infection, a common precipitating factor.
- ❑ Countering hypothermia.
- ❑ Correction of hyponatremia.
- ❑ Overall critical care.
- ❑ Avoidance of all sedatives, hypnotics and narcotics.

Rapid Replacement of Thyroid Hormone

Use of L-T_3 sodium This is a rapid acting hormone whose main use is in severe myxedema or myxedema coma. T_4 given

orally acts far too slowly and, by the time the drug takes effect, the patient may succumb. The recommended dose of T_3 is 10 μg every 4–6 hours; this can be given intravenously or by nasogastric tube till clear improvement is observed. The IV preparation is not easy to come by, but if available, is to be preferred as absorption of both T_3 and T_4 from the gut is erratic and unpredictable. If the IV preparation is not available, oral T_3 is preferred to oral T_4, as the former is quicker acting. If oral T_3 is also unavailable, then one has to rest satisfied with the oral use of T_4. In Western countries, an IV T_4 preparation is available. The dose for myxedema coma is 500 μg as an IV bolus dose, followed by 50–100 μg daily. The dosage of the replacement hormones may need modification if anginal pains are frequent. Isosorbide dinitrate 10 mg thrice daily can be used if anginal pain occurs. After recovery, the patient is kept on a maintenance dose of either T_3 or T_4.

Use of Adrenocortical Steroids

There is a possibility that patients with severe myxedema have a poor adrenocortical reserve. What is more, it is difficult in an emergency situation to distinguish hypopituitary coma from a myxedema coma. To use thyroid hormone as the sole replacement hormone in a pituitary coma would provoke disaster, as the thyroid hormones would increase the metabolic rate and precipitate a severe adrenal crisis in such a patient. Hydrocortisone in a dose of 100 mg is therefore given intravenously every 8 hours.

Respiratory and Cardiovascular Support

Hypoventilation with hypercapnic respiratory failure needs to be treated by noninvasive ventilator support or by endotracheal intubation and mechanical ventilator support if the respiratory drive is very poor. This may need to be continued for 10–15 days. The airway must be kept patent, particularly, if the patient lacks the strength to cough, or is mentally obtunded with a poor cough reflex.

Hypotension needs to be countered by a volume load, provided there is no pulmonary edema. Inotropic support with dopamine should preferably not exceed 5–7 μg/kg per minute, as these patients are invariably severely vasoconstricted. Further vasoconstriction can jeopardize tissue perfusion.

Treatment of Infection

Infection is a common precipitating cause, and may not be clinically evident because of hypothermia, and the frequent absence of leukocytosis. Infection should be countered by the use of appropriate antibiotics. Terminal bronchopneumonia is common in such patients.

Raising the Body Temperature

Marked hypothermia may have to be corrected as an emergency measure. The body temperature should be raised very gradually; whenever possible, electric blankets or a heat cradle should be used. Sudden rewarming can cause peripheral vasodilatation and a crash in the already low arterial blood pressure. Ultimately, only a rise in the metabolic rate produced by the thyroid hormones can result in a sustained elevation of body temperature.

Correcting Hyponatremia

Myxedema coma is often accompanied by severe hyponatremia. Fluids should be restricted, and when necessary, a titrated volume of 3% saline is administrated.

Overall Critical Care

This is of great importance. Hyponatremia is often present and needs to be corrected. Hypertonic saline is avoided except under exceptional circumstances. Support to various other organ systems is often necessary. Patients in myxedema coma are often very poorly responsive to inotropes and vasopressors.

EUTHYROID SICK SYNDROME (SICK THYROID SYNDROME)

Thyroid function changes rapidly in critically ill patients. A number of these patients have the euthyroid sick syndrome. This syndrome is characterized by a low serum T_3 and T_4, and an increase in the L-reverse triiodothyroxine (rT_3).[12,13] The free fractions of T_3 and T_4 remain normal. This biochemical abnormality is due to inhibition of thyroid hormone binding to protein, and to diminished 5'-deiodinase activity. In healthy individuals, this enzyme catalyzes T_4 into the usual active T_3 in organs and tissues. On the other hand, the enzyme 5-deiodinase acts on T_4 and converts it to rT_3. 5-deiodinase, unlike 5'-deiodinase, is not affected by a critical illness. Therefore, T_3 levels are low, and rT_3 levels are increased in a critical illness. These patients are clinically euthyroid and have normal TSH levels.

The euthyroid sick syndrome is an adaptive phenomenon to a serious illness. The low T_3 levels limit oxygen utilization and reduce tissue breakdown. Administration of thyroid hormone is not indicated in these patients, and may harm as it promotes a negative nitrogen balance. In an ICU setting, it becomes important to distinguish the euthyroid sick syndrome, which does not require thyroid replacement therapy from true hypothyroidism. The serum TSH is usually normal in the euthyroid sick syndrome patients and high in true hypothyroidism. In critical illnesses, in which hypothyroidism is coexistent, TSH values are, however, not always reliable, as these values are not consistently elevated. A reliable method of estimating thyroid function in a critical illness is to estimate the free T_4 levels (normal in the euthyroid sick syndrome, and low in true hypothyroidism), or to perform the thyrotropin-releasing hormone (TRH) test. The free T_4 index can be estimated directly by the equilibrium dialysis method or is computed approximately by multiplying the T_4 concentration by the T_3 resin uptake. The TRH test is performed at the bedside by administering 250–500 μg of TRH intravenously. TSH levels are measured after 30 minutes. The patient with an euthyroid sick syndrome has a two to three times increase in the TSH after TRH test. A hypothyroid patient

has a rise of six to eight times in the TSH concentration after a TRH test.

CHAPTER 60

Diabetes Mellitus

GENERAL CONSIDERATIONS

Patients with diabetes mellitus in the intensive care unit (ICU) generally present with the following problems—

- Complications of poorly controlled disease—particularly, diabetic ketoacidosis (DKA) and coma, and hyperosmolar nonketotic diabetic coma. The latter entity is also called, and synonymous with, hyperglycemic nonketotic hyperosmolar (HNHS) diabetic syndrome.
- Hypoglycemia induced by insulin or by an overdose of antidiabetic oral medications.
- One or more organ dysfunction associated with, or directly related to, poor control of diabetes.
- An unstable blood sugar with swings between hypoglycemia and hyperglycemia, induced by the stress of an unrelated critical illness.

The present section deals with DKA and coma, and with hyperosmolar nonketotic diabetic coma, both serious life-threatening metabolic disturbances associated with diabetes mellitus.

Diabetic Ketoacidosis and Coma[1,2]

Diabetic ketoacidosis is a serious metabolic disorder characterized by well-marked hyperglycemia [blood glucose >13.8 mmoL/L (250 mg/dL)], ketosis, metabolic acidosis and severe volume depletion with consequent dehydration.

Diabetic ketoacidosis chiefly occurs in insulin-dependent diabetics and its main cause is a severe lack or deficiency of insulin. It can, however, also occur, though less frequently in non-insulin (type 2) diabetes.

Failure to take insulin, or to meet the increased need for insulin during the acute stress of infection, illness or surgery, is the commonest cause of DKA. It is a common fallacy among insulin-dependent diabetics, that if they do not eat, they should not take insulin. This only serves to worsen the diabetic state, and increase the ketosis, which in turn, causes more nausea and vomiting.

Diabetic ketoacidosis is sometimes observed in a newly diagnosed insulin-dependent diabetic, the features of ketosis often drawing attention to the underlying diabetic state.

Dietary indiscretions with overindulgence in food are also observed to be a cause of DKA. Other precipitating factors include infections such as pneumonia, urinary infection, acute myocardial infarction and pancreatitis. Any condition causing high fever in an insulin-dependent diabetic can occasionally trigger DKA, if attention is not paid to the increasing requirements. The use of corticosteroids, catecholamines, inotropes and diuretics in insulin-dependent diabetics can result in a worsening diabetic state culminating in DKA.

There are many factors in an ICU setting that could potentially worsen diabetes and induce DKA. These include sepsis, use of parenteral nutrition involving a high carbohydrate intake and use of catecholamines. Even so, it is uncommon for severe DKA to develop de novo in the ICU, presumably because of increased vigilance that operates in the ICU setting.

Severe DKA is the forerunner of diabetic coma. A conscious diabetic with severe ketoacidosis should therefore be regarded and treated with the same urgency as one in diabetic coma. The dividing line between precoma and coma is thin and tenuous. Thus, a few patients remain conscious in spite of severe ketoacidosis till just some hours before death while others with the same degree of ketoacidosis lapse quickly into coma, which may be prolonged for 24–72 hours.

Box 1: Factors precipitating diabetic ketoacidosis

- Noncompliance with insulin therapy
- Newly diagnosed severe insulin-dependent diabetes
- Overindulgence in food
- Postsurgery
- Acute infections; acute febrile illness of any etiology
- Acute myocardial infarction
- Acute pancreatitis
- Use of glucocorticoids, catecholamines and diuretics
- Severe emotional, mental stress

Precipitating factors known to induce DKA are given in Box 1.

Present-day management has reduced the mortality of severe DKA and coma to 5%. Remarkably enough, there has been no further reduction in mortality. Further reduction is only possible if ketoacidosis is recognized early and treated promptly.

Pathophysiology[3]

Physiopathology of DKA is in essense a severe insulin deficiency combined with an excess of hormones that increase the blood glucose levels. Thus, insulin deficiency is associated with an increase in glucagon. This change in the insulin-glucagon ratio alters carbohydrate, fat and protein metabolism. In addition, due to the marked increase in glucagon levels, there is also a significant increase in the level of stress hormones including cortisol, growth hormones and catecholamines.

Insulin lack is furthermore associated with a varying degree of resistance to the action of insulin in DKA. The net result is an enhancement of the hyperglycemic state. Glucagon acts predominantly on the liver. It increases the activity of carnitine acyltransferase I, and enhances transport of long chain fatty acids into the mitochondria. Cortisol increases gluconeogenesis and promotes insulin resistance. Catecholamines enhance lipolysis and ketogenesis, and also accelerate gluconeogenesis. Growth hormone also increases lipolysis and contributes to insulin resistance.

Hyperglycemia

This as has already been explained is chiefly due to a marked increase in glucose production in the liver (gluconeogenesis). It is also in part due to poor utilization of glucose by the tissues. A factor that determines the degree of hyperglycemia in DKA is the extent of glucose loss through the kidneys. As long as the circulatory state is satisfactory and the kidneys remain well perfused, there is a ready leak of glucose from the blood and the extracellular space via the urine. This helps to limit hyperglycemia. Volume depletion could however lead to impaired renal perfusion, a lowered urine output and consequently a diminished leak of glucose in the urine. This could result in a sharp increase of glucose in the extracellular space, even though the hepatic glucose production remains unchanged.

Ketosis and Metabolic Acidosis

Ketosis is chiefly due to increased lipolysis in fat depots providing a source of free fatty acids as fuel. These free fatty acids are converted to ketones under the influence of glucagon. The predominant ketoacids are beta-hydroxybutyrate and acetoacetic acid, the ratio of these two ketoacids being 3:1.

Metabolic acidosis in uncontrolled diabetes is due to—

- *Uncontrolled ketosis with ketonemia* This results in an increase in the anion gap because of the buffering by bicarbonate of the hydrogen ion.
- *Hyperchloremic acidosis* Many patients have a reduction in bicarbonate which is in excess of the increase in the anion gap. This indicates the association of a non-anion gap hyperchloremic acidosis. The latter has been recognized for quite some time as a complication occurring in the later treatment stages of DKA. It may however also occur early, particularly in patients who are not so severely volume depleted. It is important to recognize hyperchloremic acidosis as it takes longer to resolve compared to acidosis due to increased ketones in the blood. This is because ketoacids are metabolized to generate equimolar quantities of bicarbonate, while hyperchloremic acidosis stands corrected only through increased generation of bicarbonate by the kidneys.
- *Lactic acid acidosis* Increased lactic acid production contributes to the metabolic acidosis of severe DKS, when tissue perfusion is impaired because of a poor circulatory state.

Fluid and Electrolyte Abnormalities

Fluid and electrolyte loss form an important feature of DKA. This loss is consequent to the osmotic diuresis produced by glycosuria that follows from severe hyperglycemia. Fluid loss may amount to 4–8 L in an average patient. There is also a marked depletion of sodium, potassium and chloride that may amount to 300–600 mEq or more. Phosphates and magnesium are also lost but in smaller quantities. The degree of electrolyte loss may not be manifested in the serum electrolyte levels, which may be only slightly reduced in concentration. Hyponatremia may, however, be observed. Hypernatremia pointing to excessive water loss, in comparison with sodium loss, is rare. This is because of the shift of water from the intracellular compartment to the hyperosmolar extracellular and vascular compartments. The hyperosmolarity of the extracellular space, which induces this shift, is due to hyperglycemia. Shift of water from the intracellular compartment is accompanied by a shift of potassium from the cells into the interstitial and vascular compartments. Metabolic acidosis accentuates the shift of potassium from the intracellular to the extracellular compartment. Serum potassium levels may thus be normal or high, in spite of a gross overall deficit of potassium in the body. Chloride loss in the urine is less than the sodium loss, because sodium is additionally lost as an accompanying cation when ketones

are excreted in the urine. Serum chloride concentration may thus not be significantly reduced.

Altered Mental State

This has not been well explained in patients with DKA. In all probability, altered mentation, obtundation, drowsiness and coma are at least partly related to serum osmolality. Patients with an altered mental state have an osmolality more than 350 mOsm/L. Ketonemia with metabolic acidosis also probably contributes to the altered mentation.

Clinical Features[3]

Nausea and vomiting are frequent presenting manifestations, and may precede drowsiness and coma by a few days. Abdominal pain may also occur and, in some patients, is severe enough to mimic an acute abdomen. Respiration is of Kussmaul's type, deep and labored, and there is a fruity smell of acetone in the breath. A history of polyuria, polydipsia, polyphagia and muscle cramps in the immediate past may be given by the patient or his relatives. The mental state is often confused and obtunded. Drowsiness progressing to coma can occur over a few hours to a few days.

Clinical examination reveals evidence of dehydration. The skin is dry, inelastic, and the tongue dry and furred. The eyeballs are soft; there is tachycardia, hypotension and oliguria. The untreated patient often progresses to drowsiness and coma from which he cannot be aroused by even the most painful stimuli. The corneal reflexes may then be lost, and the plantars become extensor. The blood pressure continues to drop, so that terminally it is unrecordable. Death results from peripheral circulatory failure or cardiac arrest.

Severe DKA is often triggered by precipitating factors, the main ones being acute infection, omission of insulin due to vomiting or diarrhea, or to poor food intake, and poor compliance. Important precipitating factors have already been listed in Box 1.

Laboratory Investigations

The urine shows glycosuria and ketonuria. The blood shows hyperglycemia, the blood sugar usually being more than 450 mg/dL. It is, however, important to stress that severe hyperglycemia is not always present. In the presence of acidosis, the diagnosis should be suspected even if the blood sugar levels are not very high. This is particularly observed in patients who eat poorly and imbibe a large quantity of alcohol, and in pregnant females. In the latter, blood sugar levels may occasionally be modestly elevated even in the presence of severe ketoacidosis.

Ketonemia is present, and the presence of metabolic acidosis is mirrored by a sharp fall in arterial pH (to below 7.3 and, at times, <7.0), a fall in the bicarbonate content (often <10 mEq/L), an increase in the anion gap, and by a marked increase in the base deficit as computed by the Astrup technique. There is compensatory hypocapnia.

There are some points to be noted in relation to acidemia and ketonemia in DKA—

- A deceptively mild acidemia may be observed in DKA if there has been sufficiently severe vomiting to produce a metabolic alkalosis. The latter neutralizes the effect of metabolic acidosis. Mixed acid-base disturbances should, therefore, be correctly interpreted with reference to the clinical findings.
- Absence of ketones in a patient with acidosis, hyperglycemia and volume depletion, should suggest predominance of beta-hydroxybutyric acid as the predominant ketone in the plasma. In the presence of lactic acid acidosis (due to hypoperfusion), the acetoacetate is largely converted to beta-hydroxybutyrate. The nitroprusside test (a semiquantitative test) only recognizes acetone and acetoacetate, so that ketonemia due to beta-hydroxybutyrate may go undetected. In these patients, treatment with insulin and fluid replacement reduces the ketonemia. Beta-hydroxybutyrate is first converted to acetoacetic acid before being metabolized. Paradoxically thus, though the patient is improving, the nitroprusside test will now show a stronger positivity to plasma ketones. A clinical assessment, and monitoring of the pH of arterial blood, gives the correct perspective in these patients.

The blood urea, creatinine and nonprotein nitrogen (NPN) are generally elevated; the azotemia is prerenal due to dehydration and also due to endogenous tissue breakdown. Serum sodium and chloride are generally modestly reduced. Hyponatremia is occasionally more marked, in which case the serum sodium is less than 125 mEq/L. Very rarely, one encounters hypernatremia when water loss significantly exceeds sodium deficit. The serum potassium in majority of untreated cases is normal or slightly elevated, even though there is an overall deficit in body potassium. Some patients may, however, present with hypokalemia right from the start. Hypokalemia is often present during treatment with insulin. Less than 10% of patients have hypophosphatemia to start with; 10% of patients may also present with hypomagnesemia. Hypocalcemia is frequent and the serum invariably shows hyperosmolality.

Well-marked leukocytosis is often present (15,000–30,000/mm^3) even in the absence of infection (Box 2).

Diagnosis[3]

The most important clinical differential diagnosis is a hypoglycemic coma due to insulin reaction or an overdosage with oral antidiabetic drugs. Severe sweating is the hallmark of hypoglycemic coma. Twitchings, seizures, the presence of a decerebrate state and even neurological focal signs are observed with hypoglycemic coma, but not in diabetic coma. Deep-labored breathing with a fruity odor of ketones in the breath should further help distinguish DKA from hypoglycemic coma. When doubt exists, blood should first be withdrawn for estimating the blood glucose level, and 50 mL of 50% dextrose is then injected intravenously. The patient

Box 2: Laboratory and other tests

- Laboratory tests—
  - CBC, ESR
  - Urine (sugar, ketones, pus cells, RBCs and casts)
  - Blood sugar (hyperglycemia)
  - Serum electrolytes (usually hyponatremia, serum K^+ normal or high to start with or low during treatment)
  - Blood urea, creatinine, NPN (usually raised)
  - Arterial pH, blood gases (pH <7.3, increased anion gap, bicarbonate <15 mEq, increased base deficit, ketonemia)
  - Serum Mg, Ca and phosphate (variable, may be low)
- Test for hyperosmolality
- Test for any precipitating factors
- ECG
- X-ray chest
- USG abdomen and pelvis

Abbreviations: CBC, complete blood count; ESR, erythrocyte sedimentation rate; RBC, red blood cell; NPN, nonprotein nitrogen; Mg, magnesium; USG, ultrasonography.

becomes alert quickly in hypoglycemic coma, but remains unchanged in diabetic coma.

Ketonuria and ketonemia can also occur in starvation and following alcohol ingestion.[4] There is no glycosuria in starvation ketosis, the blood sugar is normal or low, and the ketonemia is very mild.

Alcoholic ketoacidosis may occasionally bear a strong resemblance to DKA. There is well-marked ketonemia and ketonuria, but blood sugar levels are normal or low. Severe diabetics, who eat poorly and continue to ingest alcohol, may have severe DKA with only modest elevations in blood sugar levels.

Coma due to metabolic acidosis with a large anion gap may also occur in uremia and in some poisonings (notably methyl salicylate poisoning). The absence of ketonemia and ketonuria in these conditions, and a careful clinical and laboratory assessment, clarify the diagnosis.

A diabetic patient may become comatose following a head injury or a cerebrovascular accident. A subarachnoid hemorrhage in a diabetic is often missed, and the patient is treated for diabetic coma. This is because of the increase in hyperglycemia triggered by the bleed. Neck stiffness, a positive Kernig's sign, and continuing drowsiness after correction of metabolic abnormalities, point to the correct clinical diagnosis. Imaging of the head further clarifies the diagnosis.

Finally, ketoacidosis with coma in a diabetic should be distinguished from the rare hyperglycemic hyperosmolar nonketotic coma.

Principles of Management

The principles of management are as follows—

- *To administer sufficient insulin intravenously,* so that acidosis is corrected and the blood sugar is brought down to near normal levels. Insulin corrects hyperglycemia and ketosis by correcting the basic abnormalities in metabolism—it stops ketogenesis and lipolysis, reduces neoglucogenesis, and increases the peripheral utilization of glucose.
- *To replace the loss of water and electrolytes* which characterize the severe diabetic state. Dehydration is corrected by rapid intravenous infusions of normal saline (N-saline), and hypokalemia, which is often encountered during recovery from diabetic coma, by a monitored infusion of potassium chloride.
- *To correct severe metabolic acidosis* Insulin is mandatory for this purpose; the use of IV sodium bicarbonate is avoided as far as possible, as it probably does more harm than good. It may be used only as an emergency measure in patients who are deeply unconscious and severely acidotic.
- *To correct shock, if present, by the emergency infusion of plasma or colloids* The circulatory hemodynamics will ultimately stand corrected only if adequate replacement of fluid and electrolytes is quickly achieved.
- *To determine the precipitating factor causing severe DKA* with coma, and to treat this factor. It is extremely important to search for infection, a common and important precipitating factor.
- *To monitor patients carefully* and meticulously through all phases of management.

Details of Management[3,5]

There is one important feature that needs to be emphasized in the management of diabetic ketosis and coma. This dangerous metabolic abnormality had a high mortality almost up to the end of the 20th century. This was felt to be due to three factors—

1. Overenthusiastic and very rapid replacement of IV fluids in an attempt to quickly correct volume depletion.
2. Frequent use of IV bicarbonate to help correct acidosis
3. Overenergetic use of IV insulin so that the blood sugar was brought down too rapidly.

It is believed that all these factors predispose to the development of cerebral edema, which is the main cause of death in DKA and coma.

An awareness of these factors in management has reduced the present-day mortality to less than 5%.

Monitoring the Patient

Close monitoring is important for easy and successful management. Once the diagnosis of diabetic coma is established, blood is withdrawn form a peripheral vein through a large needle, and sent for estimation of glucose, ketones, electrolytes, urea, creatinine, blood counts and other relevant biochemical tests. Twenty-five units of actrapid insulin are injected through the same needle; this is followed by the starting of an IV infusion of N-saline. Arterial blood is also promptly collected and sent for measurement of arterial pH, blood gases and bicarbonate content. It is important to

secure a good peripheral vein immediately after admission. In addition, a central venous line is secured with the venous catheter in the superior vena cava. This allows infusion of fluids, as well as measurement of the central venous pressure. In patients who are markedly hypotensive from fluid and electrolyte loss, it is best to secure one more peripheral vein to aid in the rapid replacement of fluids.

A nasogastric tube is passed into the stomach, which is washed out by sodium bicarbonate. A Foley's catheter in the bladder allows the maintenance of an hourly urine output chart, as also examination of the urine for sugar and ketones.

Comatose patients have no control over their airways and often aspirate. They should be intubated and, if need be, given ventilator support.

The patient should be monitored as for any critical illness with special emphasis on intake-output charts, vital signs, evidence of pulmonary congestion, serum electrolytes, renal function, and above all, blood glucose and plasma ketones.

Blood glucose should be monitored hourly at the bedside, and 2–3 hourly in the laboratory. This initially provides information as to whether the insulin administered is adequate to cause a fall in the high blood glucose levels at the rate of 75–100 mg/dL per hour. Later, estimating the blood glucose enables the physician to adjust insulin administration so that blood glucose levels are maintained between 150 mg/dL and 250 mg/dL, and both hypoglycemia and a return to hyperglycemia, are avoided. Arterial pH, blood gases and serum electrolytes are monitored as often as necessary. The latter should preferably be monitored every 4–6 hours till the patient is well on the way to recovery. All data should be charted on a flow sheet for easy evaluation.

Insulin therapy and volume replacement to correct dehydration should be carried out simultaneously.

Insulin Therapy

Intravenous infusion of insulin is promptly started, so as to allow a careful and not too rapid rate of fall in blood glucose. An IV bolus of 20–25 units of insulin is given, followed by an IV infusion of insulin in N-saline titrated so as to administer 6–8 units (0.1–0.15 units/kg) of actrapid or huminsulin S insulin per hour. This can be achieved by adding 50 units of soluble insulin (actrapid or huminsulin S) to 50 mL of N-saline (i.e. 1 U/mL) and delivering this intravenously through a syringe pump either through a separate vein or "piggy-backed" into an IV fluid line. As mentioned above, initially 6 units/hour or 6 mL/hour is given and once the blood sugar starts to fall, the rate of infusion is titrated so that the blood glucose falls at the rate of 3–4 mmoL/hour. A trend of the rate at which blood glucose falls is evident in 3–4 hours. A faster rate of fall is unnecessary and perhaps may even be harmful, as it can cause hypoglycemia or even contribute to or precipitate cerebral edema.

A sliding scale (based on an hourly measurement of blood glucose) of insulin requirement that generally works is as follows—

- If blood glucose is less than 5 mmoL/L (90 mg/dL) give 0.6 units/hour.
- If blood glucose is less than 10 mmoL/L (180 mg/dL) give 2 units/hour.
- If blood glucose is more than 10 mmoL/L, give 4 units/hour.

An alternative method of delivering insulin (other than through a syringe pump) is to dilute 50 units of soluble insulin in 500 mL of N-saline and regulate delivery at the desired rate—of say 4–6 or more units per hour.

It is important to note that blood glucose and ketones will rise sharply if insulin delivery is intermittent. Close hourly monitoring of blood sugar is mandatory to start with. If the blood glucose fails to fall, it means that the infusion pump is not working or is turned off or the infusion cannula is blocked. Very occasionally the insulin requirement may be higher (8–12 units/hour to start with).

When the blood sugar levels are between 180 mg/dL and 200 mg/dL, a 5% dextrose saline infusion is started, but the insulin infusion is continued till ketosis clears. This is important as decreasing the insulin infusion at this juncture may result in a persistence of ketosis for a much longer period of time. A situation may well arise during the treatment of DKA, when the blood glucose level is normal or less than normal, and yet ketonemia and ketonuria are very evident. This is countered by an IV infusion of 5% or even 10% dextrose, and simultaneous continuation of the insulin infusion. It should never be forgotten that the main battle is to be waged against ketosis and resulting acidosis, which strongly disturb the homeostasis of the milieu interieur. Hyperglycemia is generally controlled within 12 hours; ketosis may take longer to be controlled (18–24 hours, or even more).

It is often difficult to determine when ketosis is controlled. Serum ketone measurements are useful, but positive tests for plasma ketones may persist well after acidosis is resolved. Perhaps this is because acetone is cleared more slowly than acetoacetic acid and beta-hydroxybutyric acid. The sodium nitroprusside test is a measure of the acetone in the plasma, and can give persistently positive readings for ketones, even though acetone does not alter acid-base balance. Therefore, to determine whether the ketosis has cleared, it is important to monitor the anion gap, and the arterial pH. An abolition of the anion gap and a normal arterial pH signifies the clearance or control of ketosis.

Once the patient is conscious, alert and able to eat or drink, IV fluids and IV insulin can be stopped and the patient is started on subcutaneous insulin. It is important to continue IV insulin infusion till the first subcutaneous injection of insulin has started to take effect (1 hour after actrapid insulin and 3–4 hours after a long acting insulin), else there may well be a sudden rebound increase in the blood sugar and ketones.

Fluid and Electrolyte Replacement

Severe DKA is always associated with fluid losses that may be as high as 4–8 L. However, slower fluid replenishment is now recommended compared to what was advised in earlier years.

It is vital to start fluid therapy immediately with N-saline. About 1–2 liters are given over 2 hours in patients who are not in shock. This is followed by another 1 liter over the next 4 hours. Further infusions of 4 liters may be necessary over the next 24 hours. To this is added fluid losses in urine and in vomit as observed over 24 hours.

Patients in shock as also oliguric patients may require further fluid replacement, with the use of plasma expanders to start with. On the other hand, in patients with heart failure, in those with fluid overload, or in patients suspected to have cerebral edema, fluid replacement should be slower.

Volume replacement needs to be individually assessed and often modified or adjusted in each patient on clinical grounds, and on central venous pressure readings. One has to be extra careful in older patients or in those with cardiac dysfunction for fear of inducing acute pulmonary edema.

Though N-saline is used initially for fluid replacement, 0.45% saline has been suggested to replace 1–2 liters of isotonic saline if there is marked hyperosmolality of the plasma (>350 mOsm/Ka) or in rare instances where there is marked hypernatremia (>150 mEq/L). This suggestion is debatable as the use of hypotonic saline may increase the intracellular movement of water which could well contribute to or precipitate cerebral edema.

Five percent dextrose solution should be substituted for N-saline when plasma glucose falls to 10–14 mmoL/L (180–250 mg/dL) to prevent hypoglycemia. IV insulin needs to be continued to counter ketosis and promote utilization of glucose in tissues.

Potassium replacement In the early stages of untreated diabetic coma, the serum potassium may be high in spite of a total body deficit of potassium. Once the DKA comes under control, hypokalemia often develops. This is due to the passage of glucose (and with it of potassium) from plasma to cells during conversion of glucose to glycogen under the influence of insulin, and also to a loss of potassium in urine following an improvement in urine output. Hypokalemia during recovery from DKA and coma should be corrected by a slow IV infusion of potassium chloride in dextrose. Generally, not more than 40–60 mEq of potassium are needed over 24 hours. Potassium administration must be monitored by electrocardiography and by checking the serum potassium levels periodically.

Phosphate administration Though phosphate levels in serum are known to fall during treatment of DKA, in our experience, replacement of phosphates is rarely necessary. There is, however, one group of patients in whom phosphate replacement is considered to be essential. This is a small group of probably less than 5–10%, who has hypophosphatemia (<1.5 mg/dL) at the time of admission. A further fall during treatment with insulin could lead to manifestations of hypophosphatemia. These include muscle weakness, respiratory failure due to respiratory muscle weakness, decreased myocardial contractility, hemolysis and rhabdomyolysis. Phosphate replacement during therapy is achieved by adding 5–10 mL of potassium phosphate solution (3 mmoL/mL) to the replacement fluids used for replenishing the hypovolemic state. About 1–4 mL of potassium phosphate are added to 1 liter of N-saline. Phosphate administration may occasionally produce a fall in serum calcium with resulting tetany. Serum calcium levels are monitored, and a drop in the serum calcium is treated by IV administration of 10–20 mL of 10% calcium gluconate.

Use of Sodium Bicarbonate

Metabolic acidosis is invariably corrected with insulin therapy. Sodium bicarbonate should, therefore, not be used to combat acidosis. In fact, bicarbonate therapy often can do more harm than good. The complication of cerebral edema is more likely in diabetic ketoacidotic children treated with IV sodium bicarbonate. IV bicarbonate contrary to popular belief may not improve intracellular acidosis as cell membranes are impermeable to HCO_3 ions. In fact, CO_2 can enter into cells and combine with H_2O to form H_2CO_3, which may dissociate to H^+ and HCO_3, thereby aggravating the acidosis. Bicarbonate therapy can also result in sodium overload, hypocalcemic tetany, a fall in pH in the cerebrospinal fluid and a rebound metabolic acidosis.

The only indication for IV bicarbonate is a pH less than 7.1, as this poses an immediate threat to life. A pH less than 7.1 can cause myocardial dysfunction, cerebral depression, intractable hypotension, resistance to insulin and tissue cell injury. About 100 mmoL of sodium bicarbonate in 400 mL distilled water is given at the rate of 200 mL/hour to counter a pH less than 7.1. The routine use of bicarbonate in DKA is unnecessary and perhaps harmful.

Treatment of Circulatory Collapse

In addition to the rapid infusion of N-saline, it may be necessary to use colloids—albumin and other plasma expanders—to counteract severe shock and urgently increase the volume within the vascular compartment. Vasopressors should be avoided as far as possible, as increasing the degree of peripheral vasoconstriction worsens tissue hypoxia; also catecholamines like nor-epinephrine make glucose control even more difficult as they act counter to insulin.

Detection and Treatment of the Precipitating Factor

It is important to determine the precipitating factor causing DKA and coma. An acute infection, like pneumonia, a lung abscess, a carbuncle or acute dysentery, should be recognized and treated. It is to be noted that though well marked DKA can by itself cause a significant leucocytosis (up to 20,000/mm^3), fever does not occur in these patients in the absence of infection. The presence of fever is an indication for the use of empiric antibiotic therapy if the source of infection is unidentified.

Meticulous Nursing and Critical Care

This is vital for survival. Frequent changes in posture are imperative, and a clear airway should be maintained at all

Box 3: Important complications of diabetic ketoacidosis and coma

- Hypoglycemic coma (overuse of insulin)
- Irreversible shock and circulatory failure
- Sudden death due to cardiac arrest or ventricular fibrillation, generally due to hypokalemia
- Acute myocardial infarction, or cerebrovascular accident
- Cerebral edema
- Acute lung injury and acute respiratory distress syndrome
- Acute vascular insufficiency in one or both lower limbs, particularly in older patients with atherosclerotic disease
- Acute renal shutdown
- Aspiration pneumonia
- Thromboembolism, particularly in older patients
- Infections

costs, as hypoxia due to ventilation-perfusion mismatch worsens the prognosis.

Complications during Treatment of Diabetic Ketoacidosis and Coma

Important complications of DKA and coma are described below (refer Box 3)—

- An overdose of insulin can result in hypoglycemic coma. A frequent periodic check of blood glucose should prevent this problem. Severe sweating in a patient being treated with insulin for DKA should always suggest the possibility of insulin-induced hypoglycemia. The use of 5% dextrose solution covered by insulin when blood glucose levels have fallen substantially has already been mentioned.
- Irreversible shock and circulatory failure may complicate the course of diabetic coma. This is observed when patients are brought in very late, and when severe tissue hypoxia has been present for a prolonged period.
- Sudden death due to cardiac arrest or ventricular fibrillation during recovery from diabetic coma is generally due to hypokalemia. Frequent ventricular ectopics during recovery should suggest hypokalemia. Severe hypophosphatemia may potentiate the effects of hypokalemia.
- Acute myocardial infarction or a cerebrovascular accident may occasionally complicate the course of diabetic coma. Failure to recover consciousness after ketosis has been controlled should suggest the possibility of a stroke. The persistence of shock after rapid correction of fluid, electrolyte and metabolic abnormalities should make one suspect a myocardial infarction or pulmonary embolism.
- Cerebral edema[6] is a dreaded complication. It is manifested by a deteriorating level of consciousness when the metabolic complications (including ketosis) show clear evidence of improvement. It accounts for 50% of fatalities, especially in children. It is thought to result from shifts of water and ions into the brain, particularly of water into dehydrated hypertonic brain cells when relatively hypotonic fluid reaches the extracellular compartment. Administration of hypotonic saline intravenously may perhaps aggravate this condition.

  Risk factors for cerebral edema include: (1) excess fluid replacement and fluid replacement given far too rapidly; (2) over-rapid fall in blood glucose—hence, the wisdom of using a 5% of dextrose solution together with insulin when the blood sugar approaches 200 mg/dL; (3) high doses of insulin (than those recommended) to reduce blood sugar. Why and how the last factor operates is unknown; perhaps insulin can affect various ion transport mechanisms in the brain.

  Increasing cerebral edema besides causing increasing decline in the conscious state (even after metabolic abnormalities are corrected) ultimately leads to coning and cardiovascular arrest.

  Well-marked cerebral edema is generally fatal, with a mortality as high as 90%. IV mannitol (0.2 g/kg over 3 hours) is recommended; this is repeated if there is no improvement. Dexamethasone may be used but is not thought to be of any benefit.
- A rare complication of ketoacidosis is acute respiratory distress syndrome (ARDS).[7] This is generally observed in older patients and is invariably triggered by excessive volume replacement. Other unknown factors are also probably responsible for contributing to increased pulmonary capillary permeability. Acute lung injury manifests with noncardiogenic pulmonary edema and refractory hypoxia that needs ventilatory support as outlined in the ARDS network trial. Under the above circumstances, it has a forbidding mortality.
- Recovery from coma can be complicated by acute vascular insufficiency in one or both lower limbs. This is particularly likely to occur in old patients with atherosclerotic disease, following prolonged hypotension.
- Acute renal shutdown may complicate recovery from DKA and coma.
- Aspiration pneumonia, particularly in obtunded and comatose patients, is a common complication of DKA.
- Thromboembolism may be a complication, particularly in older patients. Arterial thrombosis, if it occurs, chiefly involves the lower limb vessels. Femoral vein thrombosis is an important cause of sudden death from massive pulmonary embolism.
- *Infections* Diabetic patients are prone to infection. Urinary tract infections and respiratory tract infections are common. Nosocomial sepsis with positive blood culture is occasionally encountered. A rare but frequently fatal infection in severe diabetes and DKA is mucormycosis, caused by the fungus *Rhizopus*. The presence of a black necrotic area around the eye, nasal cavity, nose, or the presence of conjunctival injection with circumocular edema and sinusitis are strongly suggestive of mucormycosis. Proptoses of the eyes with restricted ocular movements are late features. This fungus has a tendency to invade vessels causing thrombosis and infarction. Unless recognized very early and promptly treated, death generally ensues.

Table 1: Differences in laboratory features between diabetic ketoacidosis and hyperglycemic nonketotic hyperosmolar diabetic syndrome

	HNHS	*DKA*
Blood glucose level	Very high; often >700 mg/dL	Generally not so high; 350–450 mg/dL
Serum Na	Hypernatremia ; Often >150 mEq/L	Hyponatremia often present; Hypernatremia rare
Osmolality	Marked >350 mOsm/kg	Less marked; generally <350 mOsm/kg
Ketonuria	Absent	Present
Ketonemia	Absent	Present
Anion gap	Normal	Marked
Renal dysfunction	Generally present—well marked	May be present

Abbreviations: HNHS, hyperglycemic nonketotic hyperosmolar diabetic syndrome; DK, diabetic ketoacidosis.

Hyperglycemic Nonketotic Hyperosmolar Diabetic Syndrome[3,8]

This is a rare cause of coma in diabetes. In its typical form, it is characterized by marked hyperglycemia (often >700 mg/dL), with little or no reduction in the plasma bicarbonate. There is also marked hypernatremia with serum sodium levels over 150–155 mEq/L. The plasma shows no ketonemia and ketone bodies in urine are absent. In the typical case, ketosis does not develop because insulin levels in blood are sufficient to suppress lipolysis and ketogenesis. These patients generally are elderly with type II diabetes.

A large overlap, however, exists in the clinical presentation of DKA and hyperosmolar nonketotic diabetic coma. Thus, there are patients with hyperosmolar coma who have a fair degree of ketoacidosis, just as there are patients with typical ketoacidosis with significant hypernatremia and hyperosmolarity.

Hyperglycemic nonketotic hyperosmolar diabetic syndrome is much less common than DKA and has a higher mortality, perhaps due to associated comorbidity in elderly patients, late diagnosis and improper treatment.

Precipitating factors include stroke, myocardial infarction, infection, renal dysfunction, use of glucocorticoids and use of thiazide diuretics. Mental obtundation, dementia, physical disability and any cause that reduces access to the drinking of water are often present in these elderly patients. The differences in laboratory features between DKA and HNHS are tabled in Table 1.

Presentation

- Symptoms caused by hyperglycemia include thirst, polyuria, weight loss but without features of ketoacidosis.
- Dehydration with hypotension; tachycardia may not be evident in elderly patients.
- Oliguria with raised creatinine, urea, NPN levels in blood.
- Confusion, drowsiness, disorientation and even coma.
- Complications of HNHS may be the presenting feature—these include thrombotic events, chiefly stroke manifesting with hemiparesis. Seizures may complicate the syndrome or be a presenting feature. Other thrombotic events include peripheral arterial occlusion, venous thrombosis, pulmonary embolism. These thrombotic events are due to dehydration plus increased blood viscosity.

Management[3]

Management is similar to that of DKA—

- *Insulin* Insulin is given exactly in the manner outlined for DKA. Hyperglycemia is generally easily controlled.
- *Correction of dehydration* Fluid replacement should start with N-saline or ringer lactate solution. This is followed by a replacement of the water deficit by half-strength saline or dextrose solution covered adequately with insulin, in the presence of a marked increase in plasma osmolality (>350 mOsm/kg) or marked hypernatremia. Saline replacement should be cautious and carefully monitored in elderly patients with cardiac disease.
- *Potassium replacement* Many patients have a potassium deficit. Potassium replacement, if necessary, should be given with careful monitoring of serum potassium at frequent intervals.
- *Low molecular weight heparin* Enoxaparin 0.4 mg subcutaneously once a day prophylactically is often advised. Full anticoagulation should only be given in the presence of thromboembolic complications. The risk of bleeding in these patients is high.
- *Intercurrent infections and other precipitating factors should be identified and treated.*

Most patients after recovery can be weaned off insulin and given oral antidiabetic medications.

Neurological Complications of Hyperglycemic Syndromes

Neurological complications with varying frequency can occur in both DKA and HNHS. It is important to be aware of these complications, as they may occur during the phase of metabolic derangement and, in some instances, after correction of the metabolic state. Though touched upon briefly (cerebral edema has already been discussed at length) in the descriptions of DKA and HNHS, these complications are discussed in a little more detail in this section.

Altered Mentation

This has been briefly mentioned in the pathophysiology of DKA. It is also frequently observed in the HNHS.

Drowsiness, progressive obtundation progressing to unconsciousness and coma are the usual abnormalities in DKA. Coma may be so deep that the patient is totally

unresponsive to painful stimuli. Reflexes are generally lost, plantars may be extensor. The corneal and papillary reflexes are generally present and are lost terminally.

Generally, there are no lateralizing signs. If present, a CT of the brain is mandatory. An unconscious state persisting after correction of metabolic abnormalities necessitates both a CT of the head and a toxicology screen.

It is to be noted that there is no good correlation between the degree of hyperglycemia, the degree of metabolic acidosis, the osmolality and the mental state.

Less commonly, the mental state is that of excitability, delirium accompanied by delusions and hallucinations, particularly if drug intoxication or alcohol has precipitated the metabolic abnormality. These patients may be very difficult to manage and require to be sedated with tranquilizers so as to allow treatment of the metabolic abnormalities.

Cerebral Edema

This has been discussed at length in DKA. It can also occur in patients with HNHS. Cerebral edema in children with DKA is associated with a marked increase in mortality.

Focal Neurological Deficits

Strokes due to thrombotic episodes and intracerebral hemorrhage are important complications and, at times, presenting features of HNHS. Intracerebral venous thrombosis has been reported[9] and has a poor prognosis.

Many focal neurological signs particularly in HNHS disappear after recovery from the syndrome. It is possible that they represent focal areas of poor cerebral perfusion unmasked by dehydration and increased viscosity.

Correction of fluid and electrolyte abnormalities during treatment may rarely cause pontine and extrapontine myelinolysis.[10] This can be a cause of prolonged unconsciousness after metabolic recovery and may only be picked up by a good magnetic resonance imaging (MRI) of the head.

Seizures

Generalized or focal seizures are common in the HNHS and may be resistant to the usual anticonvulsants.[11] Epilepsia partialis continua is a rare seizure disorder observed in both DKA and HNHS.[12]

Cognitive Impairment

Cognitive impairment is more common in elderly patients and may occur even after recovery from either DKA or HNHS. It may be related to a neurological deficit or it may occur without any evidence of a neurological deficit. If not caused by structural damage, it invariably improves with time.

A. RAISED INTRACRANIAL PRESSURE

Jimmy Lalkaka, BS Singhal

INTRODUCTION

Many neurological diseases cause an elevated intracranial pressure (ICP). Left untreated, it leads to cerebral ischemia, brain herniation and death. Therefore, early recognition and appropriate management of raised ICP remains the cornerstone of Critical Care Neurology. An ICP of more than 20 mm Hg for more than 10 minutes indicates an elevated ICP.[1] The time period mentioned above is to exclude transient elevations of ICP which occur during suctioning, straining and positioning of the patient. A sustained ICP greater than 40 mm Hg is a life-threatening emergency.[2]

PATHOPHYSIOLOGY

In simple terms, ICP is defined as the pressure that exists within the skull vault in relation to the atmospheric pressure. Normal ICP is 5–15 mm Hg in adults and older children in supine position. The Monro-Kellie doctrine helps us to understand the concept and dynamics of ICP. According to this doctrine, the skull is a rigid closed box, containing three noncompressible elements—brain tissue (80%), cerebrospinal fluid [CSF (10%)] and blood (10%). These three components are in a state of dynamic equilibrium with each other, so that the overall volume remains constant. Any increase in volume of one element is compensated for by a decrease in the volume of the other two. This compensatory measure is called intracranial compliance. It effectively maintains ICP at normal levels during the early stage of intracranial pathology. For instance, an initial mild increase in the size of a mass lesion will not produce much change in ICP because CSF and blood are displaced with a decrease in the volume of these elements. Measures like CSF drainage and hyperventilation reduce elevated ICP by reducing intracranial volume of CSF and blood respectively. However, with further increase in size of the lesion, intracranial compliance and compensatory mechanisms begin to fail, so that even a small increase in volume causes a dramatic elevation of ICP (Fig. 1). The extent of rise in ICP also depends on the rate at which the intracranial volume increases. A sudden rise in intracranial volume raises ICP to a greater level than a gradual increase in volume. This explains why an acute hematoma raises ICP more significantly than a slowly growing brain tumor. The type of added volume also has a differing influence on the ICP. Addition of equal volume of CSF and tumor mass does not raise ICP equally. CSF may be quickly moved down the spinal theca or absorbed into the blood, whereas a tumor is not so easily displaced and may obstruct CSF pathways, further raising the ICP.

A normal ICP is required to ensure adequate blood flow to the brain with optimum supply of oxygen and glucose to brain tissue. The cerebral blood flow (CBF) in turn depends on the driving pressure called cerebral perfusion pressure (CPP) which maintains normal circulation across the capillary beds of the brain. Conventionally, CPP is defined as the difference between mean arterial pressure (MAP) and mean ICP.

CPP = MAP – ICP (MAP = 1/3 systolic BP + 2/3 diastolic BP)

Cerebral autoregulation maintains CPP at a constant level over a wide range of MAP of 50–150 mm Hg, presuming that the ICP remains within normal limits. This is achieved by

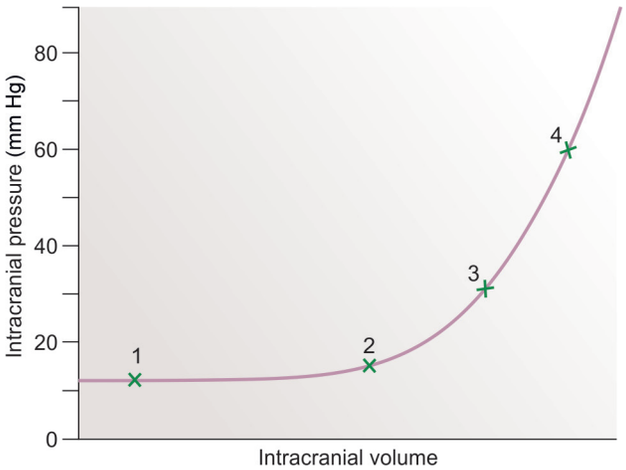

Fig. 1: Illustration of the relationship between intracranial volume and intracranial pressure. Note that beyond point 3, even a small increase in the intracranial volume produces a marked elevation of intracranial pressure

adjustments in cerebral vascular resistance. A fall in MAP causes vasodilatation of arterioles in the brain to increase CBF, while a rise in MAP produces arteriolar vasoconstriction to prevent hyperperfusion. Below a MAP of 50 mm Hg, autoregulation fails, CPP falls with reduced CBF and resultant ischemia. When ICP is increased, the CPP is reduced. However, cerebral autoregulation helps to maintain constant CBF despite reduction in CPP. However, when CPP falls below 50 mm Hg, the cerebral autoregulatory mechanism becomes exhausted and CBF falls. Cerebral tissue oxygenation suffers and neuronal ischemia results.

ETIOLOGY

Lesions with Focal Mass Effect

They include brain tumors, large cerebral infarcts, intracranial hemorrhage and cerebral abscess. The ICP in these conditions is maximum locally, due to dural partitions which cause compartmentalization of the mass and resultant tissue shifts.

Generalized Brain Edema

They include hypoxic-ischemic encephalopathy, head injury (diffuse axonal injury), acute subarachnoid hemorrhage, meningitis and encephalitis, prolonged status epilepticus, hypertensive encephalopathy and metabolic derangements (hyponatremia, hepatic and renal encephalopathy). Here the increased ICP is evenly distributed throughout the brain and tissue shifts are minimal.

Obstruction of CSF Pathways

Hydrocephalus results from obstruction of CSF pathways within the ventricles or in the subarachnoid spaces at the base of the brain. Common causes of hydrocephalus include meningitis (especially tuberculous and fungal), subarachnoid hemorrhage, cerebellar, thalamic or intraventricular hemorrhage, posterior fossa tumors and normal pressure hydrocephalus.

Increase in Cerebral Venous Pressure

It is caused by cerebral venous sinus thrombosis or jugular vein thrombosis.

CLINICAL FEATURES

Raised ICP causes brain disturbance in the following ways—

- Global hypoxic-ischemic damage caused by reduced CPP and CBF.
- Mechanical compression, shift and herniation of brain tissue due to ICP gradients across the brain compartments.

The clinical features of raised ICP vary depending on whether the underlying pathological process is focal, causing a localized mass effect, or generalized, with a diffuse rise in ICP.

Generalized Brain Edema

The elevated ICP is distributed evenly throughout the brain. Early symptoms of raised ICP are headache and vomiting. The headaches may be worse in the supine position and aggravated by coughing and valsalva maneuver. Vomiting can be projectile. Altered sensorium may follow, ranging from mild confusion and increased irritability to drowsiness and stupor. It is caused by global cerebral ischemia, once the ICP rises high enough. Diplopia due to unilateral or bilateral sixth cranial nerve palsy may also occur. The presence of papilledema signifies raised ICP of some duration. The Cushing's reflex (hypertension, bradycardia and irregular breathing) indicates severe intracranial hypertension.

Focal Mass Effect

Mass lesions initially present with focal sensorimotor deficits depending on the location of the lesion. Clinical features of raised ICP follow and are similar to those with generalized brain edema. In addition, these mass lesions can cause fatal brain herniation. A major pressure gradient between the different brain compartments causes displacement of brain structures from one compartment to another. This causes mechanical damage to the compressed surrounding brain tissue and also results in cerebral infarction due to compression of the anterior or posterior cerebral arteries against the edge of the falx or tentorium cerebelli. These devastating effects may not be accompanied by a significant elevation in global ICP, as the lesions initially remain confined to a localized compartment.

An ipsilateral dilated, nonreacting pupil is seen in uncal herniation, in which laterally placed mass lesions cause the uncus of the medial temporal lobe to herniate through the tentorium. This pupillary dilatation is followed by a decline in consciousness with accompanying hemiparesis and decerebrate posturing. Central herniation due to diencephalic lesions causes a downward displacement of the diencephalon and midbrain. Depressed consciousness occurs early, followed

by bilateral, medium-sized nonreacting pupils, decorticate posturing and Cheyne-Stokes breathing. Diabetes insipidus may occur due to hypothalamic involvement. Transfalcine herniation occurs when frontal or parietal mass lesions push the cingulate gyrus under the falx, causing occlusion of the anterior cerebral artery with contralateral leg weakness and coma. Posterior fossa lesions cause cerebellar tonsillar herniation through the foramen magnum, compressing the medulla and upper cervical cord. Hypertension, bradycardia, coma and respiratory arrest quickly follow.

Hydrocephalus

Diffuse expansion of CSF spaces occurs in obstructive hydrocephalus, causing increased pressure on adjacent brain tissue. In addition to the features of raised ICP mentioned above, bilateral frontal lobe signs develop with gait apraxia, lack of initiative and sphincter incontinence. Pressure on the midbrain by the dilated third ventricle causes impaired up-gaze.

INTRACRANIAL PRESSURE MONITORING

Direct ICP monitoring is the most accurate method of detecting raised ICP. Clinical assessment can be unreliable in judging ICP. The absence of papilledema does not exclude raised ICP in patients with acute problems. Pupillary dilatation, bradycardia, altered sensorium and decerebrate posturing are unfortunately late signs of raised ICP, by which time permanent brain damage usually occurs. Besides, in stuporous and comatose patients, early signs of neurologic deterioration may be difficult to detect on clinical examination. The goal of ICP monitoring is early detection of abnormal physiologic events which allows clinicians to intervene before a significant loss of neurological function occurs. ICP measurement can also accurately monitor the efficacy of ICP lowering treatment.

Intracranial pressure monitoring is considered in patients with an acute neurological disorder associated with an increased risk of raised ICP and a worsening neurological examination. It is most commonly used in patients with severe traumatic brain injury (TBI). Criteria for ICP monitoring in severe TBI have been listed in the subchapter Traumatic Brain Injury of Chapter Neurological Problems. ICP monitoring is also considered in patients with large hemispheric infarcts, subarachnoid hemorrhage (Grade 3 or more) with radiological evidence of hydrocephalus, intraventricular hemorrhage and spontaneous intraparenchymal hemorrhage with Glasgow Coma Score (GCS) less than 9.

Types of ICP Monitors

The intraventricular catheter and the intraparenchymal device are the most commonly used ICP monitoring devices. ICP can also be monitored by transducers placed at subdural, subarachnoid and epidural sites. However, they are not very accurate and are rarely used.

The intraventricular catheter or external ventricular drain (EVD) remains the gold standard for ICP measurement.[3] The catheter is inserted into one of the lateral ventricles and connected to an external pressure transducer. It gives the most accurate measurement of ICP of all the devices and also enables CSF to be drained when ICP is raised. The EVD also offers a portal to introduce drugs directly into CSF. It however, carries a high risk of infection (ventriculitis), especially if it is kept for more than 5 days. Use of antibiotic-coated catheters has significantly reduced infection rates. There is also a small risk of parenchymal or intraventricular hemorrhage during catheter placement. EVDs may be difficult to place if there is associated ventricular compression with chinked ventricles in diffuse cerebral edema. Presence of a coagulopathy also rules out the use of this device.

The intraparenchymal device is also commonly used for ICP monitoring. The fiber-optic transducer is inserted into the brain parenchyma. It is easily placed and carries a very low infection rate of 1%. Parenchymal ICP monitoring is appropriate for patients with diffuse cerebral edema and small ventricles which make ventricular catheter insertion difficult. The ICP measurement with this device may be misleading if ICP is not uniform throughout the brain. So if there is increased local pressure in a brain compartment produced by a mass lesion, this device should be placed ipsilateral and close to the lesion.

Normal ICP Waveforms

They are modified arterial pressure waves timed to the cardiac cycle. They reflect a transient increase in cerebral blood volume (CBV) that occurs with each arterial pulse. Normally, three pulse waves are seen: (1) P_1—percussive wave, reflecting cardiac systole; (2) P_2—tidal wave, reflecting diastole and (3) P_3—dicrotic notch, reflecting emptying of cerebral vessels. Normally the P_2 wave is smaller than P_1, indicating good brain compliance. If the P_2 wave becomes larger than P_1, it signifies poor brain compliance and impending failure of compensating mechanisms, leading to raised ICP.

Pathological ICP Waveforms

Two types of pathologic ICP waves have been described—

1. *Lundberg A waves* They are arrhythmic plateau waves. They occur suddenly, reach levels of 40–80 mm of Hg and last 5–20 minutes. They are accompanied by concomitant reduction in CPP. They are always associated with raised ICP and may herald impending herniation.
2. *Lundberg B waves* They are rhythmic waves with an amplitude of 5–20 mm Hg, occurring every 30 seconds to 2 minutes and lasting 1–5 minutes. Although less dangerous than A waves, they indicate reduced intracranial compliance and may be harbingers of plateau waves.

MANAGEMENT OF RAISED INTRACRANIAL PRESSURE

The aim of lowering ICP is to ensure an adequate CPP to maintain normal CBF and to prevent secondary ischemic

injury. An ICP of 20 mm Hg and above requires treatment. The generally accepted goal in neurocritical care is to keep the ICP at less than 20 mm Hg and the CPP between 60 mm Hg and 90 mm Hg.[4] Measures for controlling ICP can be divided into those which rapidly reverse acute rise of ICP and those which maintain it within a reasonable range. The rapidly acting measures include hyperventilation, hyperosmolar therapy and CSF drainage. Maintenance therapy includes sedation, analgesia, control of BP and prevention of fever.

General Measures

The first step in management, after securing airway, breathing and circulation parameters, is to do a computed tomography (CT) scan of the brain. An intracranial mass like a subdural/extradural hematoma or a tumor may need to be surgically evacuated at the earliest. Patients with raised ICP must be managed in the ICU with qualified medical personnel and trained nursing staff. ICP monitoring should be instituted in the appropriate situation.

Blood sugar must be maintained in the normal range. Poor outcome has been reported with both hypoglycemia and hyperglycemia. Hyponatremia must be avoided as it increases cerebral edema. Fever increases metabolic rate by 5–7% per degree celsius rise in body temperature and worsens outcome in patients with raised ICP. The temperature must be reduced with judicious use of antipyretics, cooling blankets and antibiotics, if evidence of infection exists. Seizures also significantly worsen ICP and clinical outcome and must be treated promptly with intravenous lorazepam, followed by phenytoin/fosphenytoin or valproate.

An important step in choosing the appropriate treatment strategy is to identify the intracranial compartment that is responsible for the pressure elevation. For instance, if swelling of brain tissue is responsible, osmotherapy is preferred. If increased CSF volume (hydrocephalus) is present, then placement of an EVD to divert the CSF outflow is often the most effective treatment.

Specific Measures

Position of the Head

The patient must be nursed with the head elevated at about 30° to the horizontal. This ensures adequate cerebral venous outflow through the jugular veins. The head should not be turned to one side as it can cause kinking of the ipsilateral jugular vein. Tight constricting tapes or bands around the neck should also be avoided for the same reason.

Blood Pressure and Fluids

In patients with raised ICP, hypotension must be avoided as it reduces CPP and induces cerebral ischemia. Most cases of hypovolemic shock are due to blood loss or sepsis. The patient must be maintained in an euvolemic state with 0.9% normal saline or albumin. Central venous pressure (CVP) should be maintained around 10 mm Hg. Hypotonic fluids like 0.45% saline or 5% dextrose should be avoided as they increase cerebral edema. Blood loss should ideally be replaced by blood transfusions. If the patient remains hypotensive despite fluid correction, then vasopressor and inotropic agents like dopamine or noradrenaline are used. Noradrenaline is more predictable and efficient than dopamine, especially in septic shock.

Reactive hypertension commonly occurs with acute rise of ICP. It gradually reduces over the first few days and does not require aggressive therapy. A precipitous fall of BP must not be allowed to occur in the acute stage at any cost, as, in presence of raised ICP, this will further jeopardize CPP and result in cerebral ischemia. If hypertension persists for several days, it should be gradually reduced with appropriate antihypertensive drugs.

Mechanical Ventilation

Mechanical hyperventilation is a quick and effective, but short-lasting way of reducing ICP. It is best used as a temporary measure to reduce ICP prior to definitive treatment like surgery. The patient is intubated and put on a ventilator. Settings are adjusted to keep $PaCO_2$ levels at about 30–35 mm Hg. Reducing $PaCO_2$ causes cerebral vasoconstriction through serum and CSF alkalosis with reduction in CBV, CBF and decreased ICP. An initial reduction of $PaCO_2$ by 5–10 mm Hg produces a 25–30% reduction in ICP. Care should be taken not to reduce $PaCO_2$ levels below 25 mm Hg as that may induce cerebral hypoperfusion and ischemia. Ideally, simultaneous monitoring of CBF by measuring jugular venous oxygen saturation ($SjvO_2$) should be done during hyperventilation. An $SjvO_2$ less than 45% will indicate a critically reduced CBF and impending cerebral ischemia.

Ventilator settings should also be adjusted to prevent hypercarbia ($PaCO_2$ >45 mm Hg) which cause vasodilatation and trigger sudden ICP elevation. Patients in ventilatory failure require positive end-expiratory pressure (PEEP). However, PEEP tends to increase ICP as PEEP-induced expansion of intrathoracic volume limits the venous return. It is advisable to maintain PEEP at 5–10 mm Hg. Hyperventilation becomes ineffective after more than 6 hours due to the compensatory mechanisms for CSF alkalosis, so long-term hyperventilation is not beneficial.

Hyperosmolar Therapy

Hyperosmolar therapy with mannitol or hypertonic saline (HTS) causesa rapid reduction of ICP in the short-term and remains the cornerstone of ICP management. Intravenous mannitol is the most commonly used osmotic agent because of its easy availability and frequent usage by physicians.[5] It begins to exert its osmotic effect within 15–30 minutes of infusion, drawing water away from the interstitial spaces and into the intravascular compartment across the blood brain barrier, thus reducing the water content of edematous brain tissue. A 20% solution of mannitol is usually given in a dose of 0.25–1 gm/kg every 6 hours. Its beneficial effect lasts 4–6 hours. It is

preferable to give it through a central line as extravasation of the fluid causes thrombophlebitis. Serum osmolality is monitored regularly. It must be kept less than 320 mOsm/L to avoid renal complications. Mannitol is also a potent diuretic agent, so care must be taken to avoid dehydration and maintain euvolemia with isotonic fluids like normal saline (310 mOsm/L). Adverse effects include renal toxicity, dehydration, hyperosmolality and hypernatremia. Its prolonged use may cause rebound cerebral edema, so it is usually not given for more than 3 days. It should also not be used in the presence of hypovolemia, renal insufficiency and heart failure.

Hypertonic saline is also effective in lowering ICP. In addition to reducing the brain volume by creating an osmotic gradient, HTS also expands intravascular volume and increases cardiac output without significant nephrotoxicity or diuretic effect.[6] It can be administered as a continuous infusion with 3% solution at a rate of 10–40 mL/hour or as a bolus with either 3% solution or 23.4% solution. The aim is to increase sodium concentration to a range of 145–155 mEq/L and keep serum osmolality of 320 mOsm/L. This level is maintained for 48–72 hours. HTS is given through a central venous catheter to prevent phlebitis. It causes a rapid reduction of ICP and its duration of benefit may be significantly longer than mannitol. Unlike mannitol, repeated HTS administration does not diminish the ICP-lowering effect. It is preferred in hypovolemic and hypotensive patients during initial resuscitation, as intravascular volume can be increased while reducing ICP. It can also be used in renal insufficiency and can be interchanged with mannitol when the serum osmolality exceeds the limit. This ensures continued osmotherapy while the kidneys try to clear mannitol from the circulation. HTS can cause metabolic acidosis and electrolyte disturbance. It should be tapered slowly after prolonged use to prevent rebound edema. Its use in intracerebral hemorrhage to reduce ICP remains to be clarified.

Diuretics like frusemide help to improve water clearance. The aim is to produce hyperosmolarity without depleting intravascular volume. Free water loss is replaced with isotonic solutions like normal saline. The effect of a diuretic can last up to 2 weeks as tolerance to it does not occur.

Steroids

Steroids are used to reduce the cerebral edema surrounding tumors, abscess and other mass lesions. Intravenous dexamethasone is given in a dose of 4–8 mg every 6–8 hours. Their efficacy in acute strokes and head injury has not been established. In fact, they have a deleterious effect and are not recommended in the treatment of head injury.

Cerebrospinal Fluid Drainage

Cerebrospinal fluid drainage is the treatment of choice when raised ICP is due to increased CSF volume as in hydrocephalus from SAH or IVH. This can be done by an EVD, lumbar drain or serial lumbar punctures. If an EVD is already in place for ICP monitoring, it can be used to release CSF in small volumes of 3–5 mL at a time, when the ICP is high. This results in an immediate reduction of ICP. Continuous slow CSF drainage can also be instituted. CSF drainage is most useful for brief periods to reduce the ICP during plateau waves. Its long-term benefits are unclear. Keeping the EVD in situ for more than 5 days also increases the risk of infection in the ventricles.

Sedatives, Analgesics and Neuromuscular Blocking Drugs

Sedatives like midazolam, analgesics like fentanyl and non-depolarizing neuromuscular blocking drugs like vecuroneum help to reduce ICP. They are used in ventilated patients to avoid surges in ICP during suctioning, coughing, chest physiotherapy and positioning. They are given as a bolus followed by slow infusion. Propofol can be used as a substitute to vecuroneum. Simultaneous fentanyl and midazolam infusions are a common practice followed in many critical care units. Muscle relaxants do not alter the pupillary reflex, but other brainstem reflexes are affected. Their effects can be reversed in a matter of minutes if neurological evaluation is essential, and their use is more often beneficial than detrimental. Prolonged use of these drugs, however, increases the risk of critical illness polyneuropathy (CIP) and critical illness myopathy (CIM) and predisposes to sepsis and deep vein thrombosis (Box 1).

REFRACTORY INTRACRANIAL HYPERTENSION

Decompressive Craniectomy

Urgent decompressive craniectomy (DC) is considered if the patient is deteriorating rapidly or if the ICP continues to rise despite medical management. It involves surgical removal of a large part of the skull bone with a duroplasty. This allows more room for the damaged edematous brain to expand. It results in an immediate drop in ICP and can be life-saving.[7] It may be performed early at the time of definitive surgery (for example, evacuation of subdural hematoma) or later, as a salvage procedure after medical management has failed. It is indicated in malignant middle cerebral artery (MCA) infarcts, large intracerebral hemorrhage, cerebellar hematoma or severe head trauma. It is usually performed unilaterally on the ipsilateral side of the lesion. A bifrontal craniectomy is performed in severe head injury patients with significantly elevated ICP when CT scan does not reveal a discernible lesion. Early decompressive surgery is also considered in situations where persisting with medical therapy results in loss of crucial time that could be used to salvage brain tissue at risk, if surgery is done promptly.

Pharmacological Barbiturate Coma

In intractable raised ICP refractory to all other medical and surgical therapies, high-dose barbiturate coma with pentobarbital or thiopental is induced. Barbiturate coma

Box 1: Management of raised intracranial pressure

- Urgent surgical evacuation of intracranial mass lesions, e.g. subdural/extradural hematoma or tumor, if detected on CT/MRI scan
- General measures—
  - Avoid hypoglycemia or hyperglycemia
  - Treat hyponatremia, if present
  - Maintain normal body temperature
  - Prompt treatment of seizures
- Specific measures—
  - Head position—keep head elevated at 30° to the horizontal
  - Blood pressure—
    - Maintain euvolemic state
    - Fluid correction with 0.9% normal saline or albumin
    - Vasopressor/inotropic agents if hypotension persists
  - Mechanical ventilation—
    - Effective but short lasting
    - Maintain PaCO2 at 30–35 mm Hg
  - Hyperosmolar therapy—
    - IV mannitol 0.25–1 g/kg every 6–8 hours
    - Hypertonic saline—IV 3% solution—bolus or infusion at 10–40 mL/hour
    - Diuretics—frusemide
  - Steroids—
    - IV dexamethasone—only for brain tumors and other mass lesions
  - CSF drainage—
    - In hydrocephalus (subarachnoid or intraventricular bleed) through EVD or lumbar drain or serial LPs
    - Later, if required: VP shunt
  - Sedatives, analgesics & neuromuscular blocking drugs—
    - Midazolam—sedative
    - Fentanyl—analgesic
    - Vecuronium or propofol—neuromuscular blocker
  - Refratory intracranial hypertension—
    - Decompressive craniectomy
    - Pharmacological barbiturate coma
    - Hypothermia

significantly reduces the cerebral metabolic rate, which in turn reduces CBF and CBV. This helps to reduce ICP.[1] Continuous EEG monitoring is required to maintain a burst suppression pattern. Burst suppression is an EEG pattern of alternating periods of high amplitude slow waves with periods of flat EEG and indicates adequate metabolic suppression. Thiopental was found more effective than pentobarbital in controlling refractory ICH in one study.[8] This therapy, however, is associated with the risk of major complications like severe hypotension, bronchopulmonary infection, respiratory failure, liver disturbance and disseminated intravascular coagulation. To avoid these, the minimal effective dose is given. Hypotension is aggravated by mannitol-induced dehydration and decreased cardiac filling secondary to mechanical ventilation. Vasopressor support, usually with norepinephrine is required to manage hypotension. Propofol has been used as a substitute for pentobarbital because of its reduced side effects.

Hypothermia

Hypothermia is also used to reduce refractory intractable ICH. The ICP-lowering effect is mainly due to reduction of cerebral metabolic rate. At about 30°C, cerebral metabolism reduces by 50%. Cooling to 32–36°C is attempted in patients with severe elevated ICP. Systemic hypothermia involves surface cooling by endovascular catheters or gastric lavage. Selective hypothermia involves a cooling cap or band. A greater benefit appears to accrue when the temperature is brought down to 32–34°C and when target temperature is maintained for more than 48 hours.[9] Improved outcomes in patients with severe head injury have also been recently reported with induced normothermia (36–36.5°C) which reduced fever burden and attenuated intracranial hypertension.[10] However, these benefits may be offset by serious adverse effects which include pneumonia, sepsis and cardiac arrhythmias. After the period of hypothermia, rewarming must be done slowly to avoid a rebound increase in ICP.

Hydrocephalus

Cerebrospinal fluid diversion is the treatment of choice in raised ICP due to hydrocephalus. An external ventricular drain (EVD) placed into the ventricles of the brain and connected to an external drainage system is effective in draining CSF and reducing ICP. A ventriculoperitoneal (VP) shunt cannot be performed immediately when hydrocephalus complicates meningitis or intraventricular hemorrhage as the tube would either get infected or blocked. EVD buys time. If hydrocephalus subsides, it is removed, but if it persists, then a permanent VP shunt is inserted. Endoscopic third ventriculostomy involves fenestration of the floor of the third ventricle under endoscopic vision. This fenestration enables communication between the third ventricle and the prepontine cistern.[11]

B. Traumatic Brain Injury

Jimmy Lalkaka, BS Singhal

INTRODUCTION

Traumatic brain injury (TBI) is a serious public health problem worldwide. Although it affects people of all ages, there is a disproportionately large representation of young adults and children (maximum peak of 15–24 years). These individuals are premorbidly healthy and in the prime of their lives. So the impact on society, especially in terms of productivity, is profound. This more than justifies the large resource outlay for treating and rehabilitating these people. Although TBI is maximally seen in the young, it is the elderly who have the worse outcome. A large number of patients have polytrauma. The recognition and timely management of polytrauma has a positive impact on the outcome of head injury.

COMMON CAUSES

Motor vehicle accidents are the most frequent cause of TBI in young people, comprising about 50% of all TBI cases. Sports injuries, assaults, bullet injuries and occupational injuries are also commonly seen among children and young adults. Among penetrating injuries, gunshot wounds are the most lethal, with a 90% mortality. Blast injuries are commonly encountered during war and terrorist attacks. In contrast, falls are the commonest cause in elderly subjects over 65 years of age.

MECHANISMS OF INJURY

Traumatic brain injury can be either primary or secondary. Primary injury occurs at the time of impact and is the direct immediate result of the trauma. Blunt contact force is the most common mechanism of injury. Examples of blunt force are a direct blow or fall from a height or striking the windshield in a car crash. Forces of acceleration followed by sudden deceleration result in coup and contrecoup injuries. Coup injury is the direct injury to underlying tissue. It results in skull fracture, contusion, subdural/extradural hemorrhage and arterial dissection. Contrecoup is the second injury which occurs diagonally opposite the site of impact. The sudden acceleration-deceleration causes the brain to move relative to the skull along a linear axis till it strikes the skull on the opposite side. Contrecoup injury causes contusions and subdural hemorrhage. A fall on the occiput, for instance, will cause a contusion in the frontal lobe. Rotational acceleration causes the brain to move relative to the skull along a non-linear axis. It produces injuries ranging from mild concussion to severe diffuse axonal injury (DAI).

Secondary injuries are those that occur hours to days after the initial impact. Mortality and morbidity from secondary injury may exceed that of primary injury. Cerebral edema (perilesional or diffuse), hypotension, hypoxia, fever and raised intracranial pressure (ICP), all contribute to secondary brain injury. At the cellular level, damage to neurons occurs in two ways: (1) excitotoxicity and (2) apoptosis. In excitotoxicity, release of excess amounts of excitatory amino acids like glutamate results in increased activation of proteases and lipases, calcium channel mediated neuronal injury and cell death. Apoptosis is programmed cell death with DNA fragmentation which is triggered by tumor necrosis factor.

CLINICAL ASSESSMENT

Despite its drawbacks, the Glasgow Coma Scale (GCS) still remains the gold standard and the most universally utilized scale for assessing the severity of TBI. The best eye-opening response, verbal and best motor responses are graded, noting asymmetric responses in the latter. Head injury with GCS of 13–15 is considered mild, 9–12 is classified moderate, while a score of 3–8 qualifies as severe head injury. Some pitfalls and fallacies of the GCS need a mention. Firstly, assessment is difficult if the patient has been sedated in the ambulance. Then again, an intubated patient is unable to give a verbal response. This has led to greater weightage being given to motor responses in particular. The GCS is also not powered to detect focal neurological deficits which are seen with structural mass lesions.

Traumatic brain injury rarely occurs in isolation. Most patients have polytrauma with extracranial injury seen in 35% of cases. An early thoracoabdominal assessment is essential. Fractures of long bones and any visceral injury to the abdomen must be looked into. About 6% of patients with severe TBI also have cervical spine injury. The neck must be most gently handled and preferably immobilized so as not to worsen associated cervical cord trauma. Signs of myelopathy like paraplegia, quadriplegia, impaired sensation below a level on the trunk and sphincter disturbance must be looked for.

Fractures of the skull base are often difficult to visualize on X-ray or CT scan. They carry an increased risk of meningitis due to breach of the dura mater. The diagnosis is often made on clinical signs. Suspected anterior cranial fossa fractures present with raccoon eyes—bilateral periorbital ecchymosis, anosmia due to olfactory apparatus damage and CSF rhinorrhea. The latter occurs in 25% of patients with anterior skull base fracture and cribriform plate injury. It is often self-limiting. Measures like elevation of the head end of bed and CSF aspiration/drainage are beneficial. In suspected middle fossa and temporal bone fracture, the battle sign is seen. It is an area of ecchymosis over the mastoid process behind the ear and may appear 24 hours after injury. CSF leak through the ear (CSF otorrhea) indicates rupture of tympanic membrane. A pulsating exophthalmos with a retro-orbital bruit points to a carotid-cavernous fistula.[1] Involvement of cranial nerves III, IV and VI is seen in orbital fracture and cavernous sinus injury.

Ipsilateral 7th and 8th nerve palsies occur with fracture of the petrous part of the temporal bone. A clivus fracture causes an isolated VIIth nerve palsy.

The pupillary light reflex gives valuable information. Bilateral impairment may indicate a brainstem lesion. Unilateral impairment signifies optic or oculomotor nerve lesion, which can be further differentiated by comparing the consensual and direct responses. Clinical evidence of a focal neurological deficit must be carefully sought. A drowsy, confused patient with gaze preference to one side and contralateral hemiparesis must be urgently investigated for an extracerebral hematoma. Neurological evaluation must be repeated at frequent intervals. Deterioration in TBI patients can be rapid and early signs of impending herniation must not be missed. In a comatose patient, a pupil, which starts dilating or a change in upper limb motor response from withdrawal to an extensor thrust on noxious stimulus, is an early sign of impending herniation.

NEUROIMAGING

Computed tomography scan of the head is the cornerstone of diagnosis and management of TBI. It is quick to perform and sensitive in detecting cerebral contusions, skull fractures, extracranial hematomas, subarachnoid hemorrhage (SAH) and cerebral edema with midline shift. However, it is not sensitive enough to detect abnormalities in DAI. A CT angiography (CTA) may be performed if an arterial dissection is suspected, especially if associated cervical spine injury exists. Serial CT scans are performed, depending on the patient's neurological status and to monitor the size of contusions and other bleeds, if present. About 1 in 6 patients with DAI will develop a new focal lesion on repeat CT.[2]

A magnetic resonance imaging (MRI) scan provides a vastly superior structural assessment of parenchymal brain insult, especially of the brainstem and craniovertebral junction. It detects microhemorrhages and other lesions associated with DAI. The disadvantage of MRI is that it takes longer to perform and may be risky in the initial stage when the patient is unconscious and hemodynamically unstable. Diffusion tensor imaging (DTI) is a new MRI modality which highlights the integrity and connectivity of axons.[3] It is more sensitive than conventional MRI for detecting DAI.

INTRACRANIAL INJURIES IN MODERATE TO SEVERE TBI

Cerebral Contusion

It is a bruising of the brain caused by coup and contrecoup injury. Contusions are commonly seen in the orbitofrontal and anterior temporal lobes. On a CT scan, they appear as areas of edema with foci of hemorrhage within. About 50% of them expand in the first 24–48 hours, causing increased mass effect, worsening GCS score and raised ICP. Patients on antiplatelet or antithrombotic drugs have a high risk of contusion expansion (Fig. 2).[4]

Subdural Hematoma

Acute subdural hematoma (SDH) is the most common traumatic hematoma, occurring in 35–40% of patients with severe TBI. It is a collection of venous blood between the dura and arachnoid mater. The shearing force generated by trauma causes the bridging veins between the surface of the brain and the dural sinus to tear. SDH is more likely to occur with falls than with motor vehicle accidents because acceleration-deceleration is more rapid in falls. Patients usually present with acute headache, vomiting, drowsiness, confusion and hemiparesis. CT scan shows the hyperdense crescentic-shaped blood collection in the frontoparietal subdural space. Large SDHs cause midline shift and ipsilateral ventricular compression. Thin ones may be asymptomatic and detected incidentally on CT scan (Fig. 3).

Extradural Hematoma

Extradural hematoma (EDH) is a convex collection of blood between the skull and the dura. It is seen in 1–10% of TBI and is caused by a temporal bone fracture which tears the middle meningeal artery. EDH is mainly temporal in location because the temporal bone is thinner than the rest of the skull and breaks easily, lacerating the middle meningeal artery. MVA and falls account for the majority of cases. The characteristic clinical picture is termed "talk and die". The patient wakes up after an initial period of unconsciousness. This is the lucid interval, but it is soon followed by rapid deterioration with unconsciousness. Some patients with small EDH remain neurologically intact with minimal deficits (Fig. 4).

Subarachnoid Hemorrhage

Subarachnoid hemorrhage is usually associated with contusions or SDH. The differentiation between traumatic and aneurysmal SAH may sometimes be difficult, especially if a clear history of trauma is lacking. Typically, subarachnoid blood in TBI is superficially seen over the cortex and not in the basal cisterns as in aneurysmal bleed. However, if there is a doubt, it is best to do a CTA or a digital subtraction angiography. Traumatic SAH also produces delayed vasospasm with ischemic deficit, but less than with aneurysmal SAH and is also unlikely to rebleed.

Diffuse Axonal Injury

Patients with DAI caused by severe TBI are usually comatose with pupillary asymmetry and decorticate/decerebrate posturing. CT scan of head does not reveal any obvious hemorrhage or edema. Severe deceleration and rotational forces cause widespread shearing of axons located in the deep white matter. Axolemmal disruption and axonal retraction result, which finally lead to Wallerian degeneration. MRI of brain detects small punctate hemorrhages on gradient echo sequences in corona radiata, gray-white interfaces, corpus callosum (especially splenium), midbrain and pons. Corpus callosal lesions are typically seen in this type of injury.

DAI carries a high mortality of 50% and is a common cause of persistent vegetative state. Recovery may take months to years (Fig. 5).

PREHOSPITAL EMERGENCY MANAGEMENT OF MODERATE TO SEVERE TBI

Time is a vital factor in treating moderate to severe TBI. Early and appropriate interventions help to limit or prevent secondary brain injury. Emergency management of TBI commences when medical personnel reach the trauma victim and continues all the way through ambulance transport to the hospital. Every effort should be made to ensure that the patient reaches the hospital intensive care unit (ICU) in the shortest possible time. Rapid trauma-to-hospital time and transfer to a neurotrauma center reduce mortality.[5] All precautions, especially neck immobilization, must be taken whenever the patient is moved.

Airway, breathing and circulation are priority issues to be addressed during transport. The airway can be obstructed by foreign objects like dentures or accumulation of blood, secretions and vomit. Direct pharyngeal trauma may also cause airway collapse. If pharyngeal suction is unable to clear the airway, a tracheal intubation must be done. Massive facial trauma or a significant upper airway swelling may sometimes necessitate an urgent direct tracheotomy or cricothyroidotomy which could be life-saving. The arterial oxygen tension (PaO_2) must be monitored with a pulse oximeter. Breathing may be compromised by rib fractures causing a flail chest, pulmonary contusions or hemopneumothorax. Diaphragmatic injury,

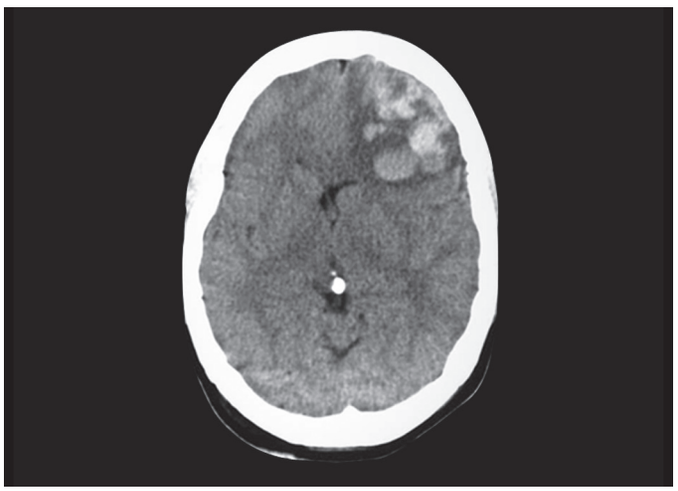

Fig. 2: Hemorrhagic contusions: CT scan reveals multiple focal areas of hemorrhage in left frontal region with mass effect on left lateral ventricle

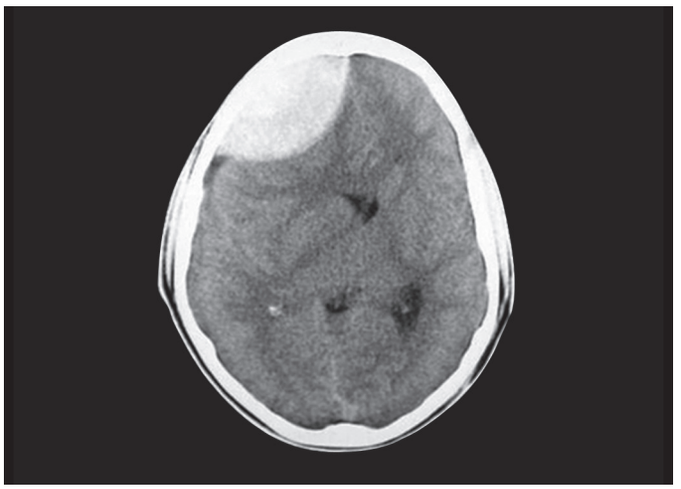

Fig.4: Extradural hematoma: CT scan reveals a large biconvex hyperdense lesion in the right frontal region causing significant mass effect representing an extradural hematoma

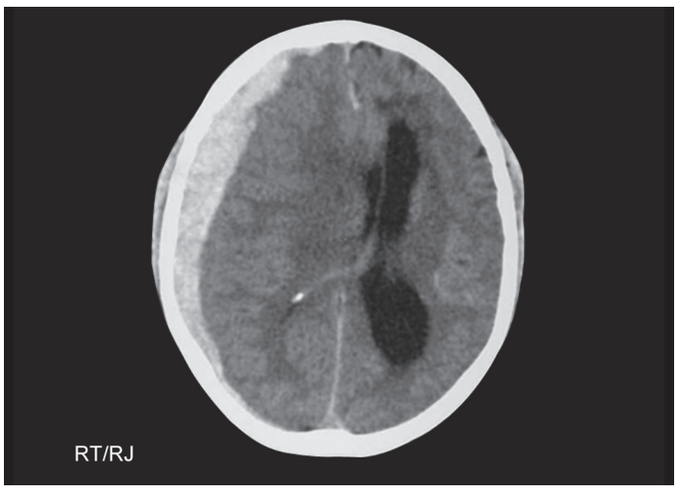

Fig. 3: Subdural hematoma: CT demonstrates a large concavoconvex hyperdensity representing a subdural hematoma causing mass effect on the right lateral ventricle and a consequent shift of the midline structures to the left

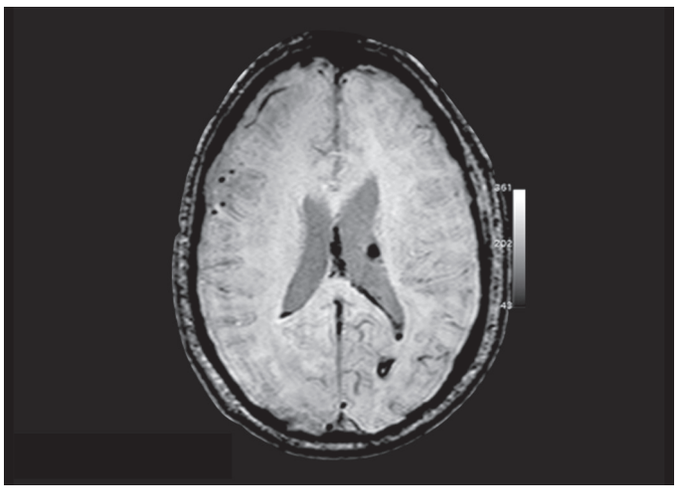

Fig. 5: Diffuse axonal injury: MRI SWI images demonstrate small SWI hypointensity representing microhemorrhages due to diffuse axonal injury

phrenic nerve paralysis due to spinal cord injury and respiratory center involvement by brainstem injury are other causes of respiratory distress. Supplemental oxygen is given through a face mask, but if the situation warrants, Ambu bag ventilation through a face mask or an endotracheal tube is instituted. Prophylactic hyperventilation is strictly avoided in the prehospital setting as it worsens tissue hypoxia and aggravates secondary brain injury.

Hypotension (systolic blood pressure <90 mm Hg) can occur due to significant scalp bleeding, internal hemorrhage or an acute abdomen. Scalp lacerations tend to bleed profusely due to a combination of rich scalp blood supply and their poor vasoconstrictive ability. It is difficult to give whole blood or packed cells in the ambulance. The only recourse is to treat the hypovolemic shock aggressively with intravenous fluids. Crystalloids (saline fluids) are preferred to colloids (albumin).[6]

ICU Management of Severe TBI

Head Posture

Patients are usually nursed in the supine position with the head elevated at about 30° to the horizontal. The neck should not be twisted and tapes around the neck avoided. These measures ensure adequate jugular venous return from the brain.

Airway and Oxygenation

Hypoxia at the time of admission is associated with a worse outcome.[7] A PaO_2 of 80–120 mm Hg, $PaCO_2$ of 35–40 mm Hg and arterial oxygen saturation more than 90% should be maintained. Indications for intubation and ventilation include a GCS score less than 9 (without sedation), declining oxygen saturation of less than 90%, signs of respiratory distress, rising $PaCO_2$ levels more than 45 mm Hg in patients without chronic obstructive pulmonary disease, copious secretions which are difficult to clear and aggressive, hyperexcitable patients who require sedation.

Blood Pressure

Systolic BP must not be allowed to fall below 90 mm Hg. The mean arterial pressure should be maintained above 70 mm Hg with CVP more than 5 mm Hg. Judicious use of fluids (saline or albumin) ± pressors help to stabilize BP. Whole blood or packed cells can be given if significant blood loss has occurred. If BP is elevated, it is wise not to acutely lower it unless systolic BP rises above 180 mm Hg. Vasodilators like sodium nitroprusside and hydralazine are avoided as they may increase ICP.

Sedatives and Analgesics

Patients with severe TBI are often extremely restless and agitated. Their breathing may not be synchronized with the ventilator settings. Coughing, repeated endotracheal suction and frequent change of body position, all result in spurts of hypertension and raised ICP. Judicious use of sedatives and analgesics help to control ICP by blunting the above effects. Intravenous propofol and fentanyl are commonly used. Propofol is the preferred sedative because of its rapid onset and short half life. It is given as an infusion at a rate of 0.1–5 mg/kg per hour. Long-term infusions are best avoided in children because of a high risk of propofol infusion syndrome (mentioned in subchapter Status Epilepticus of Chapter Neurological Problems) and hepatic disturbance. Midazolam or lorazepam can be used as an alternative to propofol. The above drugs also have antiepileptic efficacy. Dexmedetomidine hydrochloride is a new agent that has rapid on-off properties and causes little respiratory depression. It is suitable for procedural uses and for ventilator weaning and extubation.[8] Fentanyl is the commonly used analgesic in severe TBI. It has a rapid onset, quick clearance and a short-lived effect, which permit frequent neurological assessments. It may cause respiratory depression, hypotension and vomiting.

Seizure Prophylaxis

In a population-based study of seizures after TBI, 17% of patients developed seizures in the first 7 days after injury, with nearly half of them occurring in the first 24 hours.[9] Seizures in this setting can acutely increase cerebral metabolism and ICP with disastrous consequences. So, current guidelines suggest that prophylactic antiepileptic drugs (AEDs) be given to prevent early post-traumatic seizures in the first 7 days. They are not, however, indicated to prevent long-term seizures.[10] Phenytoin/fosphenytoin or levetiracetam are commonly used AEDs. Levetiracetam is being used more frequently due to its favorable side effect profile. In the paralyzed and ventilated patient, electroencephalographic (EEG) monitoring helps to detect seizures which may be masked by sedatives and muscle relaxants.

Temperature and Blood Sugar

Fever is associated with elevated ICP, more severe neurological impairment and a longer ICU stay. Hence, infections (commonly respiratory and urinary tract) must be treated adequately with appropriate antibiotics and body temperature maintained below 38°C. Prophylactic antibiotics are used prior to procedures like intubation to reduce the risk of pneumonia. Most CSF leaks resolve spontaneously in a few days; hence, prophylactic antibiotics in this setting are not recommended because of the risk of drug resistance. Blood sugar should also be maintained in the normal range. Neither hyperglycemia nor hypoglycemia is desirable. No clear outcome benefit has been reported with intensive insulin therapy.[11]

Steroids

The use of corticosteroids is contraindicated in TBI patients (Level 1 evidence). The multicenter, randomized CRASH (corticosteroid randomization after significant head injury) trial showed that the risk of death was, in fact, higher in the steroid group compared to placebo patients.[12]

Intracranial Pressure Monitoring

Intracranial pressure monitoring has been associated with better outcomes in severe TBI. It is indicated in TBI patients having GCS of 8 or less with an abnormal CT scan showing contusion, hematoma or swelling or with normal CT scan if they have two or more of the following: age over 40 years, unilateral or bilateral motor posturing or systolic BP less than 90 mm Hg.[13] An external ventricular device is the gold standard of ICP monitoring as it serves the dual purpose of measuring ICP and draining CSF as required. It is advantageous to monitor ICP for at least 3 days post-injury to cover the expected period of occurrence of cerebral edema. ICP monitoring should continue for as long as raised ICP persists and can be discontinued after 48 hours of normal pressure trace (for more details on ICP monitoring, please refer to the subchapter Raised Intracranial Pressure of Chapter Neurological Problems).

Management of Raised ICP

The frequency of raised ICP is as much as 80% in comatose, head injured patients and is a strong independent predictor of mortality and morbidity. Hence, effective management of raised ICP holds the key to a favorable outcome. The goal of ICP management is to keep ICP less than 20 mm Hg. Cerebral perfusion pressure (CPP) of more than 60 mm Hg is recommended unless there is evidence of cerebral hypoperfusion, in which case a higher CPP is necessary. However, a CPP more than 70 mm Hg increases the risk of acute respiratory distress syndrome 5 times.[14] Moderate increase of ICP up to even 30 mm Hg may be tolerated, so long as arterial pressure maintains CPP at more than 60 mm Hg.

If ICP rises, simple extracranial causes must first be ruled out. Is the airway obstructed? Is the effect of sedatives wearing off and leading to the person bucking the ventilator? Is there an elevation of arterial $PaCO_2$ or a fall of PaO_2? Is there fever or occult seizure activity? Dilutional hyponatremia due to free-water overloading can also cause cerebral edema and rise in ICP. Correction of the above disturbances, if present, would have a beneficial effect.

Ideally, treatment should focus on the main cause of raised ICP. If an increase in cerebral blood volume is the predominant factor responsible, then hyperventilation is the most suitable therapy. An increase in brain water content (cerebral edema) is best treated by osmotherapy, while increased CSF outflow resistance responds to CSF drainage. Therapy for raised ICP is described in detail in the subchapter Raised Intracranial Pressure of Chapter Neurological Problems.

Surgical Considerations

Traumatic brain injury patients with acute SDH or EDH need urgent surgical evacuation if their GCS score is less than 9, volume of hematoma is more than 30 mL or midline shift is more than 5 mm on CT scan. Pupillary inequality and a fall in GCS score by 2 or more points from the time of trauma to the time of examination also warrant emergency surgery. A cautious wait-and-watch approach is adopted if the patient has a relatively preserved sensorium with a GCS of 9 or more and if the SDH or EDH bleed is small (<30 mL) with a midline shift of less than 5 mm. These patients need close monitoring, both clinically and with follow-up CT scans.[15]

The role of early surgical evacuation of intraparenchymal hematomas and hemorrhagic contusions is debatable. The increasing trend is to manage these patients conservatively at first, keeping a close watch on the level of arousal along with continuous arterial and ICP monitoring. Deterioration of these parameters and an increased mass effect on repeat CT scan should then prompt surgical evacuation. A neurosurgical consultation should be obtained earlier rather than later. Early surgical intervention is also indicated for compound depressed skull fractures, about half of whom have an associated dural tear. Debridement, removal of contaminant materials and secure wound closure should be carried out as early as possible.

Decompressive craniectomy is considered in refractory cases of raised ICP when medical management fails. It involves removing a large portion of the skull in absence of a large mass-occupying lesion like SDH or EDH. The aim of surgical decompression is to provide room for the injured brain to expand in order to preserve the deep vital parts of the brain. Decompression may be performed on one side of the skull if there is ipsilateral pathology. A bifrontal craniectomy is done if CT scan does not reveal a discernible lesion. Although ICP is reduced in most patients, the effect on outcome remains to be clarified.

Emerging Concepts—Multimodal Monitoring

Intracranial pressure measurement only gives indirect information about brain tissue oxygenation, cerebral metabolic activity and cerebral blood flow (CBF). Multimodal monitoring enables direct monitoring of these variables and can usefully complement ICP monitoring in the management of severe TBI. The various components of multimodal monitoring include partial brain tissue oxygen tension ($PbtO_2$), CBF, cerebral microdialysis, bispectral index and jugular venous oximetry.

Direct measurement of $PbtO_2$ detects compromise of oxygen delivery to brain tissue earlier than ICP monitoring. In this method, cerebral oxygen sensor probes are inserted into an area of suspected compromise in the brain parenchyma. They can detect focal ischemia which may otherwise have gone unnoticed.[16] Regional CBF can be measured either directly with thermal diffusion probes or indirectly with transcranial Doppler ultrasound which measures blood velocities in intracranial vessels. Jugular venous oxygen saturation is also an indirect means of measuring/monitoring CBF. It is estimated with the help of a fiber-optic catheter inserted through the internal jugular vein into the jugular bulb at the skull base. Low values indicate reduced CBF and impending ischemia. Cerebral microdialysis assesses the metabolic status of the brain. A small catheter placed in the

brain parenchyma measures extracellular levels of glucose, lactate, pyruvate, glutamate and glycerol. It is used as a marker for cellular distress.[17] Microdialysis analysis has shown that very tight systemic glucose control with insulin, in fact, results in an unfavorable pyruvate/lactate ratio and increased mortality.[18] These new modalities and devices, however, have their limitations and doubts have been raised on their efficacy. Large controlled trials addressing their safety and efficacy in severe TBI are required before they can be recommended for routine use in ICUs.

Prognosis of Severe TBI

Severe TBI is associated with a 30% mortality. A further 16% of patients are disabled with severe neurologic deficits. Age, GCS score, pupillary response, hypoxia and hypotension are prognostic factors shown to correlate with outcome.[19] A midline shift of more than 5 mm on initial CT scan and compression of mesencephalic cistern are associated with high mortality. Patients with DAI usually have a poorer outcome than other forms of TBI. However, DTI studies do show restoration of axonal integrity in the long term. Comprehensive neurorehabilitation improves functional outcome, with 85% of recovery occurring in the first 6 months.[20]

Rapid progress in neuroimaging and neurocritical care over the last few years has resulted in improved outcomes of TBI patients. Today, TBI is the subject of active clinical research both on the pharmacological and surgical fronts. Biomarkers of brain injury and genetic testing will play an important role in guiding specific therapies in the future. Present TBI treatment protocols have resulted in some remarkable recoveries, making all the effort put in seem worthwhile.

C. STROKE

Jimmy Lalkaka, BS Singhal

INTRODUCTION

Of all the neurological emergencies, stroke is probably the best known and most feared by physicians and the general public alike. It is a leading cause of mortality and morbidity all over the world with an estimated 22 million people falling victim to it each year.[1] While a large ischemic stroke carries a mortality of about 15%, the figure rises to nearly 50% for a major intracerebral hemorrhage (ICH). Raised intracranial pressure (ICP) is the most common cause of death in all types of stroke. Other causes include aspiration pneumonia, pulmonary embolism and cardiac arrhythmias. Strokes can be broadly classified into two groups—(1) ischemic stroke caused by occlusion of a blood vessel with a resultant infarct (80% of strokes) and (2) hemorrhagic stroke due to rupture of a vessel with bleeding within the brain (20% of strokes).

ACUTE ISCHEMIC STROKE

Acute ischemic stroke (AIS) is usually caused by one of the following mechanisms—

- *Large vessel atherothrombosis* Atherosclerotic occlusion of a large extra/intracranial artery occurs either by an in situ thrombus or by dislodgment of an embolic fragment with distal arterial block (artery-to-artery embolism).
- *Cardioembolism* The heart is an important cause of embolic strokes. Multiple infarcts at different times in different vascular territories raise the possibility of a cardiac source of embolus. Atrial fibrillation (AF) with or without valvular disease is probably the most common cause. If AF is associated with congestive heart failure, low ejection fraction or ischemic heart disease, the risk is particularly high. Acute myocardial infarct (especially anterior wall), left ventricular (LV) thrombus, prosthetic valves, cardiomyopathy and infective endocarditis are other common causes. In a patient with multiple strokes where no cause is detected, it would be prudent to do a 24- or 48-hour Holter monitoring to detect any intermittent episodes of AF.
- *Small vessel disease* A microangiopathy affecting small penetrating arteries (50–200 μ in diameter) causes small subcortical infarcts called lacunes. Hypertension and diabetes are the most important causes. Lipohyalinosis is the underlying pathological process, although atherosclerosis is also responsible in some cases.

Other less common but important causes of AIS need a mention. Young stroke patients presenting with severe neck pain and a prior history of sudden jerking or trauma to the neck are likely to have an arterial dissection. Carotid artery dissection is associated with pain in the anterior part of the neck, while in vertebral artery dissection, the pain occurs more posteriorly. Stroke in young patients with multisystem involvement should raise the suspicion of systemic lupus erythematosis. Stroke usually occurs during the course of the illness, though sometimes it is the presenting feature. A delayed diagnosis of tuberculous meningitis can result in disabling strokes due to thick basal exudates constricting the intracranial vessels. Hematological disorders like polycythemia, thrombocytosis and leukemia can also underlie strokes.

PATHOPHYSIOLOGY OF ACUTE CEREBRAL ISCHEMIA

Occlusion or stenosis of a blood vessel impairs the blood supply to the brain tissue perfused by that vessel. The cerebral blood flow in a normal adult brain at rest is about 50–55 mL/100 g per minute. When it decreases to 18 mL/100 g per minute, a threshold of electrical failure occurs. Although neurons do not function normally at this level, they still have the potential to recover. When blood flow falls to 8 mL/100 g per minute, a threshold of membrane failure is reached, at which point neuronal cell death occurs. These thresholds represent the upper and lower limits of the ischemic penumbra, which represents damaged but potentially salvageable tissue. All attempts to re-establish blood flow are made to prevent this area from getting infarcted. This is the principle underlying the various reperfusion strategies employed in AIS management.

CLINICAL ASSESSMENT

The sudden onset of neurological symptoms points to a stroke, although other conditions mimicking stroke like acute demyelination, seizure, hypoglycemia and cerebral tumor must be excluded. Severe headache, vomiting and seizures at onset are uncommon in AIS and raise the possibility of ICH or subarachnoid hemorrhage (SAH). This distinction between an infarct and a hemorrhage is not always clear on clinical grounds. The precise time of onset of the stroke is essential to ascertain from the patient or a witness in order to plan the appropriate reperfusion strategy. If a patient wakes up from sleep with neurological symptoms, the time of onset is taken as the time he was last seen normal.

At the time of first patient contact, a quick, brief clinical and neurological examination is performed. Focal neurological deficits of stroke can be quickly assessed with the help of the National Institutes of Health Stroke Scale (NIHSS). It is a widely accepted standardized measure of the neurological deficit caused by AIS. It takes only a few minutes to perform and is used to assess the severity of a stroke. Low scores (<10) indicate a mild stroke with likelihood of a favorable outcome, while high scores (>20) indicate severe neurological deficits.[2]

DIAGNOSTIC EVALUATION

Computed tomography scan of the head is performed as soon as possible to rule out a cerebral hemorrhage. It may be normal in early AIS. Signs of a recent acute infarct on CT scan include loss of differentiation between the cortical gray and underlying white matter, sulcal effacement, swelling of cortical gyri and loss of insular ribbon. The hyperdense MCA sign on unenhanced CT scan indicates occlusion of the mainstem MCA. MRI is highly sensitive in detecting the presence and extent of an infarct. A bright signal on diffusion weighted image (DWI) with a corresponding dark signal on apparent diffusion coefficient (ADC) sequence indicates an acute infarct. Perfusion MRI/CT scans detect the presence of an ischemic penumbra representing potentially salvageable tissue. It appears as a region of low perfusion which is larger than the bright diffusion weighted region (infarct core). This is called the diffusion-perfusion mismatch. A large diffusion-perfusion mismatch indicates a large penumbra and tissue at risk and warrants a more intensive reperfusion strategy like intra-arterial thrombolysis (IAT). This mismatch is sometimes used as a criterion to select patients for intravenous thrombolysis (IVT) beyond the 3-hour window period, even up to 9 hours after stroke onset.[3] MR-Angiography (MRA) and CT-Angiography (CTA) help to visualize the entire cerebral vasculature from the aortic arch to the Sylvian branches. The degree of stenosis in extracranial and intracranial vessels is accurately determined by them. A digital subtraction angiogram (DSA) is not routinely performed except in suspected vasculitis, arterial dissection or significant carotid stenosis prior to endarterectomy.

A 2D echocardiogram (ECG) is ordered in AIS to check for a possible cardioembolic source. If it is strongly suspected and the 2D echocardiography is normal, a transesophageal ECG is done to look for abnormalities in the atrial appendage or thoracic aorta. A Holter monitor helps to detect intermittent cardiac arrhythmias. Basic hematological and biochemical tests which are carried out in all stroke patients include a complete hemogram, platelet count, prothrombin time (PTT), blood sugar, urea, creatinine, electrolytes and lipid profile. More detailed work-up is required in atypical and young strokes and those without the usual risk factors.

REPERFUSION STRATEGIES IN ACUTE ISCHEMIC STROKE

Time is the single most important factor in any strategy aimed at re-establishing blood flow in an occluded vessel. The window of opportunity for thrombolysis is small and every minute counts. In that sense, stroke management is a true emergency. Public awareness of common stroke symptoms must be created and a well-rehearsed plan put in place to ensure that stroke patients reach the hospital in the shortest possible time. Valuable time is often lost waiting for the family doctor to come home to examine the patient. The hospital must be fully geared to handle this emergency. Stroke units with involvement of the neurologist, physician, senior residents, nurses, neuroradiologist, neurosurgeon and pathologist have had a beneficial effect on outcomes. In centers lacking expertise, telemetric contact with tertiary specialist centers facilitates thrombolytic therapy and other treatment decisions.

Intravenous Thrombolysis

All patients presenting within 4.5 hours of an AIS should be considered for IVT with recombinant tPA (alteplase). The advantage of tPA over other thrombolytic agents is that it is clot specific because of its high affinity for plasminogen in the presence of fibrin. This allows efficient activation of plasminogen in the clot but very little activation in the plasma. Hence, the systemic effects are modest. The landmark National Institute of Neurological Disorders and Stroke (NINDS) trial demonstrated that AIS patients who received intravenous (IV) tPA within 3 hours of stroke onset had a more favorable outcome at 90 days than those who did not receive the drug.[4] Those who received alteplase within 90 minutes of stroke onset fared better than those who received it later than 90 minutes, emphasizing the importance of minimizing the door-to-needle time. The third European Cooperative Acute Stroke Study (ECASS III) showed that intravenous (IV) recombinant tissue plasminogen activator (rtPA) given 3–4.5 hours after onset of stroke symptoms also produced a modest but significant improvement in clinical outcome without increased risk of symptomatic ICH.[5] Results from the large, multicenter third international stroke trial (IST-3) suggest an extended benefit for IV rtPA up to 6 hours of stroke onset.[6] Most clinical trials for IVT enrolled patients less than 80 years of age. However, in the above-mentioned IST-3 trial, 53% of the enrolled patients were over 80 years and they also benefited from thrombolysis. Their risk of bleeding was no different from that of other age groups.[6]

Intravenous thrombolysis carries a significant risk of intracranial bleeding (6.4% in the NINDS trial).[4] However, the benefits of this therapy appear to outweigh the risks. A checklist of exclusion criteria for IVT exists in order to minimize the risk of bleeding and other adverse effects (Box 2). Notable contraindications to IVT include prior history of major surgery within the past 14 days, large cerebral infarct covering more than one-third of the vascular territory, prior ICH, history of gastrointestinal tract or urinary bleeding in the past 21 days, current oral anticoagulant therapy with international normalized ratio (INR) greater than 1.7 or heparin within 48 hours of presentation with prolonged activated PTT (aPTT), platelets less than100,000 and BP higher than 185/110 mm Hg. Patients with a mild deficit (NIHSS of 4 or less) and those who are spontaneously recovering are also not considered for IVT.

The dose of IV tPA is 0.9 mg/kg up to a maximum of 90 mg, with 10% of dose given as a bolus over 1 minute and the remaining 90% as an infusion over 1 hour. If BP is higher than 185/110 mm Hg, it has to be first reduced with IV labetalol (10–20 mg) before starting alteplase. It is preferable not to

Box 2: Indications and contraindications for intravenous thrombolysis

Indications—
- Acute ischemic stroke with significant neurological deficit [National Institutes of Health Stroke Scale (NIHSS ≥4)]
- Onset time within 4.5 hours
- Head computed tomography does not show hemorrhage or alternative diagnosis

Contraindications—
- Intracranial hemorrhage on CT or clinical suspicion of subarachnoid hemorrhage
- Mild or rapidly improving neurologic deficit
- Known CNS vascular malformation or tumor
- Major surgery in the past 14 days or minor surgery in the past 10 days
- Severe head trauma in the preceding 3 months
- Active internal bleeding within 21 days
- Arterial puncture at a noncompressible site within 7 days
- Patient on oral anticoagulant or use of heparin in the previous 48 hours
- PT-international normalized ratio (INR) greater than 1.7, PTT greater than 40 s, platelet count less than 100,000
- Systolic BP higher than 185 mm Hg or diastolic BP higher than 110 mm Hg
- Seizure at onset
- Blood sugar less than 50 mg% or greater than 400 mg%

insert a urinary catheter, nasogastric tube or a central line for the first 24 hours. Arterial puncture at noncompressible sites must also be avoided. BP is closely monitored every 15 minutes for 2 hours after starting the infusion, then every 30 minutes for 6 hours and then every hour up to 24 hours. No antiplatelet or antithrombotic drug is given for the first 24 hours. If the patient's sensorium or neurological deficit worsens, the infusion must be discontinued immediately and an urgent noncontrast CT scan of the head done to rule out an ICH or hemorrhagic transformation of the infarct.

Intravenous thrombolysis, as beneficial as it has been, is not without its limitations. It is not very effective in patients with severe stroke where the NIHSS score is 20 and above. Most of these patients have a large vessel occlusion (ICA, MCA, basilar artery). The recanalization rate for these occlusions with IVT is low (around 20%) compared to higher intra-arterial recanalization rates (60–70%).[7] Besides, a very small proportion of AIS patients receive IVT due to the short therapeutic window period and the presence of stringent exclusion criteria. Hence the need for other reperfusion strategies.

Intra-arterial Thrombolysis

For those patients who present beyond the window period for IVT and in whom a large penumbra (i.e. a large perfusion-diffusion mismatch on MRI) with occlusion of large extracranial or intracranial arteries (ICA, MCA or basilar artery) is observed, IAT with direct delivery of the lytic drug is considered. In this way, a high concentration of drug is delivered locally into the clot, resulting in increased recanalization rates with less bleeding and other systemic complications. IAT is also an option for those in whom IVT is contraindicated. The PROlyse in acute cerebral thromboembolism (PROACT–II) trial demonstrated benefit of intra-arterial prourokinase in the treatment of MCA occlusions within 6 hours of onset. A good outcome was observed in 40% of the prourokinase group versus 25% of the control patients. The recanalization rate was also higher in the treated group compared with the controls (66% vs 18%).[8] The window period for vertebrobasilar intervention has not been clearly defined. Intra-arterial urokinase and rtPA have been beneficial in treating basilar artery occlusions even beyond 12 hours after onset and, in some cases, more than 24 hours. This extension of the time window is based on the dismally poor natural history of severe brainstem stroke (>90% cumulative morbidity and mortality), whereas successful revascularization has the potential to significantly improve outcome. Intra-arterial urokinase administered to 106 patients with basilar artery occlusion resulted in recanalization in nearly 70% of patients, a moderate to good clinical outcome in 45% and a mortality of 41%.[9] Attempts have been made to combine IV rtPA with intra-arterial rtPA, the so-called "bridging therapy".[10] This therapy allows immediate access to IVT, but recognizes the fact that the low recanalization rate with IVT can be improved with the intra-arterial approach for large artery occlusion (MCA, ICA and basilar artery).

Mechanical Clot Retrieval Devices

Mechanical embolectomy devices like the mechanical embolus removal in cerebral ischemia (MERCI) device and penumbra device cause recanalization of the occluded vessel by mechanical removal of the clot.[11] They are used when thrombolytic therapy is contraindicated or when it has failed to cause recanalization. The therapeutic window for intervention with these devices is 8 hours from stroke onset. These two devices have got FDA approval on the basis of improved recanalization rates rather than improved stroke outcomes. The penumbra trial showed that the device is safe and effective in recanalizing occluded vessels but its impact on clinical outcome was unclear.[12] These devices are operator-dependent and good outcomes depend on the skill and experience of the interventionalist.

Stent Retrievers

Stent retrievers are combined flow restoration (FR) and thrombectomy devices. Their use combines the advantages of intracranial stent deployment with immediate FR and a thrombectomy, which removes clot from the occluded artery. During deployment, the stent retriever compresses the thrombus and partially restores blood flow to the distal territory immediately. The entire device along with the thrombus is then removed. These devices have shown far superior results in large vessel occlusions compared

with other retrieval devices in terms of recanalization rates, clinical outcomes and low rates of symptomatic hemorrhage.[13] The Solitaire with intention for thrombectomy (SWIFT) study compared the efficacy of Solitaire FR stent retriever with the Merci device in AIS patients within 8 hours of symptom onset. The trial was halted a year sooner than planned because of significantly better outcomes in the Solitaire group (recanalization rates of 83.3% vs 48.1%, good clinical outcome in 58.2% vs 33.3%). Symptomatic hemorrhage and mortality were also significantly lower in the Solitaire group.[14]

Antiplatelet and Anticoagulant Drugs in Acute Ischemic Stroke

Aspirin should be given as soon as possible after an AIS. It reduces death or dependence when given within 48 hours of onset. If clopidogrel is used, a bolus dose of 300 mg (4 tablets of 75 mg each) is given for rapid inhibition of platelet aggregation. A daily dose of 75 mg takes up to 5 days for maximal platelet inhibition. Unfractionated and low molecular weight heparin (LMWH) is commonly used by physicians in AIS. However, their efficacy in AIS has not been established. In the large International Stroke Trial, subcutaneous heparin in AIS did not show any overall benefit over placebo in stroke outcome.[15] The only clear indication for anticoagulant therapy in AIS was for deep vein thrombosis (DVT) prophylaxis. These anticoagulants may, however, benefit the subset of patients with acute cardio-embolic stroke in whom the risk of early stroke recurrence is high. They are instituted prior to oral anticoagulant therapy. The latter is also recommended in AIS due to arterial dissection, cerebral venous sinus thrombosis and a hypercoagulable state.

GENERAL PRINCIPLES OF ACUTE STROKE MANAGEMENT

The focus on reperfusion therapy in recent times should not, in any way, detract from the importance of optimum medical management of AIS. To an obtunded patient with a severe stroke, intensive medical and nursing care is as vital, if not more, as reperfusion therapy.

Airway, Breathing and Circulation

The first step in managing an acute stroke patient is assessment of the vital signs. Arterial oxygenation (PaO_2) must be adequately maintained. It is prudent to administer oxygen through nasal prongs. Mechanical ventilation may be required if the patient is unable to protect his airway or has signs of raised ICP and impending herniation. Rapid sequence intubation is generally followed. It entails preoxygenation, Sellick maneuver (pressure applied to the larynx to compress the esophagus and prevent gastrointestinal reflux into lungs), and premedication with muscle relaxants to blunt the sympathetic response which causes a spurt in ICP. Noninvasive positive-pressure ventilator support is sometimes used instead of mechanical ventilation. Volume depletion must be quickly corrected. A central line is inserted to monitor CVP and IV fluids and pressor agents given as required. Normal saline infusion at 1–2 mL/kg per hour helps to maintain fluid balance.

Blood Pressure

Acute stroke patients usually have elevated BP. This is usually a compensatory mechanism to maintain normal cerebral blood flow in the presence of ischemia. Aggressive lowering of BP is detrimental in AIS as it compromises the cerebral perfusion pressure and increases the likelihood of converting the ischemic penumbra to an infarct. Antihypertensive medication is usually withheld unless BP is higher than 220/120 mm Hg. If thrombolytic therapy is contemplated, the BP should be less than 185/110 mm Hg. A parenteral beta-blocker like labatolol (bolus of 10–20 mg, repeated if necessary) or the calcium channel blocker nicardipine is used if the BP exceeds the above limits. A very high diastolic BP higher than 140 mm Hg may require sodium nitroprusside infusion to achieve a 10–20% reduction in diastolic BP. The practice of giving sublingual nifedipine should be strongly discouraged as it can cause a precipitous fall of BP with resultant cerebral ischemia. A rapid reduction of BP in AIS is only indicated if there is evidence of hypertensive encephalopathy, acute myocardial infarct/LV failure or acute renal damage. Arterial hypotension does not normally occur in AIS. If BP falls, it is important to exclude gastrointestinal bleeding, myocardial infarction, aortic dissection and volume depletion.

Blood Sugar and Temperature

Both hyperglycemia and hypoglycemia aggravate injury to already damaged neural tissue. Hyperglycemia results in a higher regional lactic acid production and decreased survival of penumbral tissue. In acute stroke, blood sugar level is maintained with subcutaneous boluses of plain insulin as per glucometer readings. Dextrose containing fluids are avoided. Sometimes, hypoglycemia mimics a stroke with an acute focal neurological deficit. Fever increases neural tissue metabolism and adversely affects outcome. Aspiration pneumonia and infection caused by urinary catheter and central line placement commonly occur in stroke patients. The temperature must be quickly lowered with antipyretics and antibiotics. Those with a high risk of aspiration should be fed through a nasogastric tube. Patients with persistent dysphagia will require a percutaneous feeding gastrostomy tube.

Deep Vein Thrombosis

A patient with dense hemiplegia has a high risk of developing DVT and pulmonary embolism. Precautions to prevent DVT include tight elastic stockings, intermittent calf pressure compression device and subcutaneous unfractionated

heparin (UFH)/low MW heparin. Every effort must also be made to mobilize the patient as early as possible.

MANAGEMENT OF STROKE COMPLICATIONS

Cerebral Edema

Cerebral edema is a leading cause of death in AIS, especially in the first week. It develops during the first 24–48 hours, peaks around 3–5 days after stroke onset and results in neurological deterioration. Large hemispheric infarcts are usually associated with significant cerebral edema. A big cerebellar infarct causes rapid brainstem compression, hydrocephalus and herniation, because the posterior fossa provides very little space to accommodate the edema. Judicious use of osmotic dehydrating agents like mannitol or hypertonic saline and mechanical hyperventilation help to reduce cerebral edema. The role of steroids in strokes is debatable. Although their efficacy has not been established, parenteral dexamethasone is often used by physicians concomitantly with mannitol to treat cerebral edema.

Malignant infarcts are large infarcts involving practically the entire ICA or MCA territory. They are associated with a high risk of brain herniation and death (80% mortality) with conventional treatment. Early decompressive hemicraniectomy (<48 hours of stroke onset) with removal of a large bone flap can be lifesaving in these cases.[16] Decompressive suboccipital craniectomy can, likewise, be lifesaving in a large cerebellar infarct.

Hemorrhagic Transformation of Infarct

Hemorrhagic transformation of an infarct occurs in 30–40% of AIS. The advent of thrombolytic therapy has increased the incidence of symptomatic hemorrhagic transformation. Heparin also increases this risk. If the hemorrhage is large and accompanied by clinical deterioration, the antiplatelet/antithrombotic medications must be discontinued and measures to reduce cerebral edema instituted. If a minor hemorrhagic transformation is seen on CT or MRI with no clinical deterioration, no specific intervention is required.

Seizures

Early seizures within 1–2 weeks of an AIS occur more often with large cortical infarcts, multiple infarcts, embolic stroke and venous infarcts. Associated metabolic disturbances also increase seizure risk. They can be the presenting feature of cerebral venous sinus thrombosis. An early seizure requires only a short-term antiepileptic drug treatment for about 3–6 months. Late onset seizures occurring 2 weeks after stroke onset are caused by gliosis and have a high recurrence rate with subsequent development of epilepsy. Hence, they require long-term therapy. Prophylactic anticonvulsant treatment in stroke patients is not recommended.

EMERGING THERAPIES IN ACUTE ISCHEMIC STROKE

Ultrasound Enhanced Thrombolysis

Experimental evidence suggests that ultrasound enhances the thrombolytic effect of IV rtPA. It causes disruption of a thrombus with greater penetration of thrombolytic material into the clot. Low frequency ultrasound exposure along with administration of microbubbles promoted clot lysis in AIS.[17] Continuous transcranial Doppler in IVT-treated patients was associated with a higher frequency of complete recanalization and clinical recovery compared to controls.

Neuroprotective Therapy

Several neuroprotective agents have undergone trials in AIS. However, to date, no agent has been found to improve outcome. Hypothermia has the potential of protecting the brain against anoxic-ischemic insults by reducing the metabolic need of underperfused brain tissue. Trials are ongoing, but various potential clinical barriers have arisen and hypothermia is not yet ready to be included in standard management protocols for AIS.

CEREBRAL VENOUS THROMBOSIS

Occlusion of a cerebral venous sinus or cortical vein by a thrombus can also result in stroke. Cerebral venous thrombosis (CVT) accounts for 0.5–1% of all strokes.[18] It occurs more commonly at a younger age and in women of child-bearing age because of pregnancy, puerperium and use of oral contraceptives (OC).

Etiology and Risk Factors

The etiological and predisposing factors can be broadly classified into genetic prothrombotic states and acquired conditions. Hereditary conditions with a high propensity for CVT include protein C, protein S and antithrombin III deficiency and homozygous mutations of factor V Leiden and prothrombin genes. Acquired predisposing situations include pregnancy, postpartum state, oral contraceptive pills (OCP), hyperhomocysteinemia and the antiphospholipid antibody (APLA) syndrome. Most pregnancy-related cases of CVT occur during the third trimester and the first 4 postpartum weeks. Use of OC pills is associated with a fourfold increased risk of CVT. This risk is even greater among those who also have a hereditary prothrombotic state. Hyperhomocysteinemia is another important cause of CVT, occurring more frequently in the Asian population.[19] With effective antibiotic therapy, the incidence of infection-related CVT has fallen dramatically. It now accounts for only 8% of cases.[20] However, infection from parameningeal sites (ear, sinus, mouth, face and neck) still plays an important role in children. The cavernous and lateral sinuses are the ones most frequently involved in the infective process. Other important predisposing conditions for CVT

include systemic lupus erythematosis, anemia, dehydration and malignancy. CVT is typically multifactorial with nearly 50% of patients possessing more than one risk factor.[21] The cause of CVT remains undetected in 20–30% of cases.

Clinical Presentation

Patients usually present with clinical features of raised ICP and focal neurological deficits. Headache is the most frequent symptom occurring in more than 80% of patients. Papilledema accompanies headache in about 50% of patients. Seizures, focal or generalized, occur in about 40% and are the presenting feature in 12–15% of CVT cases. About half of the patients are admitted to hospitals with impaired sensorium and altered mental state. Focal neurological deficits occur due to the presence of venous infarct or ICH. The clinical features depend on the location of the affected sinus. A superior sagittal sinus (SSS) thrombosis, besides causing headache and papilledema, produces a motor weakness predominantly of the lower limbs. Lateral sinus thrombosis results in a temporal lobe infarct with contralateral hemiparesis, aphasia and hemianopia. It is usually accompanied by fever, ear discharge and mastoid pain. Thrombosis of the deep cerebral venous system (the straight sinus, internal cerebral vein and vein of Galen) causes bilateral thalamic and basal ganglia infarcts. These patients present with rapidly deteriorating sensorium without focal deficit. Cavernous sinus thrombosis presents with orbital pain, proptosis, chemosis and affection of the III, IV and V cranial nerves. ICH occurs in 30–40% of CVT patients, even prior to anticoagulant use.[22] It is important to identify these patients to enable them to receive appropriate, timely treatment. Clues to a CVT etiology in these patients include presence of prodromal headaches (unusual for other ICH causes) and bilateral parenchymal involvement.

Cerebral venous thrombosis does not always cause a stroke. Patients may present more insidiously with clinical features of raised ICP without a focal deficit. They complain of headache, vomiting, papilledema and transient visual obscurations. This pattern closely resembles benign intracranial hypertension (BIH). In fact, CVT was detected in 10% of patients diagnosed as BIH.[23]

Diagnostic Approach

Cerebral venous thrombosis should be considered in all young stroke patients with no risk factors for ischemic stroke or with an unusual ICH. The presence of bilateral signs, seizures, headache and papilledema should raise the suspicion of DVT as they occur more frequently in venous infarcts compared to their arterial counterparts. In suspected CVT, laboratory investigations must include hemogram, biochemistry profile, PTT, aPTT, antiphospholipid antibodies and homocysteine. Infection must also be ruled out and, if in doubt, a CSF examination is ordered. A genetic thrombophilia screen includes estimation of protein C, protein S and antithrombin III, along with work-up for mutations of factor V Leiden and prothrombin gene.

Neuroimaging provides valuable information in CVT patients. A hyperdense signal on noncontrast CT scan suggests the presence of a thrombus in the venous sinus or cortical vein. "The empty delta sign" observed in a contrast enhanced CT scan consists of a central hypodensity or filling defect due to the thrombus, which is surrounded by contrast enhancement of the overlying walls of the sinus. It is triangular in shape and is visualized over the posterior aspect of SSS. An acute thrombus is difficult to detect on MRI in the first few days. However, by the second week it is easily visualized as an area of hyperintensity on T1- and T2-weighted sequences. Hemorrhagic infarcts and multifocal bleeds are easily detected on CT or MRI. A venous infarct is suspected if it is hemorrhagic, does not correspond to a well-defined arterial territory and reveals disproportionate mass effect and edema. The location of the infarct gives a clue to the thrombosed sinus. An infarct located in the frontal parasagittal cortex suggests an SSS thrombosis, while a temporal cortex infarct occurs with lateral sinus occlusion. Contrast enhanced MR-venography (MRV) is a rapid and reliable noninvasive method for diagnosing CVT. It accurately demonstrates absence of flow in the affected sinus. A digital subtraction angiography is usually not required when MRV is available. It is reserved for situations in which MRV is inconclusive or if an endovascular procedure is considered.

Management Options

The mainstay of treatment in acute CVT is systemic anticoagulation with UFH or LMWH, followed by oral anticoagulation. An IV infusion of UFH is titrated to keep aPTT at twice the control, while LMWH is given subcutaneously twice a day in a dose of 180 antifactor Xa units/kg per 24 hours. Generally, LMWH is preferred because of its ease of administration. Anticoagulants are given even in the presence of a hemorrhagic infarct or multifocal bleeds. A meta-analysis of UFH and LMWH trials confirmed the safety of anticoagulation with no occurrence of new or increased bleeding.[24] Long-term anticoagulation is usually with oral warfarin with adjustment of its dose to maintain INR between 2 and 3. Newer direct thrombin inhibitors like ximelogatran and argatroban are alternatives to warfarin. Oral anticoagulants are usually given for 3 months if CVT is due to a transient, reversible risk factor and 6–12 months if the cause is not known. Recurrent attacks of CVT and severe thrombophilias like antithrombin III deficiency or APLA syndrome may require indefinite, perhaps life long, therapy.

Endovascular local instillation of thrombolytic drug (urokinase or rtPA) directly into the affected sinus with or without mechanical removal of thrombus is considered in experienced centers for severe cases or those not improving with systemic anticoagulation. In fulminant cases with impending brain herniation, a decompressive hemicraniectomy could prove lifesaving.

Appropriate empirical antibiotic therapy along with surgical drainage of the infected source is instituted in

infection-induced CVT.[25] Women with CVT during pregnancy must receive LMWH in full dose throughout pregnancy and for at least 6 weeks postpartum. Only LMWH can be given as oral anticoagulants cause fetal embryopathy and are contraindicated in pregnancy. Though the course of CVT is unpredictable, a favorable outcome occurs in the majority of patients with complete recovery in about 80%.

INTRACEREBRAL HEMORRHAGE

Causes of Spontaneous Intracerebral Hemorrhage

Spontaneous ICH refers to bleeding in the brain parenchyma which is not caused by trauma. Hypertension is the commonest cause of ICH. It damages the walls of small penetrating arteries and arterioles 50–200 μ in diameter, especially at branch points. Hypertensive ICH has a predilection for certain anatomical sites corresponding to the location of these penetrating vessels. Putamen is the commonest site, followed by thalamus, superficial subcortical white matter (lobar), cerebellum and pons. Sometimes, underlying hypertension may be detected for the first time when ICH occurs. Rupture of arteriovenous malformations (AVMs) and aneurysms is suspected when ICH occurs at atypical sites in young people with no history of hypertension. Patients who are on anticoagulant and antiplatelet drugs also have an increased risk of ICH (0.5–2% risk of ICH with warfarin).[26] This risk increases in hypertensive, elderly patients. Thrombolytic therapy is also associated with high rates of hemorrhage (6.4% in the NINDS trial). Anticoagulant and thrombolysis induced bleeds are large, multifocal (cortical and subcortical) and often contain a blood fluid level. Amyloid angiopathy is a common cause of ICH in elderly patients over 65 years. Deposition of β-amyloid protein in small arteries and arterioles of leptomeningeal vessels makes them fragile and prone to bleed. Amyloid bleeds are usually lobar (superficial cortical), occur at multiple sites and are often recurrent. Other causes of ICH include bleeding diathesis (thrombocytopenia), bleed in a tumor, vasculitis and use of cocaine and other sympathomimetic drugs.

Important Sequelae of Intracerebral Hemorrhage

Increase in Hematoma Size

A significant increase in size of the hematoma occurs within the first few hours of onset in about one-third of patients, more so in the first 6 hours. This causes a fairly rapid neurological deterioration in these first few hours. It is not clear whether hypertension contributes to this increase. Antiplatelets and anticoagulants increase the risk of significant ICH expansion. Extravasation of contrast within the hematoma on CTA or MRI is called the spot sign. It represents ongoing hemorrhage and is a strong predictor of hematoma expansion.[27]

Perihematoma Cerebral Edema

Cerebral edema usually manifests after 24–48 hours and is maximal by the 3rd–5th day or even later in some cases. It is an inevitable sequel of the interaction of blood and blood products within brain tissue. Besides direct mechanical injury to brain tissue by the expanding clot, decreased blood flow in the immediate surrounding area of the hematoma also occurs. This releases inflammatory cytokines and excitatory amino acids with resultant breakdown of the blood-brain barrier and increase in cerebral edema.

Hydrocephalus

Intraventricular hemorrhage (IVH) occurs in approximately one-third of cases of ICH, mainly due to seepage of blood into the ventricles. In few cases, it may occur as a primary event. IVH can obstruct CSF pathways and cause hydrocephalus. Thalamic and cerebellar hematomas are also likely to cause hydrocephalus by obstructing the III and IV ventricles respectively.

Diagnosis of Intracerebral Hemorrhage

Intracerebral hemorrhage presents abruptly with severe headache, vomiting and a rapidly deteriorating sensorium. A history of hypertension, recent discontinuation of antihypertensive drugs, head trauma, use of antiplatelets or anticoagulants and drug/alcohol abuse must be elicited from the patient or caregiver. Focal neurological deficits depend on the location of the hematoma. A putaminal bleed presents with contralateral hemiparesis with conjugate eye deviation toward the ipsilateral hemisphere. Patients with pontine hemorrhage are usually stuporous or comatose with quadriparesis, pinpoint pupils and hyperpyrexia. Cerebellar hemorrhage presents acutely with repeated vomiting, vertigo and ataxia.

CT scan of the head is the preferred imaging modality in ICH. It is quick, easily available and adequately detects the presence, location and size of the hematoma. Cerebral edema, hydrocephalus and mass effect are also well-visualized. Serial CT scans are performed to look for hematoma expansion or increasing cerebral edema. Gradient echo sequence on MRI scan detects punctate microhemorrhages which are not seen on CT scan. A lobar location of these microhemorrhages points to a cerebral amyloid angiopathy while deep ones occur in chronic hypertension. If the hematoma is in an unusual location or has odd features, a contrast-enhanced CTA/MRA is performed to look for an underlying aneurysm, AVM or neoplasm. A hematoma due to aneurysmal rupture is located either in the frontal or temporal lobe, largely within and around the Sylvian fissure. A DSA is the gold standard for identifying aneurysms and AVMs and may be required in some cases (Figs 6 to 8).

MANAGEMENT OF INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhage patients are often admitted in a stuporous or comatose state with unstable vital signs. Emergent measures to maintain hemodynamic stability must

take precedence over all other therapeutic considerations. For more details, please refer to the earlier Section on General Principles of Acute Stroke Management.

Blood Pressure Management

Hypertension almost invariably occurs after ICH. This acute hypertensive response typically declines by about 2 mm Hg mean arterial pressure (MAP) per hour within 6 hours of acute bleed, reaching a plateau by 24 hours.[28] A persistently high BP carries the theoretical risk of increasing hematoma size. A rapid 15–20% reduction in BP in small to moderate sized hematomas was shown to be safe and beneficial. The Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT) study also showed that early intensive BP lowering treatment was well-tolerated and resulted in reduced

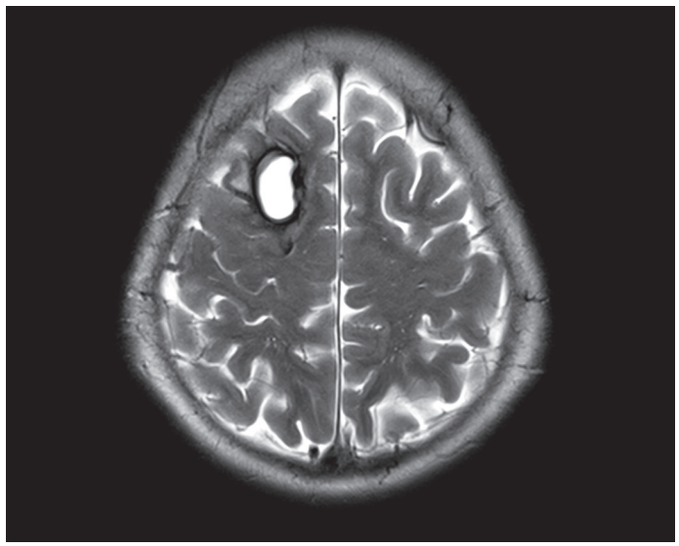

Fig. 8: Venous infarct: MRI reveals right frontoparietal hemorrhage

hematoma growth.[29] However, overaggressive BP-lowering in patients with raised ICP may reduce CPP and worsen brain injury. An acute lowering of BP is considered when the MAP is higher than 130 mm Hg or systolic BP is higher than 180 mm Hg. The aim is to lower levels to around 160/90 mm Hg or MAP of 110 mm Hg. If ICP is concomitantly elevated, then BP is lowered by first reducing ICP.

If the systolic BP is higher than or equal to 200 mm Hg or MAP is higher than or equal to 150 mm Hg, then aggressive BP reduction is warranted with continuous IV infusion of antihypertensives and BP monitoring every 5 minutes. Because BP tends to decline naturally after ICH, short-acting agents are used. Labetalol is the preferred drug. Alternatives to labetalol include enalaprilat, nicardipine and esmolol. Sodium nitropruside is usually avoided as it tends to increase ICP by vasodilatation. It is, however, used as an emergency medication when BP is higher than 240/140 mm Hg or when other agents fail to lower it.

Raised ICP and Seizures

Raised ICP in acute ICH is due to expanding hematoma size in the first few hours and cerebral edema after 24 hours of onset. Hydrocephalus also increases ICP. The therapy for raised ICP has been dealt with in the subchapter Raised Intracrenial Pressure of Chapter Neurological Problems. Early seizures occur in patients with a lobar hematoma. Deep-seated hemorrhage is usually not associated with seizures. Prophylactic use of anticonvulsants is not indicated for ICH patients, except in lobar hematomas where their use is considered optional.

Factor VIIa in Acute ICH

Recombinant factor VIIa (rFVIIa) acts on factor X on the surface of platelets, activating it and facilitating clot formation. It is

meant to stop hematoma growth. Clinical trials of this drug in acute ICH showed that though factor VIIa exerted biological effects and reduced hematoma size, it did not significantly improve patient survival or functional outcome. In fact, the incidence of thromboembolic events increased with this drug.[30] Based on these results, the routine use of rFVIIa for all patients with ICH within a 4-hour time window cannot be recommended. However, rFVIIa may still be useful in a subset of patients who present within $2^1/_2$ hours of ICH onset, have relatively small bleed (<60 mL) and are less than 70 years.[31]

Reversal of Anticoagulant and Thrombolytic Induced ICH

Warfarin-induced ICH requires discontinuation of the drug and immediate administration of IV vitamin K (10 mg slowly over 30 minutes). It, however, has a delayed onset of action of 6–24 hours. Prothrombin complex concentrate (PCC) comprising factors II, IX, X, with or without factor VII, should be given if available. It corrects INR rapidly within 10 minutes of its administration. If PCC is not available, fresh frozen plasma (FFP) is used in a dose of 15 mL/kg. It has a slower onset of action than PCC and requires infusion of a large volume which can cause volume overload. Cross-matching and thawing of the solution also use up valuable time. Factor VIIa has also shown benefit in anticoagulant-induced ICH. It is reported to reverse very high INRs and/or bleeding in patients on warfarin as early as 15 minutes after an IV bolus.

In ICH due to heparin or low MW heparin, IV protamine sulfate is given in a dose of 1 mg/100 units of heparin. The anticoagulant effect of heparin is reversed within 5 minutes of administration. This drug is given by a slow injection at a rate of less than 50 mg every 10 minutes to prevent hypotension. In patients with a high risk of embolic stroke like a prosthetic heart valve, oral anticoagulants can be restarted after 10–15 days of the bleed. ICH caused by antiplatelet drugs (especially dual antiplatelet therapy) can be treated by platelet transfusions and desmopressin which reportedly improves platelet activity and increases plasma factor VIII levels. Thrombolysis-induced ICH is treated by immediately stopping the rtPA infusion, followed by 6–8 units of platelet transfusions or FFP and 6–8 units of cryoprecipitate containing factor VIII. No therapy has, however, proved beneficial and the outcome is very poor.

15

SURGERY IN INTRACEREBRAL HEMORRHAGE

A cerebellar hematoma larger than 3 cm in size, with clinical deterioration, brainstem compression or hydrocephalus, must be urgently evacuated. This is because the cerebellum lies in a tight compartment and there is a high risk of transtentorial herniation if it is not removed. Patients with lobar hematomas greater than 30 mL, within 1 cm of the surface, and who are clinically deteriorating, should also be given the option of surgical evacuation. Being close to the surface, it is relatively easy and safe to evacuate them and the results are generally favorable. The site of the lobar hematoma also influences management decisions. A large hemorrhage may be comfortably accommodated in the occipital lobe. A similar-sized hematoma in the temporal lobe could produce a midline shift and require surgical evacuation.

The benefit of surgically evacuating other supratentorial hematomas has not been established. The multicenter surgical treatment for intracerebral hemorrhage (STICH) trial did not report a clear benefit of surgery in supratentorial ICH with the exception of lobar hematomas.[32] However, most patients in this trial underwent evacuation 12 hours and sometimes even 36 hours after ICH. Early evacuation of hematoma could result in better clinical outcomes as it would reduce perihematoma ischemia and toxic effects of blood products, thereby preventing or minimizing cerebral edema. Decompressive hemicraniectomy is indicated in large supratentorial bleeds with significant mass effect, midline shift and imminent danger of herniation. Removal of a wide bone flap can be lifesaving in such situations. Evacuation of clot can be simultaneously attempted.

Newer minimally invasive surgical procedures to evacuate deepseated hematomas are being increasingly performed. They minimize trauma to the nearby brain tissue and reduce operative time. Stereotactic aspiration of the clot entails placing a catheter stereotactically into the core of the hematoma. Urokinase or tPA is then injected locally. This liquefies the clot which is then aspirated out. Significant reduction in hematoma size and improved clinical outcomes has been reported with this technique.[33] The neuroendoscope is also a promising tool for hematoma evacuation. It is introduced through a small burr-hole and has the added ability to coagulate the bleeding vessel.[34]

In IVH, an external ventricular drain (EVD), is placed to drain out the blood. Intraventricular infusion of urokinase is used to hasten clot lysis. A recent randomized trial reported a significantly higher clot resolution rate with intraventricular instillation of rtPA through an EVD, compared to placebo in patients with large IVH. There was also a trend toward a favorable outcome in the treated group.[35] Hydrocephalus secondary to thalamic or cerebellar hematomas or IVH may initially require an EVD, with subsequent shunt surgery if required.

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage accounts for 5–10% of all strokes. While head injury is the commonest cause, rupture of intracranial saccular aneurysms (aneurysmal SAH) is the most frequent nontraumatic cause. Acute SAH carries a high mortality of 50% at 30 days,[36] with nearly 10% succumbing before they can receive any medical attention. The discussion in this section relates only to aneurysmal SAH.

Clinical Presentation

Acute SAH typically presents with a sudden onset of explosive "thunderclap" headache which is maximal at onset.

Patients describe it as the "worst headache of their lives". It is accompanied by profuse vomiting, neck stiffness and altered sensorium ranging from confusion to coma. A transient loss of consciousness sometimes occurs at the onset due to an acute spike in ICP. Fever can be caused by the presence of blood in the subarachnoid space. A subhyaloid retinal hemorrhage may be seen on fundus examination. Focal neurologic deficits like hemiparesis and aphasia indicate the presence of an associated intraparenchymal hematoma. Unruptured aneurysms may sometimes be detected on neurological testing. An ipsilateral third nerve paresis with a dilated, nonreactive pupil suggests a posterior communicating artery aneurysm. Bitemporal field defect due to optic chiasmal compression occurs with a supraclinoid carotid aneurysm, while occipital or neck pain may indicate a posterior circulation aneurysm.

The Hunt and Hess classification is a useful guide to prognosis and management options in SAH.

Hunt and Hess Clinical Classification of SAH

- Asymptomatic or mild headache with slight neck stiffness.
- Severe headache, stiff neck, no focal deficit except for cranial nerve palsies.
- Drowsy or confused, mild neurologic deficit.
- Stuporous, moderate to severe hemiparesis.
- Coma, decerebrate posturing.

Diagnosis

All patients with sudden severe unexplained headache must be evaluated for possible SAH. A noncontrast CT scan of head is the investigation of choice in suspected cases. It identifies nearly all cases in the first 24–48 hours. Its sensitivity in detecting SAH decreases as time elapses. At the end of 1 week, SAH can be detected in only about 50% of cases. Subarachnoid blood is usually seen in the basal cisterns, Sylvian fissures, interhemispheric fissure and perimesencephalic cisterns. If it occurs more over the hemispheres than the basal cisterns, an AVM or mycotic aneurysm should be suspected. Associated parenchymal hematoma and hydrocephalus may also be seen.

If the clinical history suggests SAH and CT scan fails to detect blood, a lumbar puncture (LP) must be done. CSF examination reveals innumerable red blood cells (RBCs). Xanthochromia is seen on a spin CSF specimen and helps to differentiate a subarachnoid bleed from a traumatic spinal tap. Xanthochromia may not be seen if LP is done within 6 hours of the hemorrhage.

Once SAH is diagnosed, a four-vessel DSA is performed to confirm the presence, size, location and other morphologic characteristics of the aneurysm. It can also detect a focal cerebral vasospasm. CTA and MRA are alternative noninvasive means to detect an aneurysm. If an initial angiogram fails to show an aneurysm, it may be repeated after 2–3 weeks. In about 10% of cases, subarachnoid blood is restricted to the perimesencephalic cistern (cistern around the midbrain). Blood is not seen in the Sylvian fissures or other locations. About two-thirds of these bleeds have normal angiograms with no detectable aneurysm. They are unlikely to rebleed and carry a significantly better prognosis than other forms of SAH.

MANAGEMENT OF ACUTE SAH

Initial Management

The patient should be admitted to ICU for close monitoring and kept in a quiet room. Headache must be treated with appropriate analgesics. Sometimes, mild analgesics like paracetamol may suffice. Salicylates are better avoided because of their inhibitory effect on hemostasis. If the pain is severe, codeine or a synthetic opiate like tramadol may be given. In smokers, chest physiotherapy and nebulization help to minimize coughing. Stool softeners are given to avoid straining at stools. These precautions aim to minimize the risk of rebleed.

Blood pressure should be carefully monitored and lowered to less than 140 mm Hg systolic using IV labetalol or nicardipine. If signs of raised ICP are present, measures to lower it must be first instituted before trying to lower BP. Volume depletion brought on by profuse vomiting and obtunded state must be corrected. Serum electrolytes are regularly monitored as hyponatremia commonly occurs in SAH. A baseline ECG sometimes shows changes simulating acute myocardial ischemia. A normal creatine kinase myocardial band (CK-MB) fraction excludes myocardial damage in this setting.

Oral nimodipine 60 mg every 4 hours for 21 days is given prophylactically to reduce the risk of delayed vasospasm and ischemic stroke. Prophylactic anticonvulsants (phenytoin or levetiracetam) are started as the occurrence of a seizure increases the risk of a rebleed. They should be given only for a short period and discontinued after the aneurysm is clipped or coiled. Patients in Grades IV and V have a high surgical mortality risk and need to be managed conservatively till their sensorium improves.

Treating the Aneurysm

The definitive treatment of aneurysmal SAH consists of either microsurgical clipping or endovascular coiling of the aneurysm. Surgery is the more definitive treatment. The operating microscope has made surgery safe and effective. It is especially useful when the aneurysm is located at the trifurcation of the MCA, has a size of more than 1 cm or a wide neck. Early surgery within 3 days of the initial bleed and, if possible, within 24 hours is recommended in conscious and hemodynamically stable patients. Early surgery, by removing the clot around the artery, also minimizes the threat of delayed vasospasm. Coiling with platinum (Guglielmi detachable) coils is preferred for posterior circulation aneurysms, small narrow necked anterior circulation aneurysms and those situated in other technically difficult locations. It is particularly useful in elderly patients with significant medical comorbidities where surgery is contraindicated.

COMPLICATIONS OF SAH

Rebleeding

Urgency in the treatment of SAH arises because of the high incidence of potentially fatal rebleeding in the first few days after SAH. About 25% of SAH patients have a rebleed in the first 24 hours. Mortality as high as 80% has been reported with rebleeding.[37] So, it is imperative that SAH patients (Grade III or less) undergo angiography and definitive treatment (surgery or clipping) as early as possible. Delaying treatment also makes them more vulnerable to vasospasm. The use of antifibrinolytics like epsilon aminocaproic acid (EACA) to prevent rebleed has largely been given up because of the lack of efficacy and high incidence of cerebral ischemia. However, in some cases, early treatment with a short course of EACA till surgery or coiling is completed, has been advocated.[38]

Delayed Vasospasm

Delayed ischemic neurologic deficits are caused by the presence of blood in the cisterns with resultant constriction of blood vessels. About 20–40% of patients with SAH develop clinically significant vasospasm. Its incidence peaks between the 7th and 14th day of SAH, but can occur up to 21 days postbleed. The risk of vasospasm is directly proportional to the amount of subarachnoid blood seen on the initial CT scan.[39] A thick layer of blood in the fissures more than 1 mm thick and clots larger than 5 x 3 mm in the basal cisterns significantly increase the risk of subsequent vasospasm. The clinical manifestations depend on the vessels involved and the extent of vasospasm. They range from minor neurological deficits to large, disabling strokes.

Preventing vasospasm is a priority. Early institution of oral nimodipine reduces the risk of vasospasm. Dehydration and volume depletion must be avoided with judicious use of IV fluids. However, prophylactic hypervolemia is not indicated. Hypomagnesemia occurs in more than 50% of SAH patients and increases the risk of delayed cerebral ischemia.[40] Transcranial Doppler is a useful tool to monitor cerebral blood flow velocities in intracranial vessels. Increasing velocities on serial measurements indicate early vasospasm which may precede the onset of neurologic signs by 24–48 hours, thus allowing early therapy.

In an established vasospasm, the Triple-H therapy (hypervolemia, induced hypertension, hemodilution) has shown benefit. However, this treatment can be instituted only after surgery or clipping of the aneurysm. If done before definitive treatment, the risk of rebleeding is increased. After securing the aneurysm, BP can be increased to 160–180 mm Hg with judicious use of vasopressors like dopamine or norepinephrine and volume expanders. Colloids like albumin provide additional benefit by causing hemodilution. The aim of hemodilution is to keep hematocrit at 30–32% to reduce viscosity while maintaining oxygen carrying capacity. In a recent systematic review, hypertension was found more effective in increasing cerebral blood flow than hemodilution and hypervolemia.[41] In refractory cases of vasospasm, interventional therapy with intra-arterial balloon angioplasty and intra-arterial vasodilators is considered.[42] Intra-arterial agents currently used are calcium channel blockers, verapamil and nicardipine and papaverine. Balloon angioplasty of vasospastic vessels is also a viable option, but carries a significant risk of rupture or dissection of the vessel. It is used for spasm of proximal vessels, while super-selective intra-arterial vasodilator injections are used for distal spasms.

Hydrocephalus

The presence of dense blood in the basal cisterns or ventricles obstructs CSF pathways, causing hydrocephalus. It presents with a relatively abrupt onset or persistence of stupor or coma after the initial rupture. It requires ventricular drainage of CSF through an EVD. In most cases, it resolves after the acute phase, but if it persists, a ventriculoperitoneal shunt is placed.

Hyponatremia

Hyponatremia in SAH is caused in most cases by cerebral salt wasting, though SIADH can also occur. Serum and urine osmolality and urine spot sodium help to clarify the cause of hyponatremia. The treatment for SIADH is fluid restriction while cerebral salt wasting is treated by aggressive fluid replacement with normal saline or hypertonic 3% saline. Because SIADH and cerebral salt wasting often coexist, the rational way of treating hyponatremia would be adequate sodium and volume replacement with restriction of free water.

D. Central Nervous System Infections

Jimmy Lalkaka, BS Singhal

INTRODUCTION

The era of antibiotics was ushered in nearly 70 years ago with the discovery of penicillin. Since then, giant strides have been made in the development of effective and relatively safe antimicrobial agents to treat neurological infections, in particular, bacterial meningitis. Yet, they remain an important worldwide cause of morbidity and mortality. Acute fulminant infections like meningitis, encephalitis, brain abscess and subdural empyema continue to claim several lives. The critical care of these infections requires the close collaboration of the intensivist, neurologist, microbiologist, neuroradiologist and a well-trained nursing staff. This section will focus on central nervous system (CNS) infections which present acutely and run a fulminant course.

GENERAL CONSIDERATIONS

Some important factors contributing to the threat posed by CNS infections in recent times are as follows: (1) the burgeoning number of immunocompromised patients worldwide due to the global epidemic of acquired immune deficiency syndrome (AIDS) and the increasing use of aggressive immunosuppressive therapy; (2) increasing numbers of antibiotic-resistant organisms due to widespread and often indiscriminate use of antimicrobials; (3) frequent international travel which has facilitated the global spread of emerging infections. On a positive note, the effective, widespread use of *Haemophilus influenzae* vaccine has resulted in a sharp decline in the worldwide incidence of community-acquired bacterial meningitis in children, limiting it largely to the infant, adult and elderly populations.

Early diagnosis and rational empirical therapy are the cornerstones of management in suspected CNS infection. Keeping the treatable conditions in mind, the physician must address the following issues: (1) appropriate antibiotics to combat the common community acquired pathogens *Streptococcus pneumoniae* and *Neisseria meningitidis;* (2) need to treat Gram-negative bacteria in certain situations; (3) treatment of *Listeria monocytogenes* in elderly and immunocompromised patients and (4) acyclovir for possible viral herpes simplex virus (HSV) encephalitis.

ACUTE MENINGITIS

Etiology and Risk Factors

Bacterial and viral meningitis are the two most frequent causes of acute meningitis. The term aseptic meningitis refers to meningeal involvement due to nonpyogenic bacterial infections and other causes like systemic lupus erythematosus (SLE), sarcoidosis and drugs. Acute bacterial meningitis (ABM) is commonly caused by hematogenous spread of bacteria from a distant site of infection. Other routes of entry include contiguous spread of infection from neighboring sites (sinusitis, otitis media, mastoiditis) and direct CNS inoculation following neurosurgery or a penetrating head injury. Congenital or acquired defects in the skull or spine cause recurrent attacks of meningitis.

In community-acquired ABM in children and adults, *S. pneumoniae* and *N. meningitidis* are the most common organisms, together accounting for 90% of cases. Other less common organisms include *L. monocytogenes,* group B streptococci and *H. influenzae.* Pneumococcal meningitis is responsible for more than half of all cases at all ages except for infants less than 2 months of age.[1] Over half of these patients have sinusitis or pneumonia at presentation. Immunoglobulin deficiency, sickle cell disease, splenectomy, alcoholism, diabetes and CSF leaks increase the risk of acquiring this infection.[2] Meningococcal meningitis caused by *N. meningitidis* is the most frequent cause of meningitis in children and young adults. It is highly contagious and small epidemics have occurred during overcrowding in dormitories, boarding schools and military bases and also among household contacts.[3] *L. monocytogenes* meningitis tends to occur in elderly people over the age of 55 years, third trimester pregnant women, infants less than 3 months of age and people with impaired T cell immunity (chronic corticosteroid therapy, HIV). Outbreaks of this meningitis are often food borne. These bacteria are known to contaminate soft cheese, unpasteurized milk, hot dogs and luncheon meat.

Though Gram-negative bacilli (*E. coli, Pseudomonas*, *Acinetobacter*, *Klebsiella*) cause only 3% of community-acquired meningitis, they are responsible for one-third of all nosocomial infections. *Staphylococcus aureus* is the other common pathogen in the nosocomial group.[4] If ABM is secondary to frontal or maxillary sinusitis and mastoiditis, anaerobic infection must also be kept in mind. Penetrating head injury and neurosurgical procedures like external ventricular drain (EVD) and shunt placement predispose to infection by *S. aureus,* Gram-negative bacilli, skin organisms (*S. epidermidis*) and anaerobes. Neutropenic patients are susceptible to *Pseudomonas* and *E. coli* infection.

Viral meningitis is by far the most common cause of acute meningitis. It occurs with a higher frequency than all other causes of meningitis put together.[5] Enteroviruses (mainly coxsackie and echovirus) account for the majority of cases, mainly during the late summer months. HSV-2 and varicella zoster virus (VZV) meningitis occur sporadically throughout the year, while mumps and lymphocytic choriomeningitis virus infections predominate in winter. HSV-2 causes genital herpes as well as recurrent attacks of meningitis. About 5–10% of patients with acute HIV infection develop aseptic meningitis during the early stage of illness, usually at the time of seroconversion.[6] Tuberculous meningitis (TBM) and fungal

meningitis usually cause a subacute or chronic infection. However, they sometimes present acutely and run a fulminant course. They must be considered in the differential diagnosis of acute meningitis.

Noninfectious causes of acute meningitis include collagen vascular disease (SLE and Sjogren's), sarcoidosis, Wegener's granulomatosis and polyarteritis nodosa. A toxic meningitis follows the use of intrathecal agents, intravenous immunoglobulin (IVIg), measles, mumps and rubella (MMR) vaccine, and muromonab CD3 (OKT3). Carcinomatous and lymphomatous meningitis must also be considered in the differential diagnosis of acute meningitis and cytology for malignant cells in the CSF must be asked for.

Clinical Presentation

Patients typically present with acute headache, fever, photophobia, vomiting and an altered level of consciousness. This is particularly so with ABM. Rapid clinical deterioration often occurs within hours or, at most, in a day or two. Nearly two-thirds of patients with ABM have an altered sensorium, with about 20% in coma. This differentiates ABM from viral meningitis which runs a relatively benign course with preserved consciousness, unless encephalitis coexists. Patients with viral meningitis can, however, present with severe headache and repeated vomiting which require hospitalization and parenteral analgesics. New onset seizures occur in about 20% of patients with bacterial meningitis and carry a worse prognosis. They occur more frequently in children, being the presenting feature in one-third of them.[7] The presence of seizures also raises the possibility of HSV-1 encephalitis and patients must be given the benefit of acyclovir till the definitive diagnosis is made.

Neck stiffness (resistance to passive flexion of the neck), together with Kernig's sign and Brudzinski's sign are the classic tests for meningeal irritation. If present, they strongly suggest meningitis. However, these tests have a low sensitivity. So absence of these signs does not in any way exclude the diagnosis of meningitis.[8] Elderly patients with a degenerative cervical spine also have a stiff neck, but the differentiating point is that, in them, resistance to neck movement occurs in all directions and not only on flexion as seen in meningitis. Focal neurologic deficits generally do not occur in acute meningitis. If they do, other conditions like brain abscess, encephalitis or cerebrovascular complications must be considered. However, *L. monocytogenes* meningitis can be associated with cranial nerve involvement, ataxia, nystagmus and other brainstem signs suggestive of a rhombencephalitis syndrome. A painful, predominantly unilateral ophthalmoplegia with chemosis, proptosis and visual impairment suggests cavernous sinus thrombosis. Infections of the paranasal sinuses, nasopharynx or facial soft tissues around the eye and nose are largely responsible for its occurrence.

Clues from the history and examination of the patient often provide an insight into the etiology of the meningitis. A history of close contact with another person with a similar illness raises the suspicion of meningococcal meningitis. Gastrointestinal disturbance, including diarrhea, often accompanies enteroviral meningitis. A history of CSF rhinorrhea or otorrhea following head injury points to a fracture of the skull base and increases the risk of meningitis. If a careful history is elicited, it is observed that most TBM patients have had a low grade persistent fever with headache for at least 3–4 weeks prior, which has been labeled as "viral" or "typhoid" and treated with a concoction of antibiotics. Precious time is thus lost. The thick fibrous exudates covering the base of the brain result in hydrocephalus and vasculitis, with blood vessel occlusion and stroke. Presence of a skin rash points to the diagnosis of meningococcal meningitis. A diffuse, erythematous, maculopapular eruption at onset evolves to a hemorrhagic purpuric rash over the trunk and lower limbs. Children with recurrent bouts of meningitis must be examined for anatomical defects like a meningocele or spina bifida. Meningitis can be deceptively asymptomatic in the very young, very old and immunocompromised patients in whom headache and fever may be absent. Confusion or altered sensorium may be the only sign of meningitis in these patients. Hence, a high index of suspicion is required and the threshold for lumbar puncture (LP) should be low for these patients.

Laboratory Diagnosis

Serum inflammatory markers like C-reactive protein (CRP) and procalcitonin are significantly elevated in bacterial meningitis compared to viral. Blood cultures must always be ordered prior to initiating empirical antibiotic therapy in suspected bacterial meningitis. They test positive in about 50% of cases caused by the three common bacteria. They reveal the causative organism even when CSF cultures are negative, underscoring their utility and importance in acute meningitis.

The definitive diagnosis of meningitis is made by analysis of CSF. The first CSF examination is invariably the most revealing one and must include opening pressure manometry, a glucose ratio (obtain a concurrent blood glucose sample), cell count, smears for relevant microbiology and immunostaining and appropriate CSF cultures. An LP is safely carried out if the patient is under 60 years of age, immunocompetent, able to correctly follow two consecutive commands and has had no recent seizure.[9] If any of the above criteria are not met, a CT or MRI scan is carried out prior to LP. In the absence of a mass lesion or obstructive hydrocephalus, a guarded LP can be done even with elevated intracranial pressure (ICP). There should be no delay between CSF collection and examination, because cells adhere to the collecting tube over time, causing falsely low cell counts.

Typically, the CSF in ABM is turbid with a raised opening pressure, increased white blood cells (WBC) count in thousands, mainly polymorphonuclear, elevated proteins (100–500 mg%) and a low CSF: blood glucose ratio less than 50%. Independent predictors of bacterial meningitis with more than 99% certainty include CSF: serum glucose ratio less than 0.23, glucose less than 34 mg%, proteins more than 220 mg%, WBC more than 2,000 cells and polymorphs more than

1180 cells.[10] In immunocompromised patients the CSF cell count, glucose and proteins may only be mildly abnormal.

The specific infecting organism can be identified by Gram stain, culture and polymerase chain reaction (PCR). Gram stain enables a rapid, initial detection of the organism, but requires a concentration of about 100,000 organisms/mm^3 to be positive. Bacterial culture identifies the organism in about 70% of cases along with its antibiotic sensitivity. Broad-based, multiprobe PCRs that detect bacterial deoxyribonucleic acid (DNA) within 3 hours for the three common bacterial pathogens and listeria are available. However, unlike cultures, they do not provide data on antibiotic sensitivity. The lab diagnosis of TBM is generally unsatisfactory. AFB is detected in very few CSF samples, PCR has a diagnostic reliability of only 50% and culture requires up to 7 weeks to grow the organism. Hence, therapy for TBM is usually started empirically. A chest X-ray may detect military tubercles or a cavitatory lesion. CT or MRI shows thick, basal exudates with associated tuberculomas and hydrocephalus.

The CSF in viral meningitis reveals normal sugar with mildly elevated proteins and a lymphocytic pleocytosis. Polymorphonuclear predominance may be seen in the first 24–48 hours of the infection. CSF PCR is sensitive and specific for the diagnosis of meningitis due to herpes virus, enterovirus and some arboviruses. Detection of IgM antibodies in CSF helps to identify VZV and West Nile virus (WNV) infections. Serological tests also aid in diagnosis. A positive serum IgM or a fourfold increase in IgG levels in paired serum samples (acute and convalescent sera) collected 4 weeks apart is diagnostic for HSV, VZV, Japanese encephalitis (JE) virus and Epstein-Barr virus (EBV). Although viral meningitis is usually self-limiting, its proper diagnosis is of clinical value as it limits other diagnostic testing.

Management of Acute Meningitis

A patient with suspected acute meningitis must be urgently admitted to the hospital, preferably in the ICU, if seizures, altered mental state or raised ICP are present. Bacterial meningitis has to be considered first, above all other conditions. The institution of antimicrobial therapy must be swift. Lost time can prove extremely costly in terms of neurologic sequelae. A rapid general and neurological examination on admission aims to identify the source of infection, any underlying illness and contraindication to LP. Blood is collected for routine biochemistry including hemogram, smear for malarial parasite (MP), erythrocyte sedimentation rate (ESR), liver and renal functions, coagulation profile, HIV, ANA, venereal disease research laboratory (VDRL), CRP and procalcitonin levels. A blood culture is urgently asked for. This is the only investigation that must precede antibiotic therapy. If there are no contraindications (mentioned earlier), an LP is performed just before commencing the therapy. If a CT or MRI is required prior to LP, empirical antibiotics are started first, followed by neuroimaging and LP.

Table 1: Empirical antibiotic therapy of acute bacterial meningitis

Age and associated conditions	*Likely organisms*	*antibiotics*
Children and adults	*S. pneumoniae* *N. meningitids*	Ceftriaxone or cefotaxime + vancomycin
Adults over 55 years	*S. pneumoniae* *L. monocytogenes* *H. influenzae*	Ceftriaxone or cefotaxime + vancomycin + ampicillin
Meningitis with sinusitis, otitis media or known CSF leak	*S. pneumoniae* Gram-negative bacilli *S. aureus* Anaerobes *H. influenzae*	Ceftazidime + vancomycin + metronidazole
Penetrating head trauma, neurological procedures	*S. aureus* *S. epidermis* Gram-negative bacilli	Vancomycin + ceftazidime or Vancomycin + meropenem
Immunocompromised state	*L. monocytogenes* Gram-negative bacilli *S. pneumoniae*	Ceftazidime + ampicillin + vancomycin
Nosocomial infection	Gram-negative bacilli *S. aureus*	Vancomycin + ceftazidime

Empirical Antibiotic Therapy

Empirical antibiotic therapy is the cornerstone of acute meningitis management. The choice of antimicrobials depends on the likely causative organism, which in turn depends on the age and immune status of the patient and whether the infection is nosocomial or community acquired (Table 1). It is presumed that *S. pneumoniae* is resistant to penicillin and *S. aureus* is methicillin resistant. So, treatment is initiated with vancomycin and a third generation cephalosporin. If sinusitis, otitis media or mastoiditis is the probable cause, adequate coverage of anaerobic organisms is ensured. Ampicillin is added to cover for *L. monocytogenes* in neonates, elderly and immunocompromised patients. If the patient is allergic to penicillin, chloramphenicol is used instead of cephalosporin and trimethoprim–sulfamethoxazole is the alternative to ampicillin. Nosocomial infections are treated with vancomycin and either ceftazidime or meropenem.

Current guidelines support the concurrent use of dexamethasone with antibiotic therapy in ABM. The host inflammatory response to bacterial insult may cause considerable brain injury, with bacterial lysis triggering the release of inflammatory cytokines. Steroids block this inflammatory cascade. Dexamethasone is given intravenously in a dose of 8–10 mg every 6 hours. It is started at the time of or just prior to commencing antibiotic therapy. In a large nationwide study, patients with pneumococcal meningitis, who were concurrently treated with steroids had reduced mortality, deafness and other neurological sequelae.[11] Once the organism is detected, steroids are continued only in those whose cultures have grown pneumococci.

Table 2: Specific antibiotic therapy for acute bacterial meningitis

Organism	*Antibiotics*
S. pneumonia • sensitive to penicillin • relative resistance • resistant to penicillin	 Penicillin G or ampicillin third generation cephalosporin third generation cephalosporin + vancomycin
N. meningitis	Penicillin G or ampicillin or extended spectrum cephalosporin
H. Influenzae • β-lactamase negative • β-lactamase positive	 Ampicillin third generation cephalosporin
L. monocytogenes	Ampicillin or penicillin G (alternative: trimethoprim–sulfamethoxazole)
Gram-negative bacilli	Third generation cephalosporin
Pseudomonas aeruginosa	Meropenem or cefepime
S. aureus	Vancomycin

If treatment is instituted without delay, rapid improvement is expected. Failure to observe this within 48–72 hours should prompt a review of the working diagnosis and a repeat CSF examination. Once the causative organism with its antibiotic sensitivity is identified by blood and CSF cultures, specific antibiotic therapy is initiated (Table 2). Parenteral antibiotics are given for 7 days in meningococcal and *H. influenzae* meningitis, 10–14 days for pneumococcal infection and 3–4 weeks for listerial and Gram-negative bacillary infections. The challenge in treating meningitis lies in not only eradicating the infection from the meninges, but also in locating and removing its source, so that the person is spared the ordeal of recurrent meningitis.

A high index of suspicion is required to diagnose TBM. Patients with fever, headache and stiff neck with a CSF lymphocytic pleocytosis and a mild to moderate decrease of glucose concentration (20–40 mg%) are usually started on anti-tuberculosis (TB) drugs. First line therapy usually consists of isoniazid, rifampicin, pyrazinamide and ethambutol with or without streptomycin injections. Steroids are started concomitantly, especially when CSF proteins are high or when CT or MRI shows thick basal exudates, hydrocephalus or vasculitic infarcts. A discussion on second-line drug therapy in multi-drug-resistant tuberculosis (MDR-TB) is beyond the scope of this chapter.

The treatment of viral meningitis is largely supportive as it is usually a self-limiting illness. There are, however, some exceptions. Enteroviral meningitis occurring in an immunocompromised host can be virulent and life-threatening. Pleconaril, a new antiviral agent effective against enteroviruses, can be given, though it is not freely available.[12] Sexually transmitted HSV-2 infection is treated with oral acyclovir (800 mg 5 times a day) or famciclovir (500 mg 3 times a day) or valacyclovir (1 g 3 times a week) for 2 weeks to prevent a recurrence of meningitis.

Complications and Prognosis

Cerebral edema with raised ICP commonly occurs in stuporous or comatose patients with acute meningitis. Along with the definitive treatment for meningitis outlined above, urgent measures to lower ICP must be instituted. They include hyperventilation, hyperosmolar therapy and, in refractory cases, barbiturate coma (for a more detailed account, please refer to the subchapter Raised Intracranial Pressure of chapter Neurological Problems. Hydrocephalus develops in about 8% of patients, especially those with tuberculous, fungal and listerial meningitis. It is managed with repeated LPs or by employing an external ventricular device. TBM also causes vasculitic strokes. Subdural empyema, brain abscess or venous sinus thrombosis may complicate meningitis associated with sinusitis or otitis media. Hyponatremia occurs either due to the syndrome of inadequate ADH secretion or salt wasting. Sensorineural hearing loss is a frequent and early complication of ABM. Seizures occur in 5–15% of patients with bacterial meningitis and should be treated with appropriate antiepileptic drugs. A continuous electroencephalography (EEG) monitoring helps to detect the occasional patient with nonconvulsive status epilepticus (SE). Septic shock and disseminated intravascular coagulation (DIC) are dreaded complications, more likely to occur with delayed diagnosis and treatment. Meningococcal meningitis rarely causes the Waterhouse-Friderichsen syndrome with adrenal failure and DIC.

Poor prognostic factors in ABM include age over 60 years, concomitant debilitating disease, low Glasgow coma scale (GCS) score on admission, presence of a focal neurological deficit and a low CSF cell count less than 1,000/mL.[2] Pneumococcal meningitis carries the highest mortality. Nearly 50% of survivors are left with significant disability such as developmental delay, cognitive impairment and epilepsy.[13]

ACUTE ENCEPHALITIS

Viral encephalitis is the most common cause of infective encephalitis. Several families of viruses are known to cause focal or diffuse inflammation of brain parenchyma. HSV-1 and VZV belonging to the herpes virus family are frequent causes of viral encephalitis worldwide, occurring throughout the year with no seasonal incidence. The JE virus and WNV belong to the flavivirus family, cause arthropod (mosquito)-borne disease and have a seasonal distribution. Cytomegalovirus (CMV), human herpes virus 6, EBV and enteroviruses cause encephalitis mainly in immunocompromised individuals. Rickettsial infections are caused by bacteria and transmitted by tick bite (Rocky Mountain Spotted Fever). Rabies is endemic in India due to the large number of stray, unvaccinated dogs. The causative organism remains unidentified in 40–50% of cases.

Clinical Considerations

Patients with acute encephalitis typically present with fever, headache and one or more of the following: confusion, behavioral change, decreased level of consciousness, new

onset seizures and focal neurologic deficits. The etiological organism can often be predicted on the basis of the season, area of residence, travel and contact with animals and immune status of the individual. Enteroviral (coxsackie and echovirus) and arboviral infections tend to peak during summer, while HSV and VZV occur throughout the year. A trip to India and Nepal increases the likelihood of JE, rabies and falciparum malaria. Travel to South America increases the risk of rabies, Eastern equine and Western equine encephalitis. Cases of JE tend to cluster in areas of close contact between humans and pigs. In areas of geographic prevalence, a history of tick bite may suggest kyasanur forest disease or Rocky Mountain Spotted Fever.

Some viruses cause well-defined clinical syndromes due to their predilection for specific brain regions. The flaviviruses (JE virus and WNV) predominantly affect the *basal ganglia,* producing parkinsonian features and dystonia. They also have an affinity for the anterior horn cells of spinal cord which causes an acute flaccid limb paralysis resembling poliomyelitis. Patients with HSV-1 encephalitis present with a *limbic encephalitis* with significant memory impairment, behavioral changes, confusion, word finding difficulty and seizures. A similar syndrome occurs in autoimmune encephalitis, mainly anti-NMDA (N-methyl D-aspartate) receptor encephalitis. As many as one-third of acute encephalitis cases in children are likely to be immune-mediated.[14] VZV produces a *vasculopathy* involving large and small vessels resulting in ischemic and hemorrhagic infarcts. VZV encephalitis often follows shingles, the classic dermatomal skin rash, but occurs in its absence as well. Cerebellar ataxia and myelopathy are its other neurological manifestations.[15]

Diagnostic Approach

A brain MRI is more sensitive than CT scan in visualizing the abnormalities of encephalitis. Basal ganglia, thalamic and brainstem lesions caused by JE virus and WNV are clearly demonstrated on MRI. T2-weighted and flair hyperintensities in the temporal lobes are a feature of HSV-1 encephalitis. In measles encephalitis, lesions are seen in the temporal and frontal cortical gyri. MRI can be normal in some patients. The CSF reveals a lymphocytic pleocytosis with mildly raised proteins and normal sugar. Identification of the causative agent is facilitated by CSF PCR techniques, CSF IgM antibody estimation and a fourfold increase in serum IgG titers of paired acute and convalescent serum samples.

Differential Diagnosis

Acute bacterial meningitis must always be considered in the differential diagnosis of acute encephalitis and, if doubt exists in the initial stages, empirical antibiotic therapy should be instituted. Patients with metabolic encephalopathy may also present with a similar clinical picture. Urgent blood levels of glucose, creatinine, ammonia, liver functions, calcium and thyroid along with serum and urine toxicology screen are ordered. In India, cerebral malaria and dengue must also be considered in a suspected case of encephalitis.

Autoimmune (AI) encephalitis and acute disseminated encephalomyelitis (ADEM) are close mimics of acute viral encephalitis. AI encephalitis presents as a limbic encephalitis and is often associated with paraneoplastic and other autoimmune disorders. Its onset is more gradual than its viral counterpart and it tends to progress over time. Anti-NMDA receptor encephalitis is the most common form of AI encephalitis and is usually associated with ovarian teratoma. In the California encephalitis project study, it was the most frequent cause of identified encephalitis, occurring mainly in young female patients, most of whom had no teratomas or other neoplasms.[16] These patients are treated with corticosteroids, plasma exchange, IVIg and, in some refractory cases, cyclophosphamide and rituximab. ADEM is an acute, immune-mediated demyelinating illness which usually follows a viral infection or immunization. The clinical picture resembles acute encephalitis. The presence of multifocal neurologic signs should make the physician suspect ADEM. MRI of brain shows large, asymmetric enhancing lesions involving the subcortical white matter and the gray-white junction of both cerebral hemispheres. Treatment consists of IV methylprednisolone. Plasma exchange and IVIg are alternative treatment options.

Management of Acute Encephalitis

Patients with acute encephalitis are often very ill with altered sensorium ranging from somnolence to deep coma. They require optimal critical care in the ICU. After IV access is secured, blood is drawn and sent for all investigations as discussed earlier. Empirical antibiotic therapy along with acyclovir is started without any delay. Seizures, if present, are treated with IV lorazepam followed by IV phenytoin or fosphenytoin. Many patients present with difficult to control SE. Continuous EEG monitoring ensures that nonconvulsive SE is not overlooked. Severe behavioral disturbance with psychosis and aggression require major tranquillizers like parenteral haloperidol. Raised ICP is often present and its management is described in the subchapter Raised Intracranial Pressure of Chapter Neurological Problems. Hyponatremia due to SIADH requires careful attention to fluid and electrolyte balance.

In contrast to bacterial meningitis, few antiviral drugs are available for use. Acyclovir is the drug of choice for HSV-1 encephalitis. The high suspicion of HSV encephalitis in all sporadic cases has led to its inevitable overuse. It is given in a dose of 10 mg/kg 8 hourly daily for 21 days. Nephrotoxicity due to deposition of drug crystals is avoided by controlling the rate of infusion and keeping the patient well hydrated. Acyclovir is also given in the same dose to patients with VZV encephalitis for a period of 14 days. Oral prednisolone (1 mg/kg daily for 5 days) is given to treat the inflammatory component of vasculitis in VZV infection. Alternatives to acyclovir in VZV encephalitis include ganciclovir, famciclovir

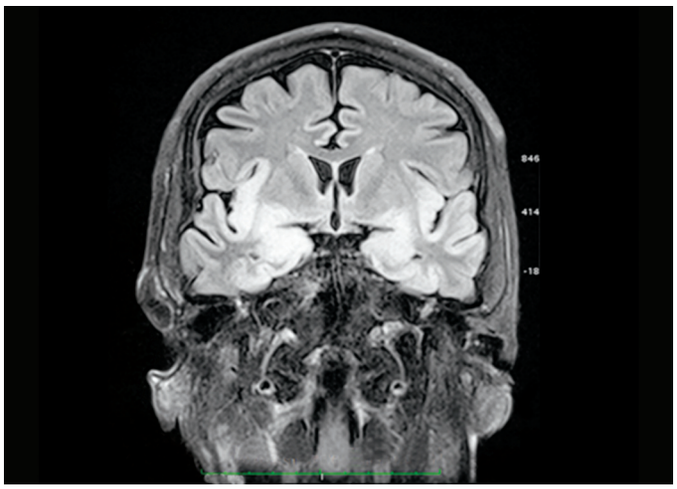

Fig. 9: Herpes simplex encephalitis: FLAIR coronal MR image I reveals symmetric restricted diffusion in insular cortex and frontal gyri due to herpes simplex encephalitis

and valacyclovir. Acyclovir has not shown any benefit in EBV encephalitis. Ganciclovir (5 mg/kg 12 hourly for 2–3 weeks) is used to treat CMV encephalitis. Foscarnet is used as an alternative agent in a dose of 60 mg/kg every 8 hours for 2–3 weeks.[17] The antiviral drug pleconaril has shown modest benefit in enteroviral infections.

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex virus 1 accounts for 90% of cases in adults. It occurs at any age and affects men and women equally. It is a focal necrotizing, hemorrhagic encephalitis with a predilection for the temporal lobes, orbitofrontal cortex and cingulate gyrus. Besides the usual symptoms of headache, fever and altered mental state, patients frequently experience seizures with olfactory or gustatory hallucinations or déjà vu phenomena. Other features of temporal lobe dysfunction include aphasia, inability to store and recall new information and upper quadrant visual field defects.[18] Occipital lobe or brainstem affection without temporal lobe involvement uncommonly occurs.

The CSF shows a lymphocytic pleocytosis of 50 or more cells per mL, mildly elevated proteins and normal sugar. Presence of RBCs or xanthochromia is due to the hemorrhagic nature of this encephalitis. MRI of brain shows T2-weighted, flair and diffusion-weighted hyperintensities over the medial temporal lobes in 90% of patients within 48 hours of onset. The insula, orbitofrontal cortex and cingulate gyrus are also affected. The EEG often shows periodic lateralized epileptic discharges. The diagnosis is established by the detection of HSV DNA by PCR technique in CSF. Its diagnostic accuracy is 98%. It tests positive within 72 hours of symptom onset. A serum to CSF HSV IgG ratio of less than 20:1 indicates intrathecal antibody synthesis and is also diagnostic. However, it takes 8 days for antibodies to be detected in CSF. The prompt administration of acyclovir has reduced the mortality from more than 70% to 14%.[19] About 30% of patients are left with permanent sequelae like seizures, aphasia and cognitive impairment (Fig. 9).

JAPANESE ENCEPHALITIS

Japanese encephalitis is the most common cause of arboviral encephalitis worldwide. It is caused by a *Flavivirus* which is transmitted by the bite of the *Culex* mosquito. Although JE virus transmission continues throughout the year in the tropics, seasonal epidemics occur during the rainy season when the mosquito density is maximum. JE must be suspected in any patient with recent travel to Asia and presenting with meningitis, encephalitis or acute flaccid paralysis. JE patients commonly have parkinsonian features with masked facies, tremors, akinesia and rigidity. A fixed limb and axial dystonia along with chorea and myoclonus may also be seen. Affection of the anterior horn cells causes flaccid limb paralysis resembling poliomyelitis. MRI scans confirm the predominant involvement of the basal ganglia, thalami and brainstem. Bilateral thalamic involvement in a patient with encephalitis residing in an endemic area strongly suggests JE. The detection of JE IgM antibodies by ELISA in CSF is diagnostic of JE. Treatment is by supportive measures only. JE carries a 25% mortality risk. About 50% of survivors have severe cognitive impairment, focal weakness, seizures and movement disorders.

RABIES

Rabies encephalitis remains a significant health problem in developing countries where dogs are not routinely vaccinated. In the West, rabies is associated with bites from bats, raccoons and foxes. It is caused by the *Lyssavirus* and its incubation period is usually a few months. It presents in two ways: (1) *Encephalitic form*—patients present with pharyngeal spasms, hydrophobia, hyperactivity and hallucinations which rapidly progress to worsening encephalopathy, limb paralysis, coma and death. (2) *Paralytic form*—initial presentation is with rapidly progressive quadriparesis which then leads to encephalopathy, coma and death. Rabies carries a nearly 100% mortality. Only a handful of surviving cases have been reported in world literature.[20] Postexposure rabies prophylaxis for nonimmunized individuals consists of five doses of human diploid cell vaccine along with rabies immunoglobulin (20 IU/kg).

CEREBRAL MALARIA

A mosquito-borne illness caused by a protozoan parasite *Plasmodium falciparum*, malaria is endemic in Africa, South America and Asia. Patients with cerebral malaria present with fever with chills and rigors, headache, malaise, vomiting, diarrhea, myalgia and a decreased level of arousal. Seizures are more frequent in children (80% vs 15–20% of adults). A sixth nerve palsy, ocular bobbing, bruxism, ataxia, tremors, cortical blindness and deceorticate/decerebrate rigidity also occur, though less commonly. The disease

tends to be more severe in children and pregnant women. Cerebral malaria must be considered in any patient with a febrile illness and encephalopathy residing in or returning from an endemic area for malaria. Diagnosis is based on an impaired level of consciousness, presence of parasitemia on a peripheral blood film and exclusion of other causes of encephalopathy. A positive falciparum antigen and elevated lactate dehydrogenase (LDH) also help to diagnose malaria.[21] The CSF may be normal or show mildly elevated proteins and cells. MRI scan of brain shows white matter hyperintensities, cortical infarcts or cerebral edema. Hypoglycemia, severe anemia, acidosis and thrombocytopenia are common complications of cerebral malaria. Multiorgan dysfunction in the form of renal failure, jaundice and acute respiratory distress syndrome carries a poor prognosis. Cerebral malaria is a medical emergency. The aim is to rapidly reduce parasitemia with effective drug therapy and carefully manage the various complications that arise. Due to widespread resistance to chloroquine, the drugs of choice are intravenous quinine or parenteral artemether compounds. Quinine can cause hypoglycemia which may go undetected in an unconscious patient unless suspected.

DENGUE FEVER

Dengue is caused by a *Flavivirus* which is transmitted by the *Aedes aegypti* mosquito. Patients present with high fever, severe myalgia and arthralgia (breakbone fever) and a petechial or macular rash. Thrombocytopenia commonly occurs. Neurological manifestations are uncommon, but when they occur, they indicate a poor prognosis. They include meningoencephalitis, coma, intracerebral hemorrhage, transverse myelitis and a Guillain-Barré-like syndrome.[22] Laboratory diagnosis of dengue infection is made by IgM ELISA in blood or CSF. The NS1 monoclonal antibody is an ELISA-based test that enables early diagnosis to be made. There is no specific antiviral therapy for dengue.

NEUROLOGICAL INFECTIONS IN HIV

Neurosyphillis occurs in HIV patients, especially in those with a low CD4 count and high viral load. The primary infection is caused by the spirochete *Treponema pallidum.* Meningovascular syphilis is the common form of neurosyphilis. Patients develop aseptic meningitis with cranial nerve involvement, in particular, optic neuritis. A CSF pleocytosis with normal sugar and mildly elevated proteins is seen. There is also a frequent occurrence of brainstem and cerebral lacunar infarcts due to the propensity of the organism to affect small arterioles. Brain parenchymal changes similar to HSV encephalitis may be seen on MRI in these patients. The diagnosis requires a positive CSF VDRL and fluorescent treponemal antibody (FTA) absorption test. Aqueous crystalline penicillin (3 million units IV every 4 hours for 14 days) is the mainstay of treatment.

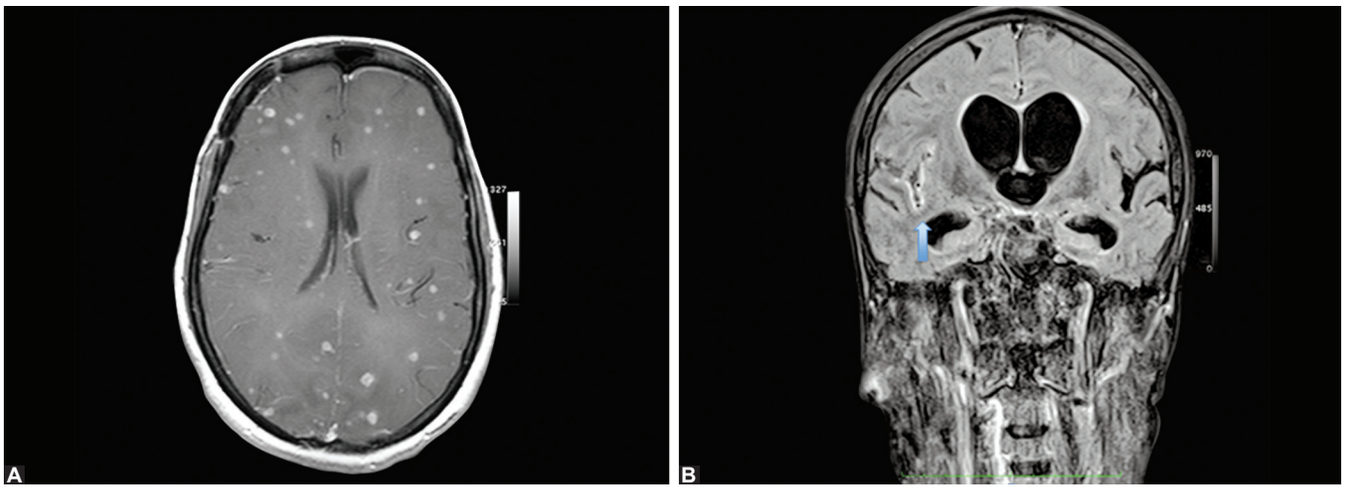
Cryptococcal meningitis is the most common CNS fungal infection in HIV, typically occurring when the CD4 count falls to less than 100 cells/mm^3. It occurs in immunocompetent people as well. The causative organism is *Cryptococcus neoformans*, an encapsulated yeast. It usually causes a subacute to chronic meningitis, but sometimes it can present fulminantly. Patients develop hydrocephalus, vasculitic strokes and cranial nerve palsies (usually II and VIII nerves). A striking feature of cryptococcal meningitis is the significantly raised ICP it causes with papilledema and markedly elevated CSF pressure in excess of 40 cm of water. In such patients, repeated (sometimes daily) LPs with CSF drainage help. A positive CSF culture with cryptococcal antigen or India ink stain clinches the diagnosis.

Treatment of cryptococcal meningitis is initiated with amphotericin (0.7–1 mg/kg per day) or its lipophilic analogue, ambisome (5 mg/kg per day) along with flucytosine (100 mg/kg per day) for a minimum of 15 days. Amphotericin can cause nephroxicity, hepatitis and bone marrow suppression. Fluconazole in a high dose of 800 mg/day can be used instead of flucytosine, given the latter's toxicity and its unavailability in developing countries. There is no role for steroids or acetazolamide in the treatment of raised ICP.[23] This induction phase is followed by a consolidation phase with oral fluconazole 400 mg/day for 10 weeks and a maintenance phase with oral fluconazole at 200 mg/day. Immunocompromised patients may require 6–12 months of treatment till CSF becomes sterile.

Tuberculous meningitis is the most common cause of death worldwide in HIV patients. A sharp increase in incidence of TBM has occurred in the wake of the global AIDS epidemic. The clinical presentation is that of subacute basal meningitis with the frequent occurrence of cranial nerve palsies, stroke and hydrocephalus. CSF in HIV patients is similar to non-HIV patients except that pleocytosis is less and proteins are not as markedly elevated. Neuropathological examination of the TBM brain in seropositive cases reveals scanty basal exudates compared to seronegative patients. The brain parenchyma is found teeming with acid-fast bacilli in them. These findings reflect the severely impaired cell-mediated immunity in seropositive cases with resultant unlimited spread of the tubercle bacilli.[24] MDR-TB must be suspected in an HIV-infected TBM patient and treated accordingly (Figs 10A and B).

Cytomegalovirus encephalitis is an opportunistic viral infection which usually occurs when CD4 counts fall to less than 50 cells/mm^3. Patients present with a subacute progressive encephalopathy with impaired memory, behavioral disorder, gait disturbance and headache. The CSF may be normal or show mild lymphocytic pleocytosis with elevated proteins. A positive CSF CMV PCR with HIV is diagnostic. CMV also frequently affects the retina, GI tract, lungs and liver. Patients are treated with IV ganciclovir or foscarnet or once-weekly cidofovir.

Toxoplasmosis is the most common cause of focal cerebral mass lesion in HIV. It is caused by *Toxoplasma gondi,* an obligate intracellular protozoan parasite. This organism mainly produces intraparenchymal abscesses. The clinical



Figs 10A and B: (A) Tuberculomas: Postcontrast MRI of brain reveals multiple ring and nodular enhancing lesions representing tuberculomas; (B) TBM with hydrocephalous: Postcontrast MRI of brain reveals dilated ventricles with periventricular lucencies due to transependymal seepage of CSF. Note basal exudates enhancing in right sylvian fissure

picture usually evolves over days to weeks with about half the patients complaining of headache, fever and lethargy.[25] Focal deficits like hemiparesis and ataxia reflect the location of the toxoplasma abscesses. CT or MRI scan shows single or multiple round, ring or nodular enhancing lesions mainly in the basal ganglia or deep white matter. The CSF ELISA test for toxoplasmosis is both specific and sensitive. However, a CSF sample is not always possible to obtain as the large mass lesion makes LP a risky procedure. A presumptive diagnosis is then made by response to a therapeutic trial. Treatment consists of a combination of pyrimethamine 75–100 mg/day and sulfadiazine 1.5 g four times a day for 3–4 weeks. Clinical benefit usually occurs in 1–2 weeks, with radiographic improvement taking 2–3 weeks. A stereotactic aspiration/biopsy is considered if there is no response to treatment or if the patient has a low risk for toxoplasmosis.

Progressive multifocal leukoencephalopthy (PML) is a subacute demyelinating CNS disease caused by the John Cunningham (JC) virus, occurring in about 5% of patients with AIDS. Progressive focal neurologic deficits like hemiparesis, ataxia and visual disturbance are accompanied by cognitive impairment and altered sensorium. The MRI shows asymmetric, multifocal, subcortical nonenhancing white matter lesions predominantly in the parieto-occipital and frontal regions. There is no effective therapy for PML. Initiation of ART improves some patients.

BRAIN ABSCESS

It is a localized collection of pus in the brain parenchyma. It commonly occurs due to contiguous spread of infection from neighboring structures like paranasal sinus, middle ear or mastoid. A disruption of the dura, as occurs in penetrating head injury and postneurosurgical procedures, also predisposes to brain abscess. Multiple abscesses also develop due to hematogenous spread of infection from a distant source as in infective endocarditis, congenital cyanotic heart disease and pulmonary diseases. The cause is not identified in 30% of cases. Brain abscess is usually polymicrobial in nature. *S. aureus* and Gram-negative bacilli are the most common pathogens following penetrating head injury or neurosurgery. Similar bacteria along with anaerobes are linked to paranasal sinusitis, otitis media and mastoiditis. *Toxoplasma*, *Nocardia*, *Listeria* and *Aspergillus* are implicated in immunocompromised patients.

An abscess usually begins as a localized area of cerebritis which later evolves into an encapsulated focus of infection. Clinical features of headache and fever are followed by focal neurological deficits like hemiparesis or ataxia depending on the location of the abscess. Features of raised ICP occur if the abscess is large. An LP is usually contraindicated due to the spaceoccupying effect of the lesion. Blood cultures are ordered as soon as possible prior to starting antibiotic therapy. A CT or MRI scan shows a single or multiple ring-enhancing lesion/s with central low density and surrounding edema.

Empirical antibiotic therapy is instituted as soon as possible. Vancomycin, ceftriaxone (or ceftazidime) and metronidazole are given. If pseudomonas is suspected, vancomycin and meropenem are used. Aminoglycosides, erythromycin and tetracyclines are avoided as they penetrate the blood-brain barrier poorly. Parenteral antibiotics are continued for 6–8 weeks depending on the clinical and radiographic response. Stereotactic CT-guided aspiration or surgical excision of the abscess is recommended if it is more than 2.5 cm in size.[26] This also enables a definitive microbiologic diagnosis to be made. Medical treatment alone is indicated when the abscess is less than 2 cm in diameter, if cerebritis is present or if the abscesses are multiple and surgically inaccessible. An initial short course of steroids is considered only if significant cerebral edema exists.

SUBDURAL EMPYEMA AND CRANIAL EPIDURAL ABSCESS

Subdural empyema refers to the presence of purulent infection over the cerebral convexity between the dura mater and arachnoid membranes. A cranial epidural abscess occupies the space between the dura mater and the inner skull table. The sources of infection, incriminating organisms and empirical therapy for both these conditions are nearly the same as for brain abscess discussed above. Subdural empyema is most likely to occur as a consequence of frontal sinus infection, while a cranial epidural abscess is often associated with osteomyelitis of the skull. Clinical features are similar to those of ABM with acute onset of fever, headache and rapid deterioration of sensorium. MRI of the brain is the imaging modality of choice for both these conditions. Urgent surgical drainage of empyema and evacuation of abscess is indicated. Simultaneously, empirical antibiotic therapy is instituted as mentioned in brain abscess. Parenteral antibiotics are usually given for 3–6 weeks, and followed by 3 weeks of oral therapy. Life-threatening complications include cortical vein or dural sinus thrombosis with hemorrhagic infarction, brain abscess and cranial osteomyelitis. Prognosis is better for cranial epidural abscess than for subdural empyema as the infection tends to be more localized.

E. STATUS EPILEPTICUS

Jimmy Lalkaka, BS Singhal

INTRODUCTION

Status epilepticus (SE) is a common neurological emergency encountered in hospital practice. It can be broadly classified into two groups, convulsive status epilepticus (CSE) with persistent motor activity and nonconvulsive status epilepticus (NCSE) with a lack of involuntary motor phenomena. Generalized convulsive status epilepticus is the commonest form of CSE. Unless specified otherwise, SE will imply generalized convulsive SE for the purpose of this chapter.

DEFINITIONS

Traditionally, SE has been defined as either a continuous motor seizure lasting 30 minutes or more or two or more seizures without regaining full consciousness between them. The newer operational definition of SE which is favored by most neurologists is that it denotes any seizure lasting more than 5 minutes, or two or more seizures with incomplete recovery of consciousness between them.[1] This definition captures the essence of SE which is that seizures become prolonged or repetitive because of a failure of normal seizure terminating mechanisms. Most seizures terminate spontaneously within 3 minutes of onset.[2] If they persist for more than 5 minutes, they are unlikely to self-terminate and, hence, the need for urgent intervention. Refractory status epilepticus (RSE) refers to SE in which seizures persist despite adequate first and second line antiepileptic drug (AED) therapy. Of those who develop SE, about a quarter progress to RSE.[3] NCSE is characterized by altered sensorium for 30 minutes or more with no convulsive body movements and EEG evidence of ongoing epileptic activity.[4] This condition is underrecognized and often misdiagnosed. It accounts for about 25% of SE cases. About 8% of patients with unexplained coma have NCSE.[5] So, it must be considered in any patient with an unclear cause of acute coma or altered sensorium.

ETIOLOGY OF STATUS EPILEPTICUS

Status epilepticus often occurs in the setting of acute and remote symptomatic seizures. Common causes include strokes (acute and chronic), CNS infections (meningoencephalitis, cerebral malaria), head injury, hypoxic encephalopathy, brain tumor, metabolic derangements (hyponatremia, hypoglycemia, hypocalcemia, hepatic and renal disturbances) and alcohol and drug intoxication.

Status epilepticus also commonly occurs in patients with prior epilepsy. In them, SE is often precipitated by AED withdrawal or poor drug compliance resulting in low AED levels. Many Indian patients who undertake fasts for religious purposes also unfortunately stop their AEDs during this period. Keeping awake for most of the night causes sleep deprivation which can trigger SE in susceptible individuals. Fever and use of drugs like penicillin, quinolones and chloroquine can also aggravate seizures. SE can occur as the initial manifestation of epilepsy about 12% of the time, especially in children.[6] No clear etiology can be identified in about 20% of cases.[7]

Some conditions are more likely to cause RSE than others. Encephalitis (herpes simplex virus, Japanese B and paraneoplastic autoimmune encephalitis) and hypoxic encephalopathy are more likely to cause RSE than AED withdrawal or alcohol-related SE. Autoimmune encephalitis is being increasingly recognized as an important cause of RSE.[8] Of the several antibodies linked to RSE, antibodies to N-Methyl D-Aspartate (NMDA) receptors have a particularly close association with RSE of unknown etiology.[9] NMDA receptor encephalitis often presents with acute psychiatric and cognitive symptoms before seizures occur. Movement disorders, especially choreoathetosis, and autonomic disturbances usually occur at a later stage. NMDA antibodies are commonly associated with neoplasms, mainly ovarian carcinoma. If detected, removal of the neoplasm could result in resolution of SE.

NEUROLOGICAL COMPLICATIONS OF STATUS EPILEPTICUS

Direct neuronal injury occurs as a result of continuous seizure activity. The severity of damage depends on the duration of seizure activity and the etiology of SE (encephalitis and cerebral hypoxia cause more neuronal damage than AED withdrawal seizures). Certain regions of the brain are particularly vulnerable to the effects of SE. They are the hippocampus, amygdala, pyramidal cells of cerebellum and thalamus. These regions have high excitatory amino acid receptor activity. Injury to these areas causes memory and cognitive impairment, gait imbalance and disturbance of affect. Besides excitotoxic injury, hypoxia, ischemia and metabolic disturbances cause diffuse cerebral edema and elevated intracranial pressure. Development of epileptogenic foci during SE increases the risk of subsequent epilepsy.

SYSTEMIC COMPLICATIONS OF STATUS EPILEPTICUS

The early stage of SE is called the compensated stage. It is marked by a spurt in the level of circulating catecholamines with sympathetic overdrive. This causes hypertension, tachycardia and hyperglycemia. Cerebral blood flow is markedly increased to compensate for the phenomenally raised cerebral metabolic rate in SE. Cardiac arrhythmias also occur at this stage. Due to continuous muscle activity, the core

body temperature steadily rises, resulting in hyperthermia and neuronal damage, particularly to the cerebellum. Prolonged SE also causes muscle breakdown and rhabdomyolysis, which lead to acute renal failure. Acidosis due to lactic acid production also occurs.

If SE continues, a late phase of decompensation is reached, in which hypotension and hypoxia occur. AEDs aggravate hypotension, particularly if general anesthetics are used. Cerebral perfusion and blood flow decrease alarmingly due to failure of cerebral autoregulation. Hypoglycemia ensues because of depletion of glycogen stores. Pulmonary edema, if present during this stage, worsens the outcome of SE.

MEDICAL MANAGEMENT OF STATUS EPILEPTICUS

Successful management of SE requires adequate and effective treatment in the appropriate window period. So a pre-established time-based plan of action must be in place in order to terminate the seizure and ensure a satisfactory outcome with minimal complications.

Initial Stage of Status Epilepticus (0–10 Minutes)

Benzodiazepines (BDZ) are universally accepted as the first line AED in SE. Intravenous (IV) lorazepam 0.1 mg/kg is given as a bolus over 1–2 minutes (maximum 4 mg). If seizures continue after 5 minutes, the above dose can be repeated. Alternative drugs are intravenous (IV) diazepam 0.2 mg/kg over 1 minute (maximum 10 mg) and IV midazolam 0.1–0.2 mg/kg. All three drugs have proven efficacy in terminating seizures. They are effective about 65% of the time in terminating SE, provided they are given early. Lorazepam is the preferred drug. It has less risk of seizure recurrence because of its prolonged drug action up to 12 hours and a decreased volume of distribution. Diazepam and midazolam have a very rapid onset of action, but they tend to redistribute from cerebral tissue to larger peripheral lipid tissue. Hence, their action is relatively short lived.

If seizures occur at home and IV access is not available, midazolam can be given by the intranasal, buccal or intramuscular route. Rectal diazepam (0.5 mg/kg in children and 20 mg in adults) can also be administered at home. Buccal midazolam was found to be superior to rectal diazepam in stopping seizures in children and was easier to administer.[10] Interestingly, a recent study of drug administration by paramedics in the early stage of SE showed that intramuscular midozolam was more beneficial than IV lorazepam because of the speed with which it could be administered.[11] Bioavailability after an intramuscular injection is 80–100% and peak levels are attained in 25 minutes. Prompt pre-hospital administration of BDZ is clearly beneficial in terminating SE early and ensuring a better outcome.

All patients with SE should be treated in the intensive care unit (ICU) of a well-equipped hospital. The first step is to ensure adequate airway, breathing and circulation status. Nasal oxygen is started. Intravenous access is ensured. Finger prick blood sugar estimation is done. Blood is collected for urgent hematocrit, electrolytes, liver and renal functions, calcium, magnesium, AED levels, arterial blood gases (ABGs) and toxicology screen. About 50 cc of 50% glucose along with 100 mg of thiamine IV are given to take care of any hypoglycemic or alcohol related disturbance. IV lorazepam or diazepam is given as mentioned earlier.

Established Status (10–30 Minutes)

In most cases, a second line, longer acting AED is used concurrently with BDZ. The second line AED is usually phenytoin or fosphenytoin. Phenytoin is given as a bolus of 15–20 mg/kg in about 50–100 cc of normal saline at a rate not more than 50 mg/minute. Regrettably, lower doses are often given and this is one of the common reasons for uncontrolled SE. Phenytoin can sometimes cause hypotension and cardiac arrhythmias. So constant monitoring of BP and ECG is essential during an infusion. The toxicity of phenytoin is more dependent on the rate of infusion than on the total dose. Hence, it is advisable to infuse it at a slower rate (20–30 mg/minute) in the elderly and those with conduction defects. Being highly alkaline, phenytoin can produce chemical phlebitis. Extravasation of phenytoin into subcutaneous tissue may cause soft tissue necrosis, thrombosis and distal limb ischemia, the so-called "purple glove syndrome". So after an infusion, the vein should be flushed with normal saline.

Fosphenytoin is a prodrug of phenytoin. As it is water-soluble with a significantly lower pH than phenytoin, tissue necrosis does not occur if it extravagates into subcutaneous spaces. It is infused using standard IV solutions, whereas phenytoin cannot be given in dextrose-containing fluids as it precipitates out. It also produces significantly less hypotension and so can be infused more rapidly at a rate of 150 mg/minute. The dose is 18–20 mg/kg phenytoin equivalents.

Sodium valproate can be used as an alternative to phenytoin or fosphenytoin. It is as effective as phenytoin in controlling SE. The advantage of valproate is that it has no cardiovascular effects, but it can rarely cause hyperammonemia, hepatic disturbance and pancreatitis. Usually, an IV bolus of 1 g (20–40 mg/kg) over 15–20 minutes is given. If seizures continue, additional doses of 500 mg of valproate or 5 mg/kg of phenytoin or fosphenytoin can be given.

Intravenous phenobarbitone is another alternative drug that can be used at this stage in patients who are allergic to phenytoin or in whom phenytoin has failed to control SE. It has a rapid onset of action and a prolonged anticonvulsant effect. However, its main disadvantages are that it causes sedation, hypotension and respiratory depression, which require prior intubation and ventilation. The recommended loading dose is 10–20 mg/kg given at a rate of 60 mg/minute.

Levetiracetam, one of the newer AEDs, is increasingly being used as an alternative to valproate or phenytoin. Its advantages are that it is water soluble, easy to administer and has very few side effects. It is given in a loading dose of 50 mg/kg over 15 minutes at a rate of 100 mg/minute (maximum 4 g). It can be given to elderly patients with medical comorbidities

and also when phenytoin is contraindicated.[12] Large randomized trials for establishing the efficacy of levetiracetam in SE are lacking. An observational study found levetiracetam to be inferior to valproate as a second line drug for SE.[13] Lacosamide is another new AED reported to have efficacy in nonrefractory SE. It is given in a dose of 300 mg IV over 30 minutes. It does not cause respiratory depression or cardiovascular disturbance. However, more data is needed before it can be routinely prescribed in SE. Given the present state of knowledge, phenytoin, fosphenytoin or valproate would still be the preferred second line AEDs in SE.

Along with drug therapy, patients with established SE must be carefully monitored for any systemic complications. Acidosis must be appropriately treated, blood oxygen levels maintained and electrolyte and renal parameters closely monitored. Hyponatremia may precipitate or aggravate SE. Hyperthermia must be reversed with appropriate cooling methods and antipyretics and a very high BP must be reduced with appropriate antihypertensives. Hypotension, if present, is treated with IV fluids and pressor agents, if required.

A CT or MRI scan of the brain should be done, especially in non-epileptic patients. However, neuroimaging must not delay AED treatment. Also, patients must be hemodynamically stable and not get a seizure during the CT or MRI scan. SE can cause hippocampal edema and posterior reversible leukoencephalopathy which are detected on MRI scan.[14] An urgent lumbar puncture (LP) must be performed in febrile patients with SE who have no prior history of epilepsy to rule out meningeoencephalitis. If LP is not safe because of ongoing SE, empirical antibiotics with or without acyclovir and antimalarials must be started immediately. CSF pleocytosis has been described within 24 hours of SE onset without any evidence of acute infection.[15]

Refractory Status Epilepticus (>30–60 Minutes)

As mentioned earlier, RSE refers to SE in which seizures continue despite adequate doses of first and second line AEDs. Failure of bolus of two AEDs to control seizures makes it unlikely that patients will respond to a third bolus dose. So, a continuous IV infusion is needed at this stage. RSE must be managed in the ICU and a continuous EEG monitoring is mandatory because many patients continue to have EEG seizure activity with only subtle clinical manifestations like focal twitches and few myoclonic jerks. Infusions of midazolam or anesthetic agents like propofol, pentobarbital or thiopental are given at this stage. Patients must be on ventilator support as these agents (especially anesthetics) cause respiratory depression. Midazolam is given as a bolus of 0.2 mg/kg (maximum 10 mg) over 2 minutes and then as a continuous infusion at a rate of 0.1–0.4 mg/kg per hour to stop clinical attacks and correct abnormal EEG activity. Hypotension is the main side effect of midazolam, which is treated by reducing the infusion rate or judiciously using pressor agents. MDZ has occasionally been given in very high doses of up to 2.9 mg/kg per hour to suppress EEG ictal activity. Tachyphylaxis can occur with midazolam infusion, increasing the risk of breakthrough seizures.

Propofol is commonly used in RSE. It is a gamma amino butyric acid-A (GABA-A) agonist with rapid onset of action within 3 minutes and easy reversibility. This short elimination half-life ensures rapid awakening within 10–15 minutes after stopping the drip. Its mode of action also includes inhibition of NMDA receptors and modulation of calcium influx. It is given as an IV bolus of 1–2 mg/kg over 5 minutes, followed by a maintenance infusion at 2–10 mg/kg per hour. Respiratory depression and hypotension are common side effects. The rate of infusion is adjusted either to terminate EEG and clinical seizure activity or to achieve a burst-suppression pattern on EEG. The latter is referred to as the "coma phase" with continuous EEG monitoring. Barbiturates like pentobarbital or thiopental in bolus doses followed by infusion are used as alternative anesthetic agents in RSE. Their mode and duration of administration are similar to propofol with the aim of maintaining burst-suppression on EEG. The barbiturates also help to lower ICP which is invariably elevated at this stage. Efficacy and mortality figures are more or less similar for midazolam, propofol and barbiturate infusions.[16] There are no clear guidelines as to which agent should be used first.

The anesthetic infusion is continued for about 12–24 hours after the last seizure. This is followed by the weaning phase in which the infusion rate is slowly reduced every 3 hours. During weaning, high therapeutic levels of phenytoin (18–30 mg/L) or valproate (70–120 mg/L) are maintained to prevent recurrent seizures during taper. The weaning process usually continues over 6–24 hours with continuous EEG monitoring to detect any seizure recurrence. If there is a recurrence of clinical or electrical seizure, then the anesthetic infusion drip is restarted and the whole process repeated. About one-third of patients with RSE will have seizures within 5 days of tapering the anesthetic medication. This is referred to as malignant SE.[17] Prolonged propofol infusion in a dose greater than 5 mg/kg per hour for more than 48 hours can cause the propofol infusion syndrome with significantly elevated creatine kinase (CK) (>2000 units/L), triglycerides (>500 mg%) and lactic acid (>2.5 mmoL/L) and low bicarbonate levels (<20 mmoL/L). Therefore, the propofol dose must not exceed 5 mg/kg per hour if the infusion is to be continued for more than 48 hours.

Other anesthetic agents like isoflurane inhalation (0.8–2%) and ketamine infusion (up to 5 mg/kg per hour) have on rare occasions been used when all the above drugs have failed to control seizures in RSE and malignant SE. Anesthesiology assistance is required during their administration. Ketamine may offer specific advantages over the other drugs in RSE.[18] It induces hypertension which may help to combat the hypotension which can occur in RSE.

Among the newer AEDs, topiramate and levetiracetam have shown efficacy in some cases of RSE. Topiramate is rapidly titrated and given in a high dose of 150–800 mg twice a day through nasogastric tube.[19] It is a carbonic anhydrase inhibitor and may cause acidosis. It should not be combined with propofol as this combination may aggravate acidosis.

Levetiracetam is given either IV at 20–30 mg/kg at 5 mg/kg per minute or orally in a dose of 1,500–3,000 mg through nasogastric tube.[20] The calcium channel blocker verapamil (120 mg/day) has also shown benefit in the occasional patient with RSE.[21]

Immunosuppressive therapy should be considered in all cases of RSE due to encephalitic illness of unknown cause as there is a high probability of autoimmune encephalitis (especially NMDA type). IV methylprednisolone 1 gm daily for 3–5 days should be given. If the drug fails to show benefit, IV immunoglobulins or plasma exchange should be tried. Rituximab and cyclophosphamide have also been successfully used in autoimmune SE in few cases (Table 3).

SUPER-REFRACTORY STATUS EPILEPTICUS

Status epilepticus that continues for more than 24 hours after the onset of anesthetic infusions is called super-refractory SE. If immune modulation has not been tried, it must be considered at this stage. A variety of alternative therapies have been suggested for this stage, but they are all either anecdotal case reports or small case series. They include electroconvulsive therapy (ECT), transcranial magnetic stimulation (TMS), hypothermia and resective surgery.[22]

MAINTENANCE THERAPY

After the seizures have been successfully controlled, it is essential to continue maintenance therapy with appropriate AEDs to prevent seizure recurrence. Generally, the same drugs used to control SE like phenytoin or valproate are continued. Doses of these drugs are adjusted to maintain their blood levels in the normal therapeutic range. For patients receiving phenytoin and who are on nasogastric tube, it is preferable to continue IV dosing as a dramatic decline (about 70%) in absorption of phenytoin occurs when it is crushed and given through the tube.[23]

In critically ill patients who are on phenytoin and valproate, the free phenytoin level is three times higher than the expected level. So even a mildly low serum phenytoin level (8–10 mg) may suffice to prevent seizures. Drug interaction between valproate and the broad spectrum antibiotic meropenem causes a significant reduction in valproate levels.[24]

MANAGEMENT OF NONCONVULSIVE STATUS EPILEPTICUS

Nonconvulsive status epilepticus accounts for about 25% of SE cases. When the diagnosis is in doubt, a benzodiazepine

Table 3: Management of convulsive SE in adults

Time window (minutes)	*Medication*	*Medical measures*
0–10	IV lorazepam • 0.1 mg/kg bolus (maximum 4 mg) If seizure continues, repeat dose after 5 minutes Alternative drugs— • IV diazepam 0.2 mg/kg • IV midazolam 0.1–0.2 mg/kg If seizure outside hospital, no IV access: rectal diazepam 20 mg or midazolam 10 mg IM or intranasal or buccal	Secure airway Nasal oxygen Establish IV access Check finger prick blood sugar Collect blood for hematocrit, biochemistry AED level, ABG, toxicology screen Give IV 50 cc 50% glucose + 100 mg thiamine
10–30	IV phenytoin 15–20 mg/kg loading dose, rate not more than 50 mg/min or IV fosphenytoin 18–20 mg PE/kg at 150 mg/min or IV sodium valproate 20–40 mg/kg over 15–20 minutes Alternative drugs— IV levetiracetam 50 mg/kg or IV lacosamide 300 mg If seizure continues: repeat phenytoin/fosphenytoin 5 mg/kg or valproate 500 mg or IV phenobarbitone 10–20 mg/kg	Identify and treat medical complications Correct hyponatremia and acidosis If fever, use antipyretics and appropriate cooling methods Keep BP under control CT/MRI and CSF, if deemed necessary and safe Alert the anesthetist
30–60 Refractory SE	IV midazolam 0.2 mg/kg (maximum 10 mg), then infuse at 0.1–0.4 mg/kg per hour or IV propofol 1–2 mg/kg over 5 minutes; then infuse at 2–10 mg/kg per hour or IV thiopental sodium 3–5 mg/kg, then infuse at 3–5 mg/kg per hour or IV pentobarbitone 5 mg/kg at 25 mg/min, then infuse at 0.5–5 mg/kg per hour If suspected auto-immune encephalitis, IV methylprednisolone or IVIG or plasma exchange	Patient must be intubated and ventilated Continuous EEG monitoring Infusion must be titrated to maintain burst suppression pattern on EEG Closely monitor for hypotension Vasopressor therapy, if required Identify and treat complications Including hyperthermia and acidosis

trial is suggested. The patient is given sequential small doses of midazolam at 1 mg per dose. After each dose, clinical and EEG parameters are checked. The trial is stopped if any of the following occurs: (1) persistent resolution of EEG pattern; (2) definite clinical improvement; (3) respiratory depression or hypotension and (4) maximal permissible dose is reached (0.2 mg/kg). The test is reported positive if the ictal EEG pattern disappears and either the clinical state improves or a normal EEG pattern with posterior dominant alpha rhythm appears. The test is considered equivocal if the EEG improves but the patient does not. Treatment of NCSE is generally similar to that of generalized SE. However, mortality and morbidity figures are less in NCSE. So intubation and anesthetic drugs like propofol and barbiturates are generally avoided.

PROGNOSIS AND OUTCOME OF STATUS EPILEPTICUS

Status epilepticus is associated with high mortality rates of 15–22%. Death may be due to the original disease producing SE, medical complications or AED related toxicity. Age, etiology of SE and duration of seizures are important determinants of mortality and morbidity. Children have lower mortality rates than adults. Elderly patients generally have a poorer outcome. Encephalitis and cerebral hypoxia are associated with higher mortality compared to AED withdrawal or alcohol withdrawal SE. Duration of SE is also an important determinant of outcome. SE lasting less than 30 minutes carried a 2.7% mortality risk, compared to 19% for SE lasting less than 1 hour and 32% for SE lasting more than 1 hour.[25] Those patients who survive SE usually have high morbidity. Deterioration in functional outcome is present in 25% of patients with 10% requiring long-term care.[26] The outlook for patients with RSE is even more dismal with a mortality of nearly 40%. Only 20% return to baseline activities on discharge.[27]

F. RAPIDLY PROGRESSIVE NEUROMUSCULAR DISORDERS WITH RESPIRATORY FAILURE

Jimmy Lalkaka, BS Singhal

INTRODUCTION

Broadly speaking, respiratory failure can be caused either by cardiopulmonary disease or a primary neurological disorder. The latter can be due to CNS affection as in cervical myelopathy or brainstem disturbance or due to neuromuscular diseases (NMDs) which affect the lower motor neuron (LMN). The motor unit or LMN comprises of the anterior horn cell, spinal root, peripheral nerve, neuromuscular junction (NMJ) and muscle. Specific NMDs have a predilection for one or more of the above sites of the motor unit. For instance, myasthenia gravis (MG) affects the NMJ, poliomyelitis damages the anterior horn cells, while polymyositis affects the muscles.

Respiratory failure and autonomic derangements are frequent accompaniments of NMD and can be fatal if not recognized and treated in time. Guillain-Barré syndrome (GBS) and MG are the most common rapidly progressive NMDs. Other less common but nevertheless important NMDs include inflammatory myopathies (polymyositis and dermatomyositis), organophosphate poisoning, porphyria, rhabdomyolysis, Lambert-Eaton syndrome and botulism. In the last few years, critical illness neuropathy and myopathy are being increasingly diagnosed in intensive care units where patients with nonneurological illnesses like burns and sepsis develop newly acquired weakness and an inability to be weaned off the ventilator. This chapter focuses on respiratory failure caused by rapidly progressive NMDs.

GENERAL CONSIDERATIONS IN SUSPECTED RESPIRATORY FAILURE

Impending respiratory failure must be recognized and managed promptly. Hypoxemia, hypercapnia and acidosis may not be apparent until respiratory failure is advanced. So action needs to be taken before they occur. Trying to intubate and resuscitate a gasping patient reflects poor clinical judgement. Warning signals of respiratory compromise include a weak cough with inability to clear secretions, rapid shallow breathing, air hunger with excessive use of accessory respiratory muscles, forehead sweating, tachycardia, disturbed fragmented sleep and orthopnea. Dysphagia is closely associated with respiratory distress and in the early stage, causes cough while swallowing and nasal regurgitation. Diaphragmatic weakness causes paradoxical breathing. Disorientation and irritability can be early features of hypoxia while hypercapnia may cause drowsiness. Sleep often precipitates respiratory distress in NMDs. Depressed activity of the accessory muscles during sleep worsens the hypoventilation already present. It is rare for respiratory muscle weakness to occur in isolation. Weakness of the neck, trunk and proximal limb muscles is usually present and must be looked for.

Measuring chest expansion during inspiration, asking the patient to cough and swallow liquids and the single breath count are simple bedside tests to evaluate the strength of the respiratory muscles. An individual with normal respiratory reserve can count loudly up to about 50 in a single breath after a deep inspiration. A single breath count of about 25 roughly corresponds to a forced vital capacity (FVC) of more than 2 liters.[1] Significant respiratory impairment is associated with a single breath count of less than 15.

Spirometry with assessment of respiratory muscle strength complements the clinical evaluation and provides valuable information. The FVC, negative inspiratory force (NIF) and positive expiratory force (PEF) are useful in assessing respiratory muscle function. It is possible to perform these tests by the bedside in the intensive care unit (ICU) with suitable equipment and qualified respiratory therapists. The FVC is normally about 60–70 mL/kg. If it falls to about 30 mL/kg, the cough becomes weak and the patient complains of dyspnea. An FVC of 15 mL/kg or 1 liter is an indication for mechanical ventilation. Tidal volume changes little in the early stage of ventilatory failure, but falls dramatically with advanced respiratory muscle weakness. The NIF is a measure of alveolar ventilation while the PEF tests the ability to cough and clear the airways. Forced vital capacity and NIF may give a false low reading if the facial and bulbar muscles are significantly weak or if there is an air leak around the mouthpiece during testing.

Patients with overt respiratory failure, shock, impaired consciousness or evidence of active aspiration are immediately intubated and ventilated. Others who have respiratory compromise but are otherwise stable should be closely monitored. When in doubt about whether to intubate or not, it is better to take the former course.

DIAGNOSIS OF THE UNDERLYING NEUROMUSCULAR DISEASES

A recent respiratory or gastrointestinal infection preceding the onset of symptoms provides the clue to a GBS or an exacerbation of MG. Acute gastrointestinal symptoms are also seen in botulism, while abdominal pain often precedes an attack of acute intermittent porphyria (AIP). Recurrent episodes of generalized weakness suggest hypokalemic periodic paralysis. Diurnal fluctuations of symptoms with increased fatigability point to the diagnosis of MG as do intermittent diplopia, difficulty in chewing, dysphagia and nasal regurgitation. A history of drug ingestion and insect bite (tick paralysis) should also be inquired into.

Neuromuscular diseases have a specific pattern of muscle weakness. Generalized areflexic weakness of all limbs is a feature of GBS. Predominant proximal muscle weakness with preserved deep tendon reflexes occurs in inflammatory muscle disease. Ptosis, eye closure weakness, bulbar involvement and proximal limb weakness with preserved reflexes point to MG. Fluctuations in pulse and BP with sweating and sphincter disturbance indicate an autonomic disturbance, commonly seen in GBS, porphyria and botulism. Skin rash is a typical feature of dermatomyositis.

Electromyography and nerve conduction study (EMG and NCV) is a valuable tool in the diagnosis of NMDs. It accurately localizes the anatomical site of involvement. Laboratory investigations are ordered depending on the probable diagnosis of the NMD. Acetylcholine and muscle-specific tyrosine kinase (MUSK) receptor antibodies are present in MG, while porphobilinogen in urine and delta-aminolevulinic acid in serum point to AIP. Serum creatine phosphokinase is significantly raised in inflammatory myopathies.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is the most common cause of rapidly progressive neuromuscular weakness. It is an immune-mediated polyradiculoneuropathy with an annual incidence of 1–2/100,000.[2] In about two-thirds of patients, an antecedent gastrointestinal or upper respiratory tract infection is reported up to 3 weeks prior to the onset of symptoms. Campylobacter jejuni is the most frequent pathogen identified. It is associated with ganglioside 1 (GM1) antibody and results in a more severe, predominantly axonal disease.

Guillain-Barré syndrome manifests in different forms. Acute inflammatory demyelinating polyneuropathy (AIDP) is the most frequent type with predominant demyelination of the proximal roots and peripheral nerves. Acute motor axonal neuropathy (AMAN) and acute motor and sensory axonal neuropathy (AMSAN) are less common forms of GBS with predominant axonal degeneration. They are usually associated with a more severe form of disease and a poorer prognosis.[3] GBS usually presents acutely with paresthesiae in the feet and distal lower limb weakness which rapidly ascends over hours or days to involve the trunk and upper limbs. Severe diffuse back pain with or without radiation to lower limbs may be a presenting feature in some cases and can be mistaken for an acute lumbar disk prolapse. The limb weakness is usually symmetrical and involves the proximal and distal muscles. It progresses to reach a peak up to 4 weeks from onset, though most patients plateau within 2 weeks. Bifacial weakness occurs in nearly 70% of cases. Generalized areflexia is a salient feature in most cases. EMG or NCV studies reveal segmental demyelination in AIDP and also identify the axonal variety of GBS. CSF proteins are elevated after the first week of illness. Cells are very few or absent. Increased cells (>50 cells) should raise the possibility of another illness like human immunodeficiency virus (HIV), poliomyelitis, neurosarcoidosis, lymphoma or leukemia with peripheral nerve or root infiltration.

Bulbar and respiratory muscle weakness and dysautonomia are dreaded complications of GBS. Respiratory failure requiring ventilatory assistance occurs in about one-third of patients. Those with rapidly progressive weakness (<7 days from onset) and involvement of shoulder and neck muscles have a high likelihood of progressing to respiratory failure. An FVC less than 15 mL/kg (<1 liter) or NIF less than 20 cm of water or a $PaCO_2$ above 50 mm Hg usually require intubation and ventilation. A decline of more than 30% in the above parameters also warrants intubation, even though levels may not be too low. Patients with bulbar involvement, aspiration pneumonia and medical comorbidities like congestive heart failure may need ventilation earlier than others. Noninvasive positive pressure ventilation (NIPPV) is tried in some mild cases, but it is generally not recommended because of the risk of aspiration, and also because most patients will require ventilation for a prolonged period of time. Autonomic disturbances occur in most GBS patients. Sudden episodes of hypertension or hypotension, along with cardiac arrhythmias—tachyarrhythmias, severe bradycardia and even asystole—can be life-threatening. They are more likely to occur during tracheal suction and position change. Severe leg weakness in GBS can lead to deep venous thrombosis (DVT) and pulmonary embolism.

Plasma exchange (PE) or intravenous immunoglobulins (IVIg) are recommended in GBS with significant and progressive motor weakness. Treatment should be instituted as early as possible, usually within 7 days of onset. Both forms of therapy are equally effective in reducing the risk of developing respiratory failure and hastening recovery.[4] In PE, five cycles are usually given at alternate day intervals—about 40–50 mL/kg for a total of 200–250 mL/kg. Replacement fluid is usually albumin or saline. Hypotension and sepsis are significant adverse effects of PE. IVIg is easier to administer, but is more expensive. The recommended dose is 400 mg/kg per day for 5 days. Intravenous immunoglobulin is contraindicated in renal failure and may rarely cause myocardial and cerebral ischemia due to hyperviscosity.

Guillain-Barré syndrome carries a 3–10% mortality risk. Respiratory failure, cardiac arrhythmias and sepsis are the main causes of death. Although most patients eventually recover with minimal deficits, about 20–30% are left with significant disability.[3] A poorer outcome is associated with axonal variants, age over 60 years, bed-bound, intubated patients, rapid onset with maximum deficit within 7 days and prior diarrheal illness.[5]

MYASTHENIC CRISIS

Myasthenia gravis is an autoimmune disorder of the NMJ characterized by the presence of antibodies directed against the acetylcholine postsynaptic nicotinic receptors. The clinical hallmarks of MG are its fluctuating course with diurnal variation of symptoms and fatigable muscle weakness. The ocular, bulbar, neck and proximal limb muscles are most commonly affected. Myasthenic crisis (MC) is an acute

exacerbation of generalized MG with inability to swallow and respiratory muscle weakness requiring mechanical ventilation. About 15–20% of patients with generalized MG experience a crisis at some point in their illness, most often during the first year after onset of symptoms.[6]

Although MC can occur as a result of disease progression, it is often precipitated by certain aggravating factors. Intercurrent infections, especially aspiration pneumonia, are a common precipitating factor, responsible for about 40% of MC cases. Drugs known to aggravate myasthenic symptoms include antibiotics like aminoglycosides (gentamycin, tobramycin), fluoroquinolones (ciprofloxacin, levofloxacin) and macrolides (erythromycin), antiarrhythmics (procainamide and quinidine), quinine, curare and penicillamine. Pregnancy, surgery and stress can also precipitate a MC. Administration of high-dose steroids to newly diagnosed generalized MG patients can paradoxically worsen symptoms and precipitate a crisis. So, steroids should be started at a low dose and gradually escalated to the desired level.

Myasthenic crisis with respiratory failure and stridor may, at times, be the presenting feature of this illness.[7] A high index of suspicion is needed to diagnose MG in this situation of unexplained respiratory failure. MG is diagnosed by a positive edrophonium or prostigmine test, EMG evidence of significant decrement of muscle action potentials on repetitive electrical stimulation and presence of acetylcholine receptor or MUSK antibodies in the serum. In the edrophonium test, IV tensilon is given initially as a 2-mg test dose, followed 90 seconds later by 8 mg to a total of 10 mg. Onset of improvement usually occurs in 30 seconds and lasts 5–10 minutes. As this drug can cause severe bradycardia and other cholinergic side effects, it is best to administer it in the ICU. Intramuscular neostigmine (2 mg) can be used as an alternative to edrophonium. Maximum improvement with this drug usually occurs in 15–30 minutes. Acetylcholine receptor antibodies (AchR Ab) are detected in about 85% of generalized MG.[8] Antibodies to the MUSK are found in about 40% of those who test negative for AchR antibodies.[9] Muscle-specific tyrosine kinase MG commonly occurs in females of 20–30 years old without thymoma. They have prominent orofacial and respiratory muscle involvement at onset and are more likely to develop MC.[10] Ocular symptoms are usually absent. They respond poorly to cholinesterase inhibitors. A CT scan of chest is done to rule out a thymoma.

Early signs of respiratory distress must be closely looked for. Indications for mechanical ventilation have been mentioned earlier. An optimal ventilator setting is chosen to combat fatigue and promote lung expansion. This can be done by selecting assist control with positive end-expiratory pressure (PEEP) of 5 cm of water. To avoid lung injury, lower tidal volumes at 6 mL/kg and faster rate of 12–16 breaths/minute may be selected. Noninvasive ventilation with BIPAP (intermittent bilevel positive airway pressure) may be used to prevent atelectasis and avoid or delay intubation and mechanical ventilation in some patients with early MC. Hypercapnic patients are unlikely to benefit from BIPAP.[11] Patients with swallowing difficulty should have a nasogastric tube inserted for feeds and medications.

Both PE and IVIg are equally efficacious in MC. Therapeutic benefit occurs in about 5–7 days with either treatment. PE is the preferred treatment option in a recent literature review.[12] High-dose corticosteroids should be given once the patient is on mechanical ventilation in order to induce a remission. The recommended dose is 60–100 mg/day until improvement in symptoms is noted, after which the dose is gradually tapered. Excessive use of anticholinesterase drugs may occasionally cause respiratory distress with increased salivation, lacrimation, diarrhea and bradycardia. This is called a cholinergic crisis. When it is difficult to differentiate it from an MC, it is best to stop the drug. In any case, once the patient is on a ventilator, this drug is withheld as it tends to increase respiratory secretions. It is reintroduced once the patient recovers from the crisis and is taken off the ventilator.

CRITICAL ILLNESS NEUROPATHY AND MYOPATHY

They are common causes of new onset weakness in critically ill patients who have been admitted to the ICU for some other reason. They are suspected when patients are unable to be weaned off the ventilator in the absence of any sedation. Critical illness myopathy (CIM) is more frequent than critical illness neuropathy (CIN), but they often coexist.[13] Long-term use of high-dose steroids is more likely to cause CIM, while CIN occurs in about 70% of patients with sepsis and multiorgan failure. Other predisposing factors include hyperglycemia, inotropic support, use of neuroparalytic agents and long ICU stay with prolonged ventilation.

Motor weakness in these patients ranges from moderate paresis to complete areflexic quadriplegia. Muscle wasting and hypotonia also occur. Facial weakness and ophthalmoparesis are not seen, so, if present, other conditions like MG or GBS must be excluded. A glove and stocking sensory impairment occurs in critical illness polyneuropathy (CIP). CPK may be normal or mildly elevated in CIM. EMG or NCV studies may be normal or show evidence of axonal neuropathy or myopathy.

There is no specific treatment available, but their occurrence can be reduced by minimizing the use of high-dose steroids and neuromuscular blocking drugs, adequate control of infections and effective blood sugar control. In patients who survive sepsis and multiorgan failure, muscle strength recovers slowly over months.

ORGANOPHOSPHATE POISONING

Organophosphates (OP) are used as insecticides and are available as household products. In India, they are frequently used for suicidal poisoning. They are potent cholinesterase inhibitors. They bind and inhibit red blood cell (RBC) acetylcholinesterase, which results in excess amounts of

acetylcholine stimulating muscarinic and later nicotinic receptors.[14] Symptoms of excess acetylcholine include pinpoint pupils, diarrhea, bradycardia, increased bronchial secretions, salivation and sweating. Widespread fasciculations are also observed. Weakness of proximal limb, bulbar and respiratory muscles appears 24–96 hours later, which may require mechanical ventilation. This stage mainly occurs with lipophilic OP due to nicotinic receptor-induced NMJ disturbance. Measurement of RBC acetylcholinesterase activity correlates with the degree of toxicity. Treatment consists of immediate gastric lavage through nasogastric tube, management of respiratory failure with 100% oxygen and mechanical ventilation and administration of large doses of IV atropine and pralidoxime (see Chapter Critical Care in Poisonings).

LAMBERT-EATON MYASTHENIC SYNDROME

Lambert-Eaton Myasthenic Syndrome (LEMS) is an NMJ disorder caused by antibodies directed against voltage-gated calcium channels (VGCC) on presynaptic motor nerve terminals. They inhibit the entry of calcium into the nerve terminals which is required for acetylcholine release, resulting in the presence of fewer acetylcholine vesicles in the synapse. In about two-thirds of cases, LEMS occurs as a paraneoplastic disorder, usually secondary to small cell carcinoma of the lung. The neurological symptoms may precede the tumor. In the remaining one-third of cases, LEMS presents as an autoimmune disorder without underlying cancer. These nonparaneoplastic cases occur more frequently in females and younger patients and can occur with other autoimmune disorders.

Symmetrical proximal muscle weakness in lower limbs followed by upper limbs occurs. It is worse on initiating a movement, improves with physical activity, but fatigues with prolonged sustained effort. Unlike MG, ptosis, ophthalmoparesis and bulbar symptoms are rarely seen. Respiratory muscle involvement is also uncommon in LEMS, though occasional cases presenting with respiratory failure have been reported.[15] Deep tendon reflexes may be diminished or absent, but may be elicitable after mild muscle contraction. Autonomic symptoms (dry eyes, reduced saliva, constipation and decreased sweating) also occur in LEMS.

Lambert-Eaton Myasthenic Syndrome is diagnosed by the presence of VGCC antibodies in serum and characteristic EMG changes of reduced compound muscle action potential (CMAP) amplitude and incrementing response on repetitive high-frequency stimulation. LEMS patients must be thoroughly searched for a malignancy. Treatment of the underlying cancer, if present, improves muscle strength. Acetylcholinesterase inhibitors (pyridostigmine) also improve symptoms, but not as effectively as in MG. 3–4, diamino pyridine blocks voltage-dependent potassium conductance, thereby facilitating acetylcholine release. Corticosteroids, PE and IVIg have also shown some benefit.

ACUTE INTERMITTENT PORPHYRIA

Acute intermittent porphyria is an autosomal dominant disorder characterized by recurrent attacks of acute motor neuropathy resembling GBS.[16] It is caused by deficiency of porphobilinogen deaminase enzyme. An attack of porphyria is often precipitated by drugs like sulfonamides, steroids, phenobarbitone and phenytoin as also in pregnancy, fasting and alcohol. The porphyric crisis typically begins with acute abdominal pain mimicking a surgical abdomen. Soon thereafter, CNS and psychiatric disturbances in the form of confusion, agitation, hallucinations and seizures occur. Within 48–72 hours, a severe symmetric, rapidly ascending predominantly motor axonal neuropathy resembling GBS develops. Proximal upper limb muscles can be maximally affected. Cranial nerves and respiratory muscles are also involved. Autonomic disturbance due to sympathetic overactivity causes pupillary dilatation, tachycardia and hypertension. The urine turns brown, if allowed to stand, due to the formation of porphobilin. Elevated levels of urinary porphobilinogen and delta aminolevulinic acid are seen. AIP is treated with IV glucose and hematin (4 mg/kg daily for 4 days).

POLYMYOSITIS AND DERMATOMYOSITIS

These inflammatory myopathies are characterized by muscle weakness, elevated blood creatine kinase (CK) levels and inflammatory changes on muscle biopsy. Dermatomyositis (DM) is more common than polymyositis (PM) and occurs mainly in children, whereas PM is usually seen in adults. They are associated with other autoimmune connective tissue disorders like systemic lupus erythematosis, scleroderma and rheumatoid arthritis and also carry an increased risk of malignancy. DM and PM present with acute or insidious onset of proximal greater than distal limb weakness. Ocular motor weakness does not occur. The main difference between the two disorders is a characteristic skin rash seen in DM which usually accompanies or precedes the muscle weakness. Bulbar and respiratory muscle involvement are uncommon but can rarely be the predominant symptom.[17] Orticosteroids are the mainstay of treatment. Other immunosuppressive drugs like methotrexate, azathioprine or mycophenolate mofetil are considered in those who do not respond to an adequate trial of steroids. IVIg is effective in improving muscle strength and resolving the immunopathology of DM and possibly PM.[18] Plasma exchange has not shown any benefit in these disorders.

RHABDOMYOLYSIS

Rhabdomyolysis refers to an acute, severe necrosis of muscle fibers with release of cellular components into the blood and urine. Myoglobinuria is the resultant excess amount of myoglobin in the urine, which imparts a dark-brown color to it. Some important conditions causing rhabdomyolysis include

inflammatory myopathies (viral myositis, pyomyositis), traumatic crush injuries, snake venom, neuroleptic malignant syndrome and overdose of cocaine, heroin and alcohol. Rhabdomyolysis presents with acute generalized pain, swelling, tenderness and weakness of muscles. Proximal limb girdle muscles are more severely affected than distal muscles. In fulminant cases, respiratory muscle involvement leads to respiratory failure. Rhabdomyolysis is associated with markedly elevated CK levels (in thousands) and myoglobinuria, with oliguria/anuria and acute renal failure.[19] Hyperkalemia secondary to muscle breakdown and renal insufficiency also occurs. The mainstay of treatment is aggressive hydration to prevent renal failure. Intermittent hemodialysis is indicated for resistant hyperkalemia, oliguria/anuria, volume overload or metabolic acidosis.

G. PERIOPERATIVE NEUROLOGICAL CARE

Late Sohrab K Bhabha

GENERAL CONSIDERATIONS

The demands of contemporary neurosurgery on critical care resources can be considerable. A good working rapport between intensivist, neuroanesthesiologist, neurologist and neurosurgeon does much to facilitate and simplify critical care. The practice of the neurologist or neurosurgeon *alone* assuming charge of critical care, while sometimes unavoidable, is to be strongly discouraged. Experience indicates that the *intensivist* should be the team leader during this crucial phase. It is also appropriate that the intensivist be involved in the preoperative care of the person whom she or he will continue to manage through critical perioperative and postoperative phases. It need hardly be stated that the results of painstaking neurosurgery can all too easily be undone, in more than one sense, by unskilled postoperative management. The scope of this chapter is to outline the critical care of the neurosurgical candidate.

PREOPERATIVE CARE

Intracranial Hypertension

The management of intracranial hypertension (ICH) in a variety of settings is discussed elsewhere. In the present setting, tumors and intracranial hemorrhage are possibly the most common causes of ICH. As always, the structural and functional bases for ICH require consideration. The operative mechanism of ICH may then be best addressed. If an intracranial drain is in position, extreme caution must be exercised in venting pressure, since intracranial compartmental shifts may pre-exist and any acute change may be disastrous. Corticosteroids are usually effective in the management of persons with peritumoral edema. Dexamethasone (16–32 mg/day), or an alternative steroid, may be started as soon as the diagnosis is made (*excepting* in suspected cerebral lymphomas) and preferably at least 48 hours prior to surgery. If the response is poor, the daily dose maybe elevated to 100 mg/day. For acutely decompensating situations, for example, impending herniation, a bolus of 100 mg may be followed by a similar daily maintenance dose. This measure, sometimes combined with an intravenous mannitol bolus (at times preceded by furosemide), hyperventilation, or both, will salvage most situations.

Seizures

Seizures, generalized or partial, are most often tumor- or bleed-associated phenomena in this setting. The incidence of seizures is higher in primary brain tumors than in secondary ones, with the exception of metastatic melanoma, which is frequently associated with seizures. Uncontrolled seizures lead to aggravation of an already decompensated intracranial pressure balance. Seizures may be anticipated in several supratentorial epileptogenic conditions, when prophylactic anticonvulsant drug (ACD) therapy should be considered. The evidence base for such prophylactic ACD use is slim.[1,2] It must also be added that contemporary literature seems to point to the underlying pathology, rather than the procedure, as the provocative factor. The presence of a seizure-provoking lesion should not prevent a search for coexistent metabolic derangements which lower seizure threshold, such as hypocalcemia, hyponatremia, hypoglycemia, alcohol-withdrawal and hepatorenal compromise. Patients with primary or secondary brain tumors who receive iodinated radiologic contrast media are at an increased risk for seizures; pretreatment with 5–10 mg oral dose of diazepam, 1 hour prior to contrast injection, reduces the incidence of such seizures.[3]

For most purposes, phenytoin is a satisfactory acute-care ACD which is available in several dosage forms. In previously untreated persons, a loading dose *must* be administered orally (15–18 mg/kg over 24 hours) *or* intravenously (rate not exceeding 50 mg/minute), preferably while monitoring heart rate and BP. We prefer oral loading. Subsequently, a daily dose of 5 mg/kg will usually maintain therapeutic serum levels. Stable serum levels should be ensured *preoperatively,* as far as possible. A seizure on the operating table is an uncommon but dreaded event. Newer agents like levetiracetam, lamotrigine, topiramate and lacosamide are alternatives to phenytoin, if the latter is contraindicated or produces side effects. Levetiracetam is, at times, preferred to phenytoin due to its better safety profile. It can be administered intravenously as well, if required. The duration of continued prophylactic ACD use is contentious; current literature appears to indicate that their use must be based upon the epileptogenic potential of underlying pathology. The presence of preoperative epilepsy or seizures requires altogether different considerations.

PERIOPERATIVE CRITICAL CARE

Head-Position and Airway

Appropriate head-positioning and fixation are vital steps, especially in the present era of microneurosurgery, image-guided techniques and neuronavigation, when head-position must be maintained over long periods of time. It is nonetheless important to ensure that the endotracheal tube is not compromised. Neck veins should not be obstructed in any way, since this will have an adverse effect on cranial venous return, hemostasis, brain edema and operating time.

Air Embolism

Twenty-five percent or more of persons operated in the sitting position may suffer from air embolism. This occurs as a result of air entry through torn cortical or diploic veins or dural

venous sinuses. Major air embolism causes right heart failure with catastrophic hypotension. Screening for a patent foramen ovale is preoperatively mandatory for any neurosurgical procedure in the sitting or "beach chair" position as well as in those procedures where one is likely to encounter prominent venous channels. Preoperative contrast-enhanced transcranial Doppler ultrasonography[4] and monitoring with transesophageal echocardiography as well as end-tidal PCO_2[5] help to define the presence of a patent foramen ovale and establish significant air embolism. Aspiration of air from a right atrial or Swan-Ganz catheter is both diagnostic and therapeutic. Inspired gas should be switched to 100% oxygen to decrease the volume-expanding effect of nitrous oxide on the air embolus, and the person should be turned to the left lateral recumbent position. Vasopressors may be required to support arterial pressure. Air embolism can lead to acute pulmonary edema,[6] pulmonary infarction, and also to delayed gas-embolic stroke.

Reversal

The abrupt elevation of intrathoracic pressure commonly associated with *rapid reversal* and its transmitted effects on intracranial venous pressure prompts many neurosurgeons to desist from this method of reversal. Their prime concerns are early intracranial bleeding and intracranial pressure elevation. Therefore, such teams continue to ventilate persons postoperatively and permit them to *emerge* or *float* out of the effects of anesthesia. If such a method is employed, it is *imperative* that the person be advised so preoperatively, to allay his anxiety when he awakens. *This cannot be overemphasized.*

Prophylaxis for *gastrointestinal bleeding, deep venous thrombosis* and *pulmonary* embolism are also important aspects of perioperative neurosurgical care and are considered elsewhere.

POSTOPERATIVE CRITICAL CARE

Effects of Anesthesia versus Immediate Neurologic Deterioration

Neurologically normal persons exhibit a variety of pyramidal signs as they emerge from general anesthesia and up to an hour (or two) thereafter. These include hyper-reflexia, ankle clonus and extensor plantar responses.[7,8] Similarly, a degree of confusion, mild worsening of previous hemiparesis, mild dysarthria and asterixis may all be residual anesthetic effects. In addition, patients undergoing craniotomy for large intracranial mass lesions awaken more slowly than patients after spinal surgery or craniotomy for small brain tumors.[9]

When confusion was not preoperatively present, its presence in the postoperative phase must be viewed as representing a fresh brain event; brain swelling or an evolving intracranial hematoma should be considered. Other worrisome pointers are progressive headache, vomiting, drowsiness, evolving hemiparesis or pupillary changes and *de novo* bradycardia. Any progressive or fluctuating deterioration should be presumed to be of serious import. Additive anesthetic and anticonvulsant toxicity may lead to toxic effects. Perioperative phenytoin administration has been associated with postoperative hiccups and vomiting. Persistent ophthalmoplegia (beyond a few hours) may indicate fresh brainstem vascular insult or may unmask a rare case of myasthenia gravis. Brain imaging with CT or MRI is the mainstay of structural redefinition in such circumstances and ought to be used early and as often as may be required. EEG and evoked response studies have a more limited role. At times, a substantial, transient change in postoperative neurological status may be anticipated, such as may occur in bulbar or ventilatory functions following some surgical procedures involving the brainstem, skull-base or craniovertebral region. This may necessitate anticipatory nutritional management (usually nasogastric intubation) or elective tracheostomy and short-term ventilation.

Hematomas

Hematomas can occur at the site of surgery, or remotely, in established spaces such as the extradural or subdural space. Occasionally, they are seen distant to the operative site. Established systemic hypertension predisposes a person to this complication; tumor (typically meningioma) and arteriovenous malformation resection are the most common settings. With gliomas, gross total resection is associated with a lower incidence of intraparenchymal hematoma development than subtotal resection.[10] Extradural hematomas can sometimes be prevented by tenting sutures, especially where the dura has been drawn away from the inner table. Subdural hematomas may result from abrupt brain decompression, such as occasionally occurs when spinal or ventricular drainage is established or when brain swelling responds to bolus mannitol. Surgery in the seated position also predisposes to subdural hematoma, because of traction on bridging veins, particularly after posterior fossa surgery.

Blood Pressure Control

Established *systemic hypertension* should be kept well-controlled both before and after craniotomy, since it has been associated with increased mortality in the critical care setting. The precise levels that represent a risk for cerebral edema postoperatively are difficult to define and depend on the surgical pathology, surgical trauma and preoperative control. In such persons, their regular antihypertensive treatment is started at approximately half to two-thirds the dose, as soon as possible postoperatively. Sedation often reduces antihypertensive requirements.

Hypertension after *carotid endarterectomy, angioplasty* and *arteriovenous malformation* surgery presents special problems. Malignant cerebral edema and hemorrhage may occur. *Dysautoregulated hyperperfusion* is thought to underlie such developments. When mean arterial pressure exceeds 110–120 mm Hg, nitroprusside or labetalol may

be the best choices to employ (see Chapter Hypertensive Emergencies and Aortic Dissection in the ICU). Nitroglycerin and nifedipine are preferably avoided.

Aneurysmal subarachnoid hemorrhage poses several challenges to the intensivist. Among these are the management of *vasospasm* and *dysnatremia*. The former may occur as early as a few days (2–4 days) of bleed or may set in as late as 2 weeks post-bleed. The result is variable ischemic brain insult, even catastrophic infarction, which may significantly mar the quality of outcome. The currently favored form of therapy is early intervention (either clipping via craniotomy or endovascular interventional obliteration) followed by a combination of induced hypertension, intentional hypervolemia and hemodilution, also known as "triple H therapy".[11] This form of therapy has never been subjected to controlled study, however.[12] Sodium metabolic derangements related to subarachnoid hemorrhage are a complex of disorders, as yet not fully pathophysiologically understood. Generally, hypernatremia carries a graver prognosis than hyponatremia does.[13] Bedside cerebral microdialysis is establishing itself as a useful tool for directly monitoring regional cerebral metabolic changes, some of which may help us to define impending neurological events.[14]

Intracranial Hypertension

Intracranial hypertension may be heralded by a failure to awaken as expected in the immediate postoperative period, a delayed change in the level of arousal (consciousness) after initial recovery, or the development of an unexpected change or loss of neurological function. Its important causes include hematomas (discussed earlier), perilesional brain edema, hydrocephalus, tension pneumocephalus and brain infarction (discussed later). Neuroimaging usually differentiates these and guides more specific treatment.

Postoperative *perilesional brain edema* peaks at 36–72 hours. The tempo of evolving ICH is slower in edema than in hematomas. Patients usually awaken as expected from anesthesia, but between 6 and 36 hours postoperatively, they become lethargic or develop fresh neurologic deficits. Brain imaging is obtained to exclude a bleed; as soon as this is done, the steroid dose is increased and free water administration is decreased. Further measures to monitor and combat the resultant raised intracranial pressure, such as sedation and hyperventilation (discussed elsewhere), may be required.

Postoperative *hydrocephalus* is most often associated with posterior fossa or intraventricular neurosurgery, the latter carrying the greatest likelihood of introducing blood into the CSF pathways. Patients with symptomatic third ventricular tumors may abruptly develop hydrocephalus and decompensate to coma and sudden death. The latter phenomena are probably a result of *plateau waves*. A ventricular drainage procedure is most often indicated.

With the advent of skull base surgery, the incidence of *tension pneumocephalus* has increased. Continual efflux of CSF from the basal cisterns creates a negative pressure, which sucks in air intracranially. Operative measures to prevent this include dural closure, skull base reconstruction, re-expansion of the intracranial contents and the placement of an extradural drain. Clinical signs of tension pneumocephalus usually appear 2–4 days postoperatively, when the intracranial air, due to its mass effect, mimics a space occupying lesion. Persons at risk should be nursed in the head-low position, for 4 days postoperatively. A plain skull film or CT scan readily makes the diagnosis clear. Once diagnosed, 100% oxygen is administered and if rapid decompensation is encountered, needle aspiration or silastic catheter placement may be imperative. Water-seal drainage may be required to prevent reaccumulation. Definitive surgery may be the final corrective measure.

Postoperative Stroke

When encountered in the immediate postoperative setting, this event has invariably occurred intraoperatively. Precautions in this direction therefore must be adopted *before* and *at the time of surgery*. Rarely, brain infarction occurs as a postoperative event. Preventive measures include ensuring a normovolemic state and normal arterial pressure. The postoperative, volume-depleted, hypotensive, hyponatremic, altered hemorrhagic state predisposes to stroke. Careful fluid and electrolyte monitoring are therefore essential.

The goal of fluid and *electrolyte* management in the postoperative period is to keep the person normovolemic and normo to slightly hyper-osmolar, at the same time ensuring normal sodium balance. Several brain-related factors may cause fluid and electrolyte disturbances, e.g. secretion of antidiuretic hormone (SIADH) and cerebral natriuresis. These should be carefully considered and appropriately treated (see Section Fluid and Electrolyte Disturbances in the Critically Ill).

Fever and Infection

Unsustained fever below 38.5°C can usually be attributed to atelectasis and the postoperative state. Higher temperature or persistence beyond the first 6 hours requires further investigations. Clinical examination, chest X-ray, sputum and urine cultures are the next step. *Central fever* is distinctly uncommon and should only be diagnosed when unremitting hyperthermia (>40°C) occurs in patients with massive hemorrhage or basal brain lesions in proximity to the anterior hypothalamus. Fever may sometimes be due to a sinusitis, caused or exacerbated by nasogastric intubation over several days. Drug fever, usually associated with an antimicrobial or an anticonvulsant, must also be considered. When fever persists beyond 24 hours and is unexplained by the foregoing, spinal fluid must be examined. Bacterial meningitis must be differentiated from its aseptic counterpart.[15] This is not always easy, since glucose ratios and cell counts are not so helpful. Fever, CSF leak, peripheral leucocytosis and culture positivity are better differentiators and favor bacterial meningitis. *S. aureus* and Gram-negative bacilli are the leading causes of

postoperative bacterial meningitis. Even with satisfactory therapy, CSF cultures may still show Gram-negative bacilli for up to 2 weeks. CSF leaks require definitive management if treatment is to be lastingly effective. Other factors causing fever at this stage are craniotomy infections, subgaleal fluid collections or hematomas, salivary gland inflammation, deep venous thrombosis and acute adrenal insufficiency.

The use of prophylactic antimicrobials in *clean* neurosurgical procedures, whether monitoring ones (ICP monitoring, drains, microdialysis) or formal surgery, is undergoing a process of continual review and rationalization.[16] The emerging trend is away from prophylactic use (particularly for monitoring ones) and increasingly toward extremely brief (single-dose, single-day, 3-day) use in formal ones.

Critical Care after Open Heart Surgery

- Critical Care after Open Heart Surgery

CHAPTER 62

Critical Care after Open Heart Surgery

GENERAL CONSIDERATIONS

Open heart surgery has made great strides in India. The number of centers for open heart surgery in the large metropolitan cities of the country is increasing year by year. In our center, 12–15 open heart surgeries are performed every week, and very often half the surgical intensive care unit (ICU) beds are engaged at any one time in the postoperative care of these patients. Coronary artery bypass grafting (CABG) is the most frequently performed open heart surgery, followed in order of frequency by valve replacements, and by repair of congenital defects in the heart. Even so, the overall number of patients subjected to CABG has fallen significantly. Advances in cardiology which include reperfusion therapy, angioplasty, stenting and use of drug eluting stents have lessened the need for a surgical approach, except in complicated problems or following failure of other modalities. The recently developed sirolimus-coated coronary stent has been associated with very good results. There is now no significant difference when comparing stents with CABG for left main disease with regard to mortality figures, or of the composite end-point of death, Q-wave infarction or cerebrovascular accident.[1]

The success of good surgical technique and good perioperative care can be easily ruined if critical care in the postoperative period is poor. In our unit, the mortality following CABG surgery is less than 1%. In fact, in patients with good preoperative left ventricular function, the mortality over the last several years has been nil. The surgeons are taking on more and more patients with poor left ventricular function (often with ejection fractions in the region of 15–20%. Many of these poor-risk patients have associated problems in the form of aneurysmal dilatation of a part of the wall of the left ventricle, and blocked coronary arteries which not only need to be bypassed, but also require an endarterectomy. Patients who have a very poor pump function and have to be taken up for CABG surgery or some other open heart surgery, are often given dopamine support (5–7 μg/kg per minute) as a preoperative measure for 1–2 days prior to surgery. In spite of the complexity of the surgical procedures, the mortality in what are really poor-risk cases is less than 2%.

The frequently observed adverse effects related to cardiopulmonary bypass (CPB) as also the increasing age of patients undergoing cardiac surgery has led to the development of less invasive techniques. These include minimally invasive direct coronary artery bypass (MIDCAB) and off pump coronary artery bypass (OPCAB).

Minimally invasive direct coronary artery bypass differs from conventional CABG in that instead of the conventional median sternotomy incision, access is obtained via a left or right thoracotomy, a parasternal incision or a partial sternotomy. The surgeons in our unit do not use this technique, but prefer to use the OPCAB which is performed on a beating heart without using CPB. The OPCAB technique is now used in many centers in India and the rest of the world with very good results. CPB is reserved for surgery on complicated coronary artery disease, for the surgical management of aneurysms of the aorta or ventricular wall, for valve replacement surgery and for surgery on congenital heart defects. Off-pump CABG surgery has been shown to decrease complications and shorten time for recovery. High-risk patients, unsuitable for CABG surgery using CPB, can now be successfully operated upon by this off-pump procedure. Though technically refined, CPB is still an abnormal state of perfusion. Anticoagulation, hypothermia, the absence of pulsatile perfusion and trauma

to the cellular elements of blood by exposure to air, tubings, filters and suction, are necessary but harmful features of this abnormal circulatory state. The effects of CPB are to an extent responsible for a number of management problems encountered during the postoperative phase. It is therefore necessary for the intensivist to be aware of the basic procedure and problems during CPB. This chapter however confines itself to management problems after patients undergoing cardiac surgery have been transferred to the ICU for post-operative critical care.

MONITORING ON TRANSFER TO THE ICU

Before transfer to the ICU, the practice in our unit is to intravenously inject 500,000 units of aprotinin postoperatively, and then 500,000 units in an infusion over the next 12 hours, so that postoperative bleeding is reduced. Some units prefer to use the drug preoperatively and, if for any reason the risk of bleeding is increased, the postoperative dose can be suitably raised as well, up to 500,000 units/hour till the bleeding stops.

Patients are continuously monitored on arrival to the ICU. The arterial blood pressure is monitored through an arterial line, the central venous pressure (CVP) through a central venous line, the urine output by an indwelling Foley's catheter, the echocardiogram (ECG) by a single lead ECG, and the oxygen saturation by a pulse oximeter. In addition, in selected instances, temporary epicardial atrial and ventricular pacing wires are left in situ for a few days, for the management of arrhythmias.

A Swan-Ganz catheter is often inserted to measure the pulmonary capillary wedge pressure, particularly in patients with poor pump function or in patients with complex problems. Contrary to published literature we have noticed neither an increase in mortality nor morbidity following its use. The Swan-Ganz is removed on the third or the fourth day or even earlier.

The mediastinum and the left pleural space have chest drains, and the drainage is measured every hour to determine if excessive bleeding is present. When both internal mammary arteries have been used as grafts, or if for any reason the right pleural space has been opened, a chest drain in the right pleural space becomes imperative as well. The rectal temperature, the heart rate and the respiratory rate are continuously monitored. The patient has an endotracheal tube in place, which is connected to a ventilator. The ventilator settings are noted—in particular, the respiratory rate, the tidal volume, the minute ventilation, and the peak and pause inflation pressures.

A 12 lead ECG and a chest X-ray are taken immediately on arrival to the ICU. Blood is also collected for complete blood count (CBC), packed cell volume (PCV), platelet count, serum electrolytes, urea, creatinine, glucose, arterial pH and blood gases. Relevant studies in relation to the blood chemistry, clotting parameters, and arterial pH and blood gas analysis are repeated as and when necessary.

IMMEDIATE POSTOPERATIVE MANAGEMENT

Immediate postoperative goals include restoration of normal body temperature, monitoring of hemodynamic and respiratory functions with prompt correction of any abnormalities or complications that may arise, restoring and maintaining fluid, electrolyte and acid-base balance, and replacing blood loss which is estimated both clinically and by noting the volume of drainage through chest tube drains. Intravenous (IV) infusions should maintain adequate filling pressures within the ventricular chambers. The rate and quantity of IV infusions depend on the circulatory state after surgery, the ongoing blood loss and the urine output.

In our unit, patients undergoing CABG are often transferred from the operating theater with an ongoing infusion of nitroglycerin at a rate of 5–10 μg/kg per minute, to increase vascular capacitance in the immediate postoperative period, and to counter coronary artery vasoconstriction. They occasionally are also on an infusion of dopamine (5–7 μg/kg per minute), for immediate postoperative inotropic support. These infusions are tapered and stopped after the first 24 hours if the circulatory state is satisfactory, and the immediate postoperative period is uneventful. Aspirin (300 mg) is administered 8 hours after surgery and continued once daily throughout the postoperative period. After discharge, the patient should continue 150 mg daily on an indefinite basis. Low molecular weight heparin is begun on the second or the third day after surgery and continued for 7 days. Both aspirin and heparin may need to be omitted in the presence of excessive postoperative bleeding.

The following features are worthy of note in the immediate postoperative period—

- Serum K^+ levels during the early postoperative phase can fluctuate markedly. Serum K^+ should be maintained between 3.5 and 4.5 mEq/L.
- Uncontrolled hyperglycemia is frequent in diabetics and needs carefully titrated administration of insulin so as to keep the blood sugar less than 150 mg/dL. In nondiabetics, blood sugar levels to start with may also be high—between 250 and 350 mg/dL. Carefully titrated actrapid insulin is given every 4–6 hours to maintain blood sugar levels less than 150 mg/dL. Insulin is generally not necessary in nondiabetics after 48–72 hours.
- Significant acid-base disturbances, e.g. metabolic acidosis or metabolic alkalosis may be present and need to be corrected.
- Shivering is common, as the early period after CPB is characterized by a fall in the core temperature. Shivering commonly occurs during this phase, as patients begin to re-warm after the effects of the anesthetic and muscle relaxant begin to wear off. Shivering interferes with effective mechanical ventilation, and causes an increase in the CO_2 production. It also increases oxygen consumption

and myocardial work, thereby making undue demands on a heart recovering from the effects of aortic cross-clamping and CPB. Minute ventilation should be appropriately increased to counter increased oxygen consumption and CO_2 production till such time as the patient's temperature slowly rises and remains stable. This may take 2–8 hours. Severe shivering, particularly when associated with hemodynamic instability, should be countered by the use of a muscle relaxant (pancuronium 2–4 mg intravenously). This controls the shivering and allows the patient to rewarm slowly.

- Bleeding is one of the commonest problems encountered in the early postoperative period. Bleeding may be due to several causes—heparin rebound, acquired qualitative platelet defects due to CPB or drugs, thrombocytopenia, clotting factor deficiencies, local or systemic fibrinolysis, and disseminated intravascular coagulopathy.[2] The activated clotting time, bleeding time (BT), prothrombin time (PT), partial thromboplastin time (PTT) and platelet counts are routinely estimated and repeated as necessary. A full coagulation profile is often asked for, but results are generally available only after the lapse of some precious hours. Therefore, initial management of bleeding is more often than not empiric. Since heparin rebound is fairly common, (the PTT will be raised), protamine (50–100 mg) is given in an attempt to effectively neutralize heparin. Fresh frozen plasma should be given to replace a possible deficiency in the clotting factors. The prothrombin time will be raised in these patients. Desmopressin may be given in an infusion over 10 minutes, in a dose of 0.3 µg/kg, to increase levels of von Willebrand's factor and to restore platelet function.[3] Thrombocytopenia (<80,000/mm^3) or a prolonged template BT is managed by adequate platelet infusions. If the serum fibrinogen level is less than 125 mg/dL, 8 U of cryoprecipitate are administered. If there is evidence of fibrinogenolysis with high levels of fibrin degradation products (FDP), epsilon aminocaproic acid may be given in a dose of 5–10 g intravenously in the first hour, followed by an infusion of 1 g/hour for 3–5 hours. Transfusions of red blood cells or whole blood should be guided by the rate of blood loss, the hematocrit and the existing hemoglobin values in blood. We prefer to maintain a hemoglobin concentration of between 10 g/dL and 11 g/dL.

The surgical decision to re-explore the chest for excessive bleeding through chest tube drains is dependent on the volume and rate of blood loss, and the basic coagulation status. If this status (platelet count, CT, BT, PT, PTT, fibrinogen levels) is satisfactory, or if an existing coagulopathy has been adequately corrected, exploration is considered if the blood loss exceeds 1,000 mL in the first 12 hours. Sudden increase in the blood loss to more than 300 mL/hour for 2 hours should prompt a possible re-exploration. Blood loss of 300 mL in the first hour, 250 mL in the second hour and 150 mL/hour subsequently has been correlated with surgically correctable bleeding.[4] Surgeons generally prefer to err on the safer side and risk a re-exploration, rather than await a possible hemodynamic collapse. Re-exploration may be rewarded by the presence of a discrete major source of bleeding which can be promptly controlled. Not uncommonly, a number of small bleeding points are present. Evacuation of a clot and cauterization of these points generally suffice to stop the bleeding. It is of critical importance to realize that a sudden cessation or sharp decrease in the chest tube drainage in a hemodynamically unstable patient may be due to excessive bleeding within the chest with clots blocking the drains. If bleeding persists but drainage ceases, tamponade can result. A chest X-ray in these patients shows a pleural opacity, and the presence of hypovolemic shock should clarify the diagnosis. Urgent re-exploration with evacuation of the clots, with special attention to the bleeding points within the chest, is mandatory.

When bleeding from the chest drains is uneventful and within the normal range, the drains are generally removed by the third or fourth postoperative day. By this time, chest tube drainage is generally less than 100 mL/day. Some surgeons prefer to remove drainage tube earlier, by the second day.

An infrequent but life-threatening reaction soon after cardiopulmonary surgery is a protamine reaction. Parillo describes three kinds of reactions.[5] The first is caused by rapid administration of protamine; this leads to hypotension due to release of histamine from mast cells. The second is an anaphylactic reaction resulting in hypotension, bronchospasm and vasodilatory shock. Anaphylaxis is more frequently observed in diabetics exposed to protamine insulin and in patients with a history of fish allergy. Also, patients who have undergone cardiac surgery in the past are at greater risk. The third kind of reaction is due to heparin-protamine complexes causing a release of thromboxane from the capillary bed. This results in acute pulmonary hypertension, right-sided heart failure and a low-output syndrome with hypotension. Treatment consists in the use of steroids, antihistamines, inotropes, vasopressors and volume infusions. We are fortunate in not encountering serious life-threatening protamine reactions, or perhaps we have missed them, attributing hypotension and low-output states to other common causes.

CARDIOVASCULAR COMPLICATIONS

With cross-clamping of the aorta during CPB, coronary blood flow ceases, and there is global myocardial ischemia. Myocardial preservation is optimized by the use of potassium-rich cold cardioplegia at 4°C, administered directly into the coronary arteries every 20–30 minutes. The shorter the cross-clamp time, the quicker the recovery of the myocardium after bypass. Cross-clamp time of 120 minutes or even more is well tolerated, particularly by patients with good preoperative left ventricular function. Even so, there is a significant degree of transient depression in myocardial function, which may last

from 6 to 12 hours. This depression is often more marked and longer lasting if the cross-clamp time is excessive, particularly in patients who have poor left ventricular function to start with.

The important cardiovascular complications are discussed below.

Low-Output Syndrome and Hypotension

This is one of the most frequently observed and important complications after open heart surgery. A persistent low cardiac output in the immediate postoperative period is associated with an increased frequency of multiple organ dysfunction, chiefly involving the renal, respiratory, hepatic and central nervous systems. It is clinically manifested by cold peripheries, low systolic arterial blood pressure (<90 mm Hg), decreased urine output (<30 mL/hour) and increasing acidosis. If hemodynamic measurements are made, these patients are noted to have a lowered cardiac index (often <2.2 L/minute) and a low mixed venous oxygen saturation.

There are two points worth noting in the recognition of low-output states—

1. Low-output states can occur with a systolic arterial blood pressure more than 90 mm Hg when a compensatory increase in peripheral vascular resistance helps to maintain arterial blood pressure.
2. It is important to distinguish hypotension caused by low-output states from hypotension due to vasodilatation.

Hypotension due to vasodilatation generally occurs in the first 24 hours after surgery. Vasodilatation results from decreased sympathetic tone leading to a reduced peripheral systemic vascular resistance (<1,000 dynes/sec/cm^5). It should be suspected when hypotension is associated with warm peripheries and a normal to low CVP. Inhibition of sympathetic tone may be due to anesthetic agents used during surgery, and to a marked increase in venous capacitance that occurs during the rewarming phase. Patients after CABG surgery are often shifted to the ICU with a nitroglycerine infusion to counter postoperative coronary vasoconstriction. The infusion may be too rapid, or the vessels may vasodilate due to marked sensitivity to the drug. At times, vasodilatation is aggravated if the patient is on continuous dobutamine support. In the above instance, nitroglycerine infusions must be slowed or stopped and dobutamine replaced by dopamine. If both dopamine and dobutamine are being used for inotropic support, infusion rate of the former is increased and that of the latter reduced. Volume loading these patients further helps in restoring a satisfactory circulation.

Vasodilatation in the immediate postoperative period can occasionally also result from an adverse protamine reaction. Hypotensive vasodilatory shock after cardiac surgery has been attributed in some patients to a relative deficiency of vasopressin.[6] Administration of arginine vasopressin corrects this form of hypotension.

Low-output states can be due to reduced preload, to poor myocardial contractility, to an increased afterload, to cardiac tamponade, cardiac arrhythmias, to metabolic derangements or to the adverse effects of antiarrhythmic drugs. Fulminating sepsis can also result in a low-output severely hypotensive shock (Box 1).

Box 1: Causes of a low-output syndrome and/or hypotension

1. Reduced preload—
   - Hypovolemia due to blood loss, fluid loss, excessive diuresis
2. Increased afterload—
   - Vasoconstriction from increased endogenous catecholamine secretion
     - Painful stimuli
     - Hypothermia
     - Pre-existing hypertension
   - Vasoconstriction from excessive exogenously administered catecholamines
3. Poor pump function—
   - Myocardial depression (impaired contractility)—
     - Perioperative infarction
     - Functional depression (<24 hours)
     - Myocardial ischemia
     - Inadequate myocardial preservation, intraoperatively
     - Pre-existing poor ejection fraction
     - Uncorrected mechanical lesions
     - Incomplete vascularization
     - Mechanical valve dysfunction
     - Undetected or uncorrected valvular stenosis or insufficiency
   - Metabolic complications—
     - Hypo- and hyperkalemia
     - Hypomagnesemia
     - Hypercalcemia
     - Hypoxia, acidosis
4. Arrhythmias and conduction defects
5. Antiarrhythmic drugs
6. Cardiac tamponade
7. Vasodilatation—
   - Due to anesthetic agents
   - Iatrogenic (e.g. nitroglycerine)
   - Poor sympathetic tone (e.g. diabetes, elderly)
   - Relative deficiency of vasopressin
   - Protamine reaction
   - Anaphylaxis to a drug
8. Fulminant septic shock

It is important to consider each of these factors if appropriate treatment is to be administered. More than one factor is often present in a given patient—

- *Reduced preload* The commonest cause of a low cardiac output and hypotension in the postoperative period is a reduced preload due to hypovolemia. Hypovolemia is due to excessive bleeding, loss of tissue fluids and/or excessive diuresis. Hypovolemia immediately after transfer to the ICU can be due to insufficient return of fluids during CPB. It can also occur from leaking capillaries, a feature of the post-pump syndrome. Cold peripheries, hypotension, tachycardia, a normal rectal temperature and a low CVP

(<5 cm H_2O) suggest hypovolemia. If a pulmonary artery catheter is in place, the pulmonary artery occlusion pressure (PAOP) and pulmonary artery diastolic pressure are low—often less than 10 mm Hg. Hypovolemia is corrected by infusion of colloids, crystalloids, and by the transfusion of packed red blood cells if there is increased blood loss. In addition to a volume load, the patient is often also put on inotropic support.

- *Poor pump function* Poor pump function may be due to left ventricular dysfunction and failure, or due to right ventricular dysfunction and failure, or may result from a global hypokinesia. When severe, pump dysfunction leads to cardiogenic shock. As mentioned earlier, poor pump function may not be related to an intrinsic abnormality within the myocardium but to metabolic disturbances, to arrhythmias, and to the effect of antiarrhythmic drugs. Impaired ventricular function after CABG surgery can be due to perioperative or postoperative myocardial infarction or severe ischemia, to inadequate revascularization at surgery, or the post-CPB reperfusion injury. Some degree of postoperative functional myocardial depression is at times observed, particularly after prolonged or difficult cardiac surgery. This generally lasts for not more than 24–36 hours. Myocardial edema, ischemia and even myocardial necrosis can result from inadequate myocardial preservation during surgery. After valve replacement surgery, pump dysfunction with a low-output syndrome can result from mechanical valve dysfunction. Severe left ventricular failure besides causing a low-output syndrome with hypotension also results in an increased pulmonary capillary wedge pressure and pulmonary edema. This is recognized clinically on a chest X-ray and by noting a progressive increase in the peak inflation pressures while on the ventilator without any change in the ventilator settings.

  Severe right ventricular failure and global hypokinesia are characterized by a poor forward flow and poor tissue perfusion, but not necessarily by increased left ventricular filling pressures (i.e. increased pulmonary capillary wedge pressures).

  The management of poor pump function is dealt with in a previous chapter, but is briefly recapitulated below for convenience.

- Ensure that the left ventricular filling pressure is maintained between 15 mm Hg and 20 mm Hg. Associated hypovolemia is thus countered by a volume load.
- If a low-output syndrome with hypotension is observed in the presence of high filling pressures, use inotropic support to an extent that ensures a satisfactory increase in the cardiac output and blood pressure. A continuous infusion of dopamine 5–20 μg/kg per minute helps to raise cardiac output and blood pressure. Dobutamine has little α-adrenergic activity but pronounced β_1 and β_2 adrenergic activity. It increases cardiac output by increasing cardiac contractility and rate and by its vasodilating effect. In patients with a low-cardiac output and a marked increase in systemic vascular resistance, dobutamine is preferred to dopamine. Dobutamine is given in an infusion at 5–20 μg/kg per minute. Dopamine and dobutamine can be given together but in separate infusions, the dosage of each being titrated to obtain an optimal circulatory effect. When dopamine and/or dobutamine are ineffective, an epinephrine infusion is used in a dose of 1–10 μg/minute. Epinephrine increases myocardial contractility and rate and in higher doses raises the blood pressure through its α-mediated vasoconstrictor effect on peripheral vessels. Norepinephrine which has both α- and β-adrenergic activity increases both myocardial contractility and blood pressure. It is given in an infusion at the rate of 4–10 μg/minute. Amrinone and milrinone are two inotropic drugs which increase cardiac output independent of adrenergic stimulation. Milrinone is an effective vasodilator as well, and should be tried in patients with low-cardiac output who are severely vasoconstricted. The drug is given in a loading dose of 50 μg/kg over 10 minutes, followed by an infusion of 0.375–0.75 μg/kg per minute.

  In difficult cases, two or more inotropes and vasopressors may prove necessary to increase cardiac output and blood pressure.

- Severe right ventricular failure can result in a markedly poor forward flow and a shock-like state. Though right atrial and CVPs are elevated, pulmonary capillary wedge pressures need not be high. Volume load and inotropic support as outlined earlier form the mainstay of management.
- Intravenous frusemide should be used in the presence of pulmonary edema.
- A low-cardiac output with hypotension can result from a marked increase in the systemic vascular resistance (afterload). An increase in the afterload could be due to excessive endogenously produced catecholamines resulting from unrelieved pain, hypothermia, non-pulsatile flow during CPB, or pre-existing hypertension. An increased afterload can also be caused by exogenously administered vasopressors.

  Factors contributing to an increased afterload should be corrected when possible. A titrated dose of IV nitroglycerine or IV nitroprusside also reduces afterload. The current trend is to avoid using nitroprusside except in patients with marked hypertension unresponsive to nitroglycerine and other anti-hypertensive drugs.

- Hypoxia, metabolic acidosis and electrolyte imbalance, notably in relation to K^+, Mg^{++}, Ca^{++} can aggravate or cause myocardial dysfunction. These factors should be recognized and corrected. Antiarrhythmic drugs are myocardial depressants and may well contribute to myocardial dysfunction.
- Shock-like syndromes after cardiac surgery may be due to rhythm disturbances and should be promptly rectified. These may be missed, as with supraventricular

tachycardias with A-V block, or in A-V dissociation with a fast atrial and ventricular rate. Loss of effective atrial contraction may tilt the balance against the patient.

- Bradycardia can lead to a low-cardiac index and hypotension. This is because the cardiac output is a product of the stroke volume and heart rate. IV atropine or atrial or atrioventricular (AV) pacing at 80–100/minute can restore a normal circulatory state.
- Cardiac tamponade is an important cause of a low output hypotensive syndrome.
- Myocardial assist devices become necessary for cardiac support if poor pump function persists after optimizing rate, rhythm, preload, myocardial contractility, afterload, and if factors such as metabolic disturbances, arrhythmias and drug reactions are non-existent or stand corrected. Intra-aortic balloon pump support reduces the afterload of the left ventricle and helps to relieve myocardial ischemia. Patients with very poor ejection fractions who undergo CABG surgery or those who suffer complications during surgery should best have a balloon pump inserted in the theater before transfer to the ICU. Ventricular assist devices are more effective in increasing cardiac output as compared to the aortic balloon pump but we have no experience with these devices.

In summary, though a volume load and the use of inotropes is the usual response to a low output state and/or hypotension, it is important to tailor therapy appropriate to the cause. Thus, for example, the steps detailed above would provide only temporary respite in a patient whose low-cardiac output is due to tamponade or to graft closure.

- *Septic shock* Hypotension with a shock-like state which to start with is associated with a normal or high cardiac output and a lowered systemic vascular resistance, characterizes septic shock. This condition has been dealt with at length in an earlier chapter. Sepsis may occur within the first 48 hours after surgery, or may occur later and interrupt an otherwise satisfactory progress. Sepsis may arise from a source in the operation theater, or may be related to gadgetry used for invasive monitoring and treatment. Occasionally, it results from a seeding into the blood from a source of infection within the body, e.g. from the urinary tract, the lungs, an infected anal fistula, or an infected pilonidal sinus. It should be a dictum to avoid cardiac surgery till such time as a pre-existing infection is appropriately treated. Patients running even a low-grade fever should not be taken for elective cardiac surgery till the cause of the fever is discovered and eradicated.

In critically ill, low-output hypotensive patients' management is significantly assisted by monitoring and measurement of circulatory hemodynamics through a Swan-Ganz catheter.

Cardiac Tamponade[7]

Hemodynamic instability in the postoperative period should promptly arouse suspicion of possible cardiac tamponade. Hypotension, a low CO, tachycardia with shock-like state and evidence of a rise in the right or left or both atrial pressures should lead to a prompt ECHO study to help confirm the diagnosis. Cardiac tamponade is usually caused by a leak at the site of right atrial cannulation; the resulting hematoma compresses the right atrium and superior vena cava, restricting inflow of blood into the right atrium. There is a progressive elevation of right atrial and CVP with a fall in cardiac output, tachycardia and hypotension. A rising right atrial pressure with an impaired filling of the right ventricle leads to a loss of the Y-descent in the right atrial pressure tracing. Equilibration of pressures in the right and left heart may not be observed when tamponade is due to a localized hematoma pressing upon the right atrium. Exploration to remove the hematoma is mandatory.

Cardiac tamponade due to pressure on both right and left ventricles can occur with mediastinal bleeding or from an extension of the right atrial hematoma over the front of the heart, or from a leak at the anastomotic site of a graft in CABG surgery. In addition to the clinical features of hypotension and raised CVP, there is invariably a widening of the mediastinal shadow. Cardiac tamponade should always be thought of when brisk bleeding and drainage through the chest tubes suddenly lessen or cease and the X-ray chest shows a widened mediastinum. Tamponade can well occur even in the presence of well-placed mediastinal drains. An increasing mediastinal shadow on chest X-ray, a diastolic collapse of the right atrium and right ventricle on echocardiography, coupled with the clinical findings stated above is diagnostic of cardiac tamponade. These patients would show equilibration of the right and left heart pressures on a hemodynamic study. A volume load and inotropic support should be given and the patient promptly taken up for surgery in order to remove clots and blood causing the tamponade.

Perioperative Myocardial Infarction

The recent Bypass Angioplasty Revascularization Investigation study revealed that the incidence of Q-wave infarction after bypass surgery was 4.6%.[8] Possible causes of infarction include incomplete revascularization, hemodynamic stress (in particular, hypotension and arrhythmias) during surgery, or during intubation, diffuse atherosclerotic disease of distal vessels, formation and extension of a clot in an endarterectomized coronary vessel, coronary artery spasm, embolism or thrombosis of native coronary vessels or bypass grafts.[9,10]

The diagnosis of perioperative myocardial infarction is based on the following—

- Appearance of new Q-waves after surgery. ST-T changes occurring alone without Q-waves are less specific.
- Creatine kinase-myocardial band (CK-MB) levels which are significantly or markedly elevated (>80 mg/dL).[11] A mild to moderate degree of rise in CK-MB is to be expected after cardiac surgery, without signifying a fresh infarction.
- Peak troponin I levels greater than 3.7 µg/L and troponin T levels greater than 3.4 µg/L.[12,13]

- The presence of a new regional wall abnormality on echocardiography. It is worth noting that the removal of the restraining effect of the pericardium consequent to surgery may lead to a false positive reading of a new regional wall motion abnormality in the high anterior septal area.

Small perioperative myocardial infarcts do well; larger infarcts have a high postoperative mortality which may be due to pump failure or due to uncontrolled ventricular arrhythmias. Patients, who are hemodynamically unstable or those with a large area of the myocardium in jeopardy, should be taken to the catheterization laboratory to determine if a graft is occluded. If so, the graft should be opened up through a balloon plasty.

Cardiac Arrhythmias[14]

Postoperative cardiac arrhythmias are common. They should be promptly recognized and treated. Hypokalemia, hyperkalemia, acidosis, bleeding, poor pump function, ongoing myocardial ischemia, or perioperative myocardial infarction can all trigger arrhythmias in these patients. These precipitating factors should be looked for and, if present, promptly corrected. Excessive use of inotropics for cardiovascular support is an often forgotten cause of malignant ventricular arrhythmias. Nebulization of large doses of salbutamol in patients with airways obstruction can enhance supraventricular and ventricular arrhythmogenic activity in the postoperative phase of open heart surgery. Arrhythmias are commoner and more persistent in patients who have had an aneurysmorrhaphy or an aneurysmectomy performed during CABG surgery.

Arrhythmias may be supraventricular or ventricular. Premature atrial contractions may be ignored except when they trigger repeated episodes of atrial fibrillation, or compromise circulation in patients who depend on a synchronized atrial contraction for a proper stroke volume. Cordarone should be used to suppress ectopic activity in these patients.

Paroxysmal atrial fibrillation is frequently observed, generally occurring 2–3 days after open heart surgery. It often reverts to sinus rhythm spontaneously. In a recent multicenter study of patients undergoing CABG surgery, the incidence of atrial fibrillation was noted to be 27%.[15] The most common risk factor for peri- and postoperative atrial fibrillation is advanced age. If atrial fibrillation with a fast ventricular rate persists and compromises circulation, then the ventricular rate should be slowed. 300 mg of IV amiodarone is administered as a bolus, followed by an IV infusion of 700 mg–1 g of amiodarone over 24 hours. Conversion to sinus rhythm is frequently observed. The dose of amiodarone is gradually reduced over the next 2 days, oral amiodarone being finally substituted for the infusion as prophylaxis. IV digoxin, followed, if necessary, by 5 mg increment doses of verapamil can also be administered to slow the ventricular rate in atrial fibrillation (see Chapter Tachyarrhythmias in the Intensive Care Unit). Electrical cardioversion is unnecessary in most patients. It should only be used in the presence of acute decompensation caused by a very rapid ventricular rate, which is uncontrolled by IV digoxin. Repeated episodes of paroxysmal atrial fibrillation or persistent atrial fibrillation in the postoperative phase may be due to pericarditis or pulmonary emboli. IV dexamethasone 4–8 mg offers dramatic relief and a return to sinus rhythm when the underlying cause is pericarditis. Supraventricular arrhythmias are perhaps more frequent in patients who have had an endarterectomy of the right coronary artery during CABG.

Transient second and third degree AV blocks are common after valve surgery. These are best treated with the aid of atrial and ventricular epicardial pacing wires placed during surgery. AV sequential pacing at a rate of 80–100/minute is preferred because of the contribution of atrial systole to cardiac output.

Ventricular arrhythmias are life-threatening. Ventricular tachycardia, not responding to a bolus dose of lidocaine, and which results in hemodynamic instability, should be converted to sinus rhythm by a synchronized DC shock of 200 J. Ventricular fibrillation needs prompt cardioversion. If 200 J is unsuccessful, a 300 J DC shock should be used. A bolus dose of lidocaine (1–2 mg/kg) is given after cardioversion in ventricular fibrillation; this is followed by a maintenance lidocaine drip at the rate of 1–3 mg/minute. Frequent ventricular ectopy is also treated with lidocaine as detailed above. If this drug fails to control multiple ventricular ectopics, or the patient has recurrent ventricular tachycardia or fibrillation, amiodarone 300 mg intravenously is given as a bolus dose followed by 1 g in an infusion over 24 hours. This is continued for 2–3 days, and followed by oral amiodarone. Currently, amiodarone is used in preference to lidocaine and is the drug of choice in the treatment of ventricular tachycardia (see Chapter Tachyarrhythmias in the Intensive Care Unit). The use of beta-blockers (metoprolol) administered intravenously in a titrated dose often restores sinus rhythm in ventricular tachycardia unresponsive to lidocaine or amiodarone. Rarely overdrive pacing may be required for control of persistent or recurrent ventricular tachycardia.

In patients who have received digitalis, digitalis toxicity should always be considered in the presence of multiple ventricular ectopics, atrial tachycardia with block, AV dissociation and ventricular tachycardia. Digitalis toxicity can occur even with serum digoxin levels within the therapeutic range. Details of management of various cardiac arrhythmias have been dealt with in an earlier chapter (see Chapter Tachyarrhythmias in the Intensive Care Unit).

Pericarditis

Pericarditis is common in the first 3–7 days following CPB. A pericardial friction rub is always present, and may persist for over 5–7 days. In the asymptomatic patient, no treatment is required. Symptoms of the post-pericardiotomy syndrome generally occur 2–8 weeks after open heart surgery. Symptoms include fever, tachycardia, chest pain, a raised erythrocyte

sedimentation rate (ESR) (often close to 100 mm/hour), a left-sided pleural effusion, occasionally a pericardial rub, and a tendency to supraventricular arrhythmias. The clinical condition improves with the use of nonsteroidal anti-inflammatory agents, particularly indomethacin. If the condition still persists, we prefer a short course of corticosteroids; a small maintenance dose may be required for weeks or months. Rarely constrictive pericarditis is a sequel to the post-pericardiotomy syndrome.

Postoperative Hypertension

The incidence of postoperative hypertension with a systolic blood pressure more than 140–150 mm Hg occurs in over 40% of patients.[16]

The mechanisms of postoperative hypertension include: (1) elevated circulating catecholamine levels with excessive sympathetic nervous system activity; (2) rebound effect from withdrawal of preoperatively given beta-blockers; (3) pressor reflexes originating from the heart, coronary vessels and the aorta. Postoperative hypertension should be controlled promptly. Increase in systemic arterial blood pressure, which is most often seen in the immediate postoperative period, can cause an increase in postoperative bleeding, disruption of suture lines of the grafts, aortic dissection, increase in afterload with ventricular dysfunction, and an increased incidence of strokes. A mild to moderate rise in blood pressure is best treated with a titrated dose of nitroglycerin in an IV infusion. A sharp marked rise in blood pressure is treated with a titrated IV infusion of labetalol or sodium nitroprusside. Hypertension and tachycardia following beta-blocker withdrawal is treated with IV esmolol 50–250 µg/kg per minute or IV metaprolol. The need for oral antihypertensives after the first 2 days should be assessed for each patient. Oral beta-blockers should be restarted in patients who were on these drugs prior to surgery. They effectively control the hypertension and tachycardia in these patients.

RESPIRATORY CARE

Patients are generally weaned off ventilator support within 4–12 hours. Low risk, younger patients undergoing CABG surgery are often extubated in the recovery room before being transferred to the ICU. The indications for weaning are the same as those discussed in the Chapter Mechanical Ventilation in the Critically Ill. The patient must be awake, hemodynamically stable with no significant abnormality on an X-ray chest. He should not be tachypneic on disconnecting the ventilator, and the blood gases after being kept on a T-tube for 2 hours should show neither hypoxia nor hypercapnia. He could then be extubated. Pain relief is important to enable the patient to breathe freely. He should be given oxygen through nasal prongs so as to keep the O_2 saturation well over 90%. We have always weaned patients by the T-tube method and have never found the need to use synchronized intermittent mandatory ventilation (SIMV). In patients who are difficult to wean because of atelectasis or edema, we use continuous positive airway pressure (CPAP) before graduating to the T-tube, CPAP or biphasic positive airway pressure (BiPAP) through an orofacial mask can be continued after extubation. Patients with poor left ventricular function [left ventricular ejection fraction (LVEF) <20%)] those with respiratory complications, or serious complications involving other organ systems, are kept on ventilator support for 24–48 hours, or even longer. It is unwise to remove support prematurely in these patients. The increased work of breathing in hemodynamically unstable patients can induce respiratory fatigue, hypoventilation and atelectasis with a progressive deterioration in the cardiorespiratory system.

More prolonged ventilator support is often necessary in those with chronic lung disease, particularly those patients with airways obstruction. If case selection has been correct, these patients generally can be weaned off support within 12–48 hours. Nebulization with salbutamol 4–6 hourly and ipratropium bromide 12 hourly is of help in keeping the airways open. A marked difference between the peak and pause inflation pressures is a guide to the severity of airways resistance. Corticosteroids should be avoided except in patients who are steroid-dependent, or in patients with asthma, who have a severe exacerbation of airways obstruction after surgery. The arrhythmogenic effects of beta-2 agonists and aminophylline in these patients should be borne in mind. The dangers of wound sepsis, other infections, and poor healing always accompany the use of corticosteroids.

Factors predisposing to prolonged ventilator support with difficulties in weaning are listed in Box 2.

Box 2: Factors predisposing to prolonged ventilator support with difficulties in weaning following open heart surgery

- Stormy postoperative period
- Re-exploration
- Left ventricular (LV) dysfunction
- Renal failure
- Infection (sepsis, pneumonia)
- Malnutrition
- Chronic airways obstruction
- Injury to phrenic nerve
- Aged, debilitated, poor-risk patients
- Multiple organ dysfunction/failure
- Stroke/encephalopathy

PULMONARY COMPLICATIONS

These include pulmonary edema, acute respiratory distress syndrome (ARDS), atelectasis and nosocomial pneumonia.

- Pulmonary edema is generally due to raised left ventricular filling pressures consequent to left ventricular failure. Acute lung injury (ARDS) can occasionally result as a consequence of CPB even in the absence of infection or transfusion reactions. It is due to exposure of blood to foreign surfaces during prolonged CPB. Damage to the

alveolar capillary membrane is induced by clumping of platelets, leucocyte sequestration and activation of the coagulation cascade, the complement and the fibrinolytic system. The mortality against the background of recent cardiac surgery is over 70%.[17] Risk factors include hypertension, smoking, emergency surgery and a low-output syndrome after surgery.[18]

- Pulmonary atelectasis invariably occurs because of poor respiratory care leading to retained respiratory secretions. Good physiotherapy, proper suction and frequent change of posture are necessary, particularly in obese patients with short, thick chests. The use of positive end-expiratory pressure (PEEP) during ventilator support is of help in opening up atelectatic areas.

  The commonest cause of perioperative respiratory failure (Type III failure) is atelectasis. Atelectasis may present with obvious atelectatic shadows in one or both lung fields. It, however, often presents with small volume lungs on an X-ray chest with high diaphragms. The small lung volumes on either side need not be symmetrically equal. Clinically, the patient is tachypneic off the ventilator, breathes poorly, coughs poorly and ineffectively. This problem in our experience is commoner in females, particularly those with short, stocky chests. Ventilator support for a longer period with the use of PEEP helps to keep the lungs open. Physiotherapy and pain relief help in breathing and clearing secretions. After extubation these patients should be given either CPAP or BiPAP through the night and for several hours during the day to keep the lung volumes from shrinking.
- Nosocomial pneumonias are infrequent in our set-up. Remarkably enough, the incidence is higher in those with poor left ventricular function (see Section Fever and Acute Infections in a Critical Care Setting).
- Pleural effusion is common after cardiac surgery; it generally resolves spontaneously and should be tapped only if it produces symptoms. Rarely pleural effusion of moderate severity persists for weeks or months after CABG surgery. Infection, in particular tuberculosis, should be excluded. When noninfective and persistent, a pleurodesis generally solves the issue.
- *Diaphragmatic paralysis* Partial paralysis is frequent on the left side and is due to phrenic nerve injury or due to freezing of the phrenic nerve because of the ice slush used for myocardial preservation. The raised left dome of the diaphragm is generally not associated with increased morbidity. In a very small number of these patients, total one-sided diaphragmatic palsy may be symptomatic, in that it can cause left lower lobe atelectasis and pose problems in weaning from ventilator support. A paradoxical movement of the dome of the diaphragm on sniffing confirms diaphragmatic paralysis. Ventilator support may be required for a longer period of time in these patients. Bilateral phrenic nerve injury with diaphragmatic palsy occurs even more rarely. The patient becomes cyanosed on lying down and is promptly relieved on sitting up. We have had three patients with bilateral diaphragmatic paralysis following open heart surgery. Recovery occurred over a period of 6–10 weeks, during which time mechanical ventilator support was necessary.

If ventilator support is necessary for more than 14 days, an elective tracheostomy becomes necessary. The danger of sternal wound infection following a tracheostomy always exists, and this could involve the mediastinum to produce mediastinitis, mediastinal abscess, empyema, and a communication between the empyema and the mediastinal abscess. These complications are fraught with great danger and result in a very high morbidity and mortality. It is therefore unwise to do a tracheostomy when the sternal wound shows signs of infection. As far as possible, the operative wound must be clean and well healed before tracheostomy is advised for prolonged ventilator support.

NEUROLOGICAL COMPLICATIONS[19]

Cerebrovascular accidents manifesting as transient ischemic attacks or strokes are an ever present danger of open heart surgery. Massive cerebral or brainstem infarction or a massive bleed must always be suspected if the patient does not recover from anesthesia, and if the possibility of hypoxic brain damage is unlikely because of a smooth intraoperative and immediate postoperative course. If possible, patients who are unresponsive for 48 hours following surgery are sent for computed tomography (CT) scanning to determine the presence of organic disease or cerebral edema. Mannitol 150 mL 8 hourly intravenously, dexamethasone 4 mg intravenously 6 hourly and hyperventilation to allow a $PaCO_2$ of around 25 mm Hg are tried to counter increased intracranial pressure. Unfortunately, the patient with focal or global cerebral damage is diagnosed too late for any therapeutic measures to be effective. Risk factors for cerebrovascular accidents include the presence of preoperative carotid bruits, previous history of a cardiovascular accident or a transient ischemic episode,[20] postoperative atrial fibrillation,[21] and prolonged CPB. Patients with symptomatic carotid bruits caused by significant carotid artery stenosis have successfully undergone carotid endarterectomy with their cardiac surgery in a single operative session.

Spinal ischemia can occur after cross-clamping the thoracic aorta for repair of an aneurysm of the descending aorta. Encouraging results have been obtained by drainage of the cerebrospinal fluid and intrathecal injection of papaverine.[22]

Rarely rib resection during a thoracotomy can produce a hematoma causing compression of the thoracic spinal cord. This may present with paraplegia or a Brown-Séquard syndrome. A CT scan or a magnetic resonance imaging (MRI) can prove the diagnosis; compression should be relieved by surgery.

Box 3: Causes of cerebrovascular accident after cardiac surgery

Embolism—
- Debridement or replacement of calcified aortic valve
- Dislodgement of atherosclerotic plaque during aortic cannulation
- Introduction of air into circulation during surgery
- Atrial fibrillation
- Thrombosis of mechanical prosthetic valve
- Thrombus within the left ventricle
- Dislodgement of fragment of left atrial myxoma

Hemorrhage—
- Perioperative anticoagulation
- Hypertension

Infarction—
- Cerebral hypoperfusion while on CPB or during period of postoperative shock particularly when this occurs against a background of cerebral atherosclerosis or carotid or vertebral artery stenosis

Neuropathies in the upper limbs chiefly involving the ulnar nerve can occur following brachial plexus compression or traction injury. Recovery generally ensues in 2 months but may take as long as 9 months to a year. Box 3 lists the causes of cerebrovascular accidents following bypass surgery.

GASTROINTESTINAL COMPLICATIONS

These are rare but carry a high mortality. Ileus is often present for a few days if the gastroepiploic artery is used for revascularization. In patients with diffuse atherosclerotic disease, mesenteric ischemia may lead to the picture of an acute abdomen. This is particularly seen in hypoperfusion states and in surgery on the abdominal aorta. Acute pancreatitis possibly related to hypoperfusion may occur suddenly and can lead to rapid deterioration in the clinical state. A high index of suspicion is necessary for a diagnosis. The diagnosis should not be solely based on high serum amylase levels as these are observed in over 30% of patients undergoing CPB. Elevated serum lipase levels in conjunction with the clinical picture are of greater help in diagnosis. In patients with a low-output syndrome, which is severe or long-lasting, liver cell dysfunction is observed with marked elevation of the enzymes and a rise in bilirubin. This shock-liver syndrome improves if cardiac output, arterial blood pressure and tissue perfusion recover. Acute noncalculous cholecystitis often attributed to visceral hypotension, is a rare but important complication within the first week after surgery. It is characterized by pain and tenderness in the right hypochondrium, increase in liver enzymes and fever. The diagnosis can be confirmed by ultrasound examination. The overall mortality in these patients is over 30%,[23] the gall bladder being frequently gangrenous on explorative surgery. Gastrointestinal bleeds from acute erosions or ulcers are common, particularly in patients with a prolonged stormy postoperative course, in those who are septic, and following the use of corticosteroids. Most patients should receive sucralfate. H_2-antagonists or proton pump inhibitors are specifically indicated for high-risk patients and to counter GI bleeds. Table 1 lists the causes of some common GI complications seen after cardiac surgery.

Table 1: Common causes of gastrointestinal (GI) complications after cardiac surgery

Complications	*Common causes*
Elevated serum bilirubin—	
• Early (1–10 days)	• Hemolysis during cardiopulmonary bypass (CPB) • Shock-Liver Syndrome • Right-sided heart failure
• Late (10–90 days)	• Infection [Cytomegalovirus (CMV) or Hepatitis C virus)] • Cholecystitis
GI bleeds	• Stress gastric erosions or ulcerations • Peptic ulcer disease
Mesenteric ischemia	Low cardiac output, embolic or due to thrombi, or vascular dissection by intra-aortic balloon pump (IABP)
Pancreatitis	Hypotension, splanchnic vasoconstriction
Ileus	Use of gastroepiploic artery for revascularization; related to mesenteric ischemia
Acute noncalculous cholecystitis	Probably related to hypoperfusion

RENAL COMPLICATIONS[24]

Acute oliguric failure after open heart surgery is rare (0.7–4.3%) but carries a grave risk and a high mortality. The incidence of a quickly rising creatinine, oliguria, anuria, the need for dialysis, and the occurrence of other complications is higher when preoperative serum creatinine levels are beyond 1.7 mg/dL.[25] The occurrence of oliguric renal failure after open heart surgery often precipitates fluid overload and pulmonary edema. Early use of continuous arteriovenous hemofiltration to remove excess fluid is always indicated in these patients. Three patterns of renal failure are generally observed. The first occurs as a result of a renal insult at or soon after surgery. It is characterized by a rise in serum creatinine from the second to the fifth postoperative days. Renal function then improves and serum creatinine levels return to normal over a week. During the phase of impaired renal function, it is important to omit as far as possible all nephrotoxic drugs, in particular, nonsteroidal anti-inflammatory agents and aminoglycosides. The second pattern is characterized by a more prolonged course of acute renal failure. It occurs in patients, who, in addition to a perioperative renal insult, have hemodynamic instability and poor tissue perfusion in the initial postoperative phase. Recovery of renal function occurs after 3–4 weeks. The last and the most serious pattern of renal

failure is when complicating sepsis or a massive GI bleed is an added insult to early circulatory disturbances. This form of failure is often seen in patients who develop multiple organ failure, and carries a high mortality.

The principles of management of acute renal injury have been discussed in another chapter (see Chapter Acute Kidney Injury). We prefer to use continuous arteriovenous hemofiltration rather than hemodialysis in our patients of acute renal failure. We initiate hemofiltration early in the natural history of the disease.

INFECTIOUS COMPLICATIONS

These include wound infections, urinary tract infections, pneumonia and sepsis. Gram-negative organisms [very often extended spectrum beta-lactamases (ESBLs)] are most frequently encountered. Staphylococcal infections are also observed. A nasty nosocomial wound infection is indeed a dreaded complication of open heart surgery. Healing may be protracted and difficult. In the worst scenario, the sepsis syndrome with multiple organ failure results. At times local dehiscence may cause a total separation of the sternal wound with exposure of the mediastinum. Wound infections often necessitate prolonged ventilator support. Healing of infected wounds is doubly difficult in patients with poor pump function. The risk of nosocomial wound infection in the unit is significantly increased if there is even one patient with severe wound infection, who continues to need prolonged critical care within the unit.

Local attention to the wound should be left to the surgical team. Appropriate cultures of discharge from the wound should guide systemic antibiotic therapy. Mediastinitis, mediastinal abscess, pleural effusion (unilateral or bilateral), empyemas may all complicate a bad sternal wound infection. These need to be diagnosed and surgically treated. Wound infections are further discussed in a separate chapter (see Section Surgical Infections in the Intensive Care Unit).

INFECTIVE ENDOCARDITIS

Prosthetic valve endocarditis is a rare complication of cardiac surgery, occurring in 2–4% of patients. Half of these are classified as early (<60 days after surgery), and half as late cases (>60 days following surgery). Early endocarditis is most often due to *Staphylococcus aureus (S. aureus)*,[26] and then in descending order of frequency, to Gram-negative bacilli, diphtheroids and fungi. Late endocarditis is more often due to the streptococcus species, and the microbiologic spectrum causing infection is similar to that observed in native valve endocarditis. Mechanical valves typically show a ring abscess or a myocardial abscess, whereas infected porcine valves show stenosis or regurgitation. Antibiotic therapy depends on the organisms grown on blood culture. The regime against early endocarditis should include vancomycin to cover methicillin-resistant staphylococci. Indications for surgery include prosthetic valve dysfunction, myocardial abscess, perivalvular infection and abscess, persistently positive blood cultures, relapse after antibiotic therapy, embolic episodes and cardiac dysfunction or failure.[27]

PERIPHERAL VASCULAR COMPLICATIONS AND PULMONARY EMBOLISM

Embolic or thrombotic occlusion of vessels in the limbs, (particularly the lower limbs), may occasionally occur. Thrombectomy or revascularization surgery of the lower limbs may be necessary to salvage the limb. Heparinization is indicated.

Deep vein thrombosis of the calves is a frequent complication. Rarely this may result in a massive pulmonary embolism. Sudden hypotension with a shock-like state occurring after the sixth day of surgery should suggest this complication. Major pulmonary embolism can be easily proven by a high-resolution computed tomography (HRCT) pulmonary angiography. Heparin in full doses, 5,000 units intravenously to start with, followed by 1,000 units/hour, to keep the PTT to 2–2.5 times normal should be given. Most intensivists prefer to use enoxaparin (low molecular weight heparin) 0.6 mg subcutaneous 12 hourly in preference to unfractionated heparin. Streptokinase is avoided in view of major surgery in the very recent past.

MULTIPLE ORGAN DYSFUNCTIONS

This is a rare but dreaded complication of open heart surgery. It can occur very rarely because of a systemic inflammatory response syndrome initiated during CPB. In these cases, it manifests initially with mild to moderate degree of acute lung injury (ARDS). Progressive multiple organ dysfunction is more likely to occur if the patient has suffered a myocardial insult resulting in a prolonged period of poor perfusion, during or after surgery. Provided there is scope for recovery of myocardial function, and there is no complicating sepsis, multiple organ failure in this situation does not carry the grim prognosis forecast by many workers in the West. We have had three patients who suffered an insult causing severe hypoperfusion before, during and after bypass surgery. They developed severe multiple organ failure involving all organ systems for more than 2 weeks, but still made a complete recovery. If severe sepsis complicates the above picture, then the prognosis is extremely grim, and death invariably results.

The Immunocompromised Patient

- The Immunocompromised Patient

CHAPTER 63

The Immunocompromised Patient

INTRODUCTION

Immunocompromised patients who get infections and are seriously ill under intensive care are under grave risk and have a far greater mortality as compared to patients with a normal immune status. It is almost certain that in years to come intensive care units (ICUs) will be populated by an increasing number of immunosuppressed or immunocompromised patients. The occurrence of infection in compromised patients reflects the interaction between these patients' immune defense system and their endogenous and exogenous microbial environment. It is impossible to discuss in detail the normal immune defense mechanisms in this chapter, but a brief outline of immune responses that help fight infection is of basic importance to doctors working in ICUs. This is because specific defects in the immune defense system predispose immunocompromised patients to certain specific infections. Unfortunately in acutely ill patients it is not always possible to quickly identify these specific deficits, nor is it advisable to perform elaborate tests to do so.

BASIC HOST DEFENSE MECHANISMS

Host defense mechanisms are complex interacting systems. These mechanisms chiefly include—

Inflammatory Response

Circulating phagocytes and, in particular, the neutrophils form the most important part of this inflammatory response. A wide variety of bacteria as well as fungi are capable of being ingested, digested and killed by neutrophils. Severe neutropenia strongly predisposes a patient to infection by Gram-negative and Gram-positive bacteria, especially *Pseudomonas aeruginosa*, *Klebsiella, Enterobacter* species, *Escherichia coli* and *Staphylococcus aureus*. Fungal infections, notably of the *Aspergillus*, *Candida* and *Mucor* species are also observed in neutropenic patients.

Complement System

The complement cascade especially C3a and C5a together with other mediators promotes and directs phagocytes to the areas of inflammation. If the organisms within the area of infection have been opsonized by complement or antibodies, phagocytosis and destruction of the organism are facilitated. A complement deficiency therefore also predisposes to bacterial infection, particularly of the *Neisseria* species.

Reticuloendothelial System

Circulating micro-organisms are cleared from the bloodstream by tissue phagocytes derived from circulating monocytes. The most important tissue phagocytes include the Kupffer cells in the liver, phagocytes in the spleen, lymph nodes, lung (alveolar macrophages), kidney (mesangial cells) and brain (microglial cells). Suppression or poor function of the reticuloendothelial system can lead to bacteremia and sepsis from exogenous and/or endogenous microbial flora.

IMMUNE RESPONSE

The B-cell lymphocyte response to infection is the production of antibodies (IgG, IgA, IgM, IgE) and the T-cell lymphocyte response leads to a cell-mediated immune defense. Humoral defense through antibody production and cell-mediated immunity are closely interrelated, inter-reactive and interdependent.

17

Humoral deficiency exposes the patient at times to overwhelming infection, particularly to *Streptococcus* and *Haemophilus influenzae pneumonia*.

Cell-mediated immune deficiency often renders the patient susceptible to protozoal, fungal, viral and rarer bacterial infections. Infections with *Pneumocystis*, *Toxoplasma gondii, Cryptococcus neoformans*, mycobacterial infections [tuberculosis and *Mycobacterium avium*-complex (MAC) infections], infections by the *Legionella* species, and by *Listeria monocytogenes* are observed in these patients. Viral infections include infections due to cytomegalovirus (CMV), herpes simplex and herpes zoster virus.

The following groups of immunocompromised patients are often seen in ICUs.[1]

Solid Organ Transplant Recipients

Most common in this group are patients who have received a kidney and liver transplant. In western countries, patients with heart, lung and pancreas transplants are also additionally seen. These patients are all immunosuppressed, as they must have lymphocyte depletion so that the transplants survive. They demonstrate an increase in suppressor T-lymphocytes and limited T-cell cytotoxic activity. In addition, they suffer from the effects of prolonged corticosteroid administration and the use of cyclosporine. Infection, sometimes sudden and overwhelming, is an important and dreaded complication in all organ transplant recipients. Different infections generally occur in different time frames (early or late after transplant) and this serves as a rough aid in diagnosis (see Chapter Critical Care of the Transplant Patient).

Hematopoietic Stem-Cell Transplant Recipients

Hematopoietic stem-cell (HSC) transplants are increasingly used as therapy for various hematological malignancies, hemoglobinopathies, immunodeficiency disorders and even for solid tumors. Autologous stem-cell transplant is associated with neutropenia as the primary immune defect. Allogeneic transplants lead to a broader range of immune defects with more wide-ranging complications.

Patients with Malignant Disease

Advanced malignancy leads to immunosuppression; lymphomas and, in particular, Hodgkin's lymphomas are also associated with immunosuppression of the cellular immune reaction.

Patients on Corticosteroid Therapy

Corticosteroids are amongst the most frequently used drugs in medicine, and the doctor in a critical care unit may be unaware of the history of corticosteroid ingestion by an acutely ill patient admitted as an emergency. Corticosteroids suppress the immune response and mask the underlying pathology and inflammation. Patients on maintenance steroid therapy for long periods of time may easily go into an acute adrenal crisis in the presence of overwhelming infection, if the attending doctor is unaware of the history of steroid ingestion, and if the dose of corticosteroids is not suitably increased during such a crisis.

Patients on Antimitotic Drugs

All antimitotic drugs are immunosuppressive and therefore predispose to infection. Cyclophosphamide and nitrogen mustard affect cell replication and bone marrow function. Antimetabolites affect and interfere with purine and pyrimidine metabolism, and prevent an adequate cellular immune response to infection.

Splenectomized Patients

These patients have an altered immune function. Immunoglobulin M (IgM) production in response to bacterial antigen is markedly slow, and patients are particularly prone to fulminant infections by *pneumococcus* and other encapsulated organisms.

Immune Suppression in Chronic Disease

This is one of the most important groups encountered in our ICUs, and includes patients with liver cirrhosis, liver cell failure, chronic renal failure, patients on chronic hemodialysis, severe diabetics, alcoholics and those with myeloproliferative disorders. In our country as well as in other third-world countries, poor nutrition is a frequent background factor against which many acute infections evolve. These patients are prone to acute infections and are more likely to die of these infections in ICUs.

Immune Suppression in Human Immunodeficiency Virus Infection

According to the WHO report in 2011, about 34 million people worldwide are infected with the human immunodeficiency virus (HIV), with nearly 90% of the infected residing in developing countries.[2] In 2009, it was estimated that 2.4 million people were living with HIV in India, which equates to a prevalence of 0.3%. While this may seem low, because India's population is so large, it is third in the world in terms of the greatest number of people living with HIV.

HIV causes depletion in T4 lymphocytes with a marked deterioration in cell-mediated immunity. The most serious feature of acquired immunodeficiency syndrome (AIDS) is the occurrence of infectious complications, particularly by opportunistic organisms.

APPROACH TO THE ACUTELY ILL IMMUNOCOMPROMISED PATIENTS

The following features are worthy of note—

- Acute infections in immunocompromised individuals can be sudden, overwhelming and rapidly fatal.
- The clinical manifestations of such infections are not usually of the same intensity and degree as compared

to those in patients with normal immune mechanisms. Diagnosis is doubly difficult because of the paucity of signs and the short time available between the onset of symptoms and possible death.

- Complications due to noninfective causes may interfere with the diagnosis of actual infection. For example, fluid overload, atelectasis and pulmonary infarction may cast lung shadows on an X-ray chest that may be mistaken for infection.
- The clinician must recognize that the immunosuppressed patient is exposed to, and is likely to be infected by two groups of microbial pathogens—
  - The usual pathogens which can also afflict immunocompetent patients.
  - Opportunistic organisms which invariably affect immunosuppressed patients only.
- The nature and specificity of infection to an extent is related to the degree of immunocompromised state. For example, in HIV patients, computerized tomography (CT) enhancing discrete brain lesion is more likely to be due to toxoplasmosis or central nervous system (CNS) lymphoma, whereas similar lesions in solid organ transplant patients are chiefly caused by filamentous fungi (e.g. *Aspergillus*). Also *M. avium* complex lesions occur more frequently in advanced AIDS, rather than in solid organ, hematologic transplant or in patients on corticosteroids.
- There are characteristic time windows during which specific pathogens generally cause infections in immunocompromised patients. This is elaborated upon later in this chapter.
- Early diagnosis is imperative as the likelihood of quick deterioration and death is often seen. An aggressive diagnostic methodology must prevail. Tissue diagnosis whenever possible obviates the need for the use of dangerous drugs.
- Treatment of acute infections in immunocompromised individuals in ICUs should be prompt. It is often empirical and tailored to counter more than one possible infection depending on the clinical picture, and on the background against which this picture evolves. Therapy for immunosuppressed patients often involves the use of drugs directed against opportunistic organisms, and is often different from therapy in acute infections afflicting patients with normal immunological responses.

ACUTE OR CRITICAL INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

In a critical care setting, infections in immunocompromised individuals generally present in the following manner—

- Fever with neutropenia.
- Sepsis and septic shock.
- Pneumonia.
- Mucocutaneous manifestations—
  - Stomatitis.
  - Esophagitis.
  - Skin rashes.
  - Discrete skin lesions.
- Disseminated tuberculosis.
- Meningitis and CNS infections.
- Disseminated syndromes involving more than one organ system.

Pyrexia of Unknown Origin with Neutropenia

This is generally observed in patients with myeloproliferative disease, lymphoma and cancers after aggressive chemotherapy. Severe neutropenia results in a loss of phagocytic function leading to infectious complications. Associated B-cell and T-cell dysfunction further contributes to these complications. The risk of infection depends on the degree and duration of neutropenia. The infection rate is significantly increased if the neutrophil count is less than 1.0×10^9/L and is highly probable, if it further falls to 0.5×10^9/L. Infection invariably results if the duration of severe neutropenia is more than 10 days. Many infections result from the patient's own endogenous flora (i.e. from the skin, gut and lungs); approximately half of the infections are nosocomial in origin. In our unit, the organisms most frequently involved are the Gram-negative organisms such as the *P. aeruginosa*, *Klebsiella*, *Enterobacter*, *Serratia* and Gram-positive organisms. *S. aureus* (including the methicillin resistant) and *Staphylococcus epidermidis* are uncommon infections in our unit; though they form important pathogens in other CCUs, particularly in the West. Invasive fungal infections due to *Candida, Aspergillus* and *Mucor* species are increasingly observed.

The organism causing fever in patients with severe neutropenia is microbiologically identified in less than a quarter of cases. In another quarter, the clinical symptomatology suggests an infection, though the nature and site of infection again remain unproven, and in half or more patients the fever remains of unknown origin. Thus, in many such patients, a complete physical examination, basic radiological, ultrasound tests, blood tests including cultures of blood, urine and body secretions are all negative. A CT of the chest and abdomen should always be done in these patients. Pneumonia not evident on an X-ray chest may show up on a CT chest and a CT abdomen may reveal a focal abscess that would otherwise go unrecognized. It is therefore imperative that in patients with severe neutropenia (to the extent described above), with fever (defined as a single oral temperature of 38.3°C or 38°C for at least one hour), empiric antibiotic therapy should be promptly commenced after relevant blood tests, culture of blood, urine other body secretions and a chest X-ray have been done. One should never await results. We generally prefer to cover Gram-negative organisms (in particular *Pseudomonas*) with a third-generation cephalosporin or a piperacillin derivative, plus an aminoglycoside. Gram-positive cover is provided with intravenous (IV) amoxycillin + clavulinic acid. If there is a strong suspicion of methicillin resistant *Staphylococcus* causing infection, vancomycin is substituted for amoxycillin + clavulinic acid. Further modification in antibiotic coverage depends on results of tests, and on response to therapy.

We also administer the granulocyte stimulation factor daily to help increase the leucocyte and neutrophil count to safe levels.

Patients with a pyrexia of unknown origin (PUO) and neutropenia who fail to respond within 2 days of a broad-spectrum antibiotic cover should in addition be given amphotericin B to cover a possible fungal infection. Amphotericin B is used even earlier if the patient deteriorates quickly, if there is a background known to significantly increase fungal super-infection (as in patients on prolonged corticosteroid therapy), or if pleuritic pain, cough, hemoptysis point to infection in the chest and a high-resolution computerized tomography of the chest is suggestive of a possible fungal infection.

Fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial biopsy should be performed only if the patient fails to respond to the above management protocol. This is because opportunistic infections such as *P. jirovecii* are rare in patients with fever and neutropenia, except in patients with underlying lymphoma or in those on long-standing corticosteroid therapy.

Surgical biopsy is very rarely indicated, when for example, infiltrates in the lung persist in spite of therapy and the patient is deemed fit to withstand the surgical procedure.

The mortality of patients with fever and severe neutropenia is significantly reduced with the empirical therapy described above. A febrile neutropenic patient should be watched closely and should avoid external contact with other individuals.

Sepsis and Septic Shock

Sepsis or septic shock is probably the most dreaded complication in immunocompromised individuals. The source and nature of sepsis is at times obvious, and at times remains undetermined in spite of all investigations. The important sources of sepsis are—

- An abscess or infected hematoma anywhere within the body for which the patient requires critical care.
- *Intra-abdominal sepsis* The most frequent cause of this is a perforated gut due to any etiology, with peritonitis. A delayed diagnosis and late surgery are sure pointers to a very high mortality in spite of excellent surgical techniques and good postoperative care. If the source of infection within the peritoneal cavity cannot be completely eradicated, death is inevitable.
- Sepsis is sometimes related to a community-acquired bacterial infection—chiefly pneumonia.
- Sepsis also follows upon opportunistic infections, in particular, viral and fungal infections.
- An immunocompromised patient may be admitted to an ICU for trauma or following surgery. These patients are extremely prone to nosocomial infections. Nosocomial pneumonia, and nosocomial sepsis through central lines, catheters, ventilator tubings and nebulization equipment are frequent, and carry a forbidding mortality. Sepsis may arise from the overgrowth of pathogenic bacteria in the gut and their translocation into the systemic circulation.
- As mentioned earlier, the source and nature of sepsis at times remains undetermined.

The diagnosis of sepsis and septic shock has been discussed in an earlier chapter. In immunocompromised patients, fever and leukocytosis may not be as high as in patients with a normal immune system. In fulminant cases, hypothermia and leucopenia may be observed. Physical signs are subtle, and may be easily missed or ignored. Deterioration is often rapid, with a quick onset of multiple organ dysfunction and failure.

The principles of management discussed under septic shock are applicable to immunocompromised patients. It needs to be stressed that however ill the patient, a localized source of infection if accessible should be promptly dealt with surgically. An abscess simply must be drained, and abdominal sepsis must be surgically tackled. The choice between aspirating a localized abscess under ultrasound or CT guidance, or incising and draining it should be left to the surgeon.

It is often necessary to start appropriate empiric antibiotic therapy promptly, after collection of secretions and of blood for culture has been done. We generally start with amoxycillin + clavulinic acid 1.2 g 8 hourly intravenously to counter possible coccal infections, a third-generation cephalosporin like ceftazidime 2 g intravenously 8 hourly which acts against Gram-negative infections including *Pseudomonas aeruginosa*, and an aminoglycoside which also acts against Gram-negative infections. Any antibacterial regime against Gram-negative infections should preferably include a combination of two antibiotics to provide wide coverage.

In nosocomial infections, the choice of antibiotics is governed by the nosocomial organisms most frequently encountered in a particular intensive care setting. In our unit, *P. aeruginosa*, *Klebsiella* and *Enterobacter* are the common organisms responsible for nosocomial infections. There is a marked increase in the incidence of the extended spectrum beta-lactamase (ESBL) producing organisms in ICUs in India, resistant to most antibiotics. The regime recommended is a carbapenem plus an aminoglycoside. When there is a possibility of a staphylococcal infection, or in very ill patients, or in those who show no response within 36 hours of starting the above standard regime, we add vancomycin 500 mg 6 hourly intravenously to the management protocol.

In certain clinical settings the standard regime may need to be modified—

- If culture reports suggest that the patient is colonized and probably infected by an organism resistant to the regime chosen, or if the patient is admitted to a unit where an uncommon, resistant organism is known to be responsible for frequent infections, a drug acting against such an organism is added or substituted in the regime.
- If the clinical situation suggests an associated anaerobic infection (as in abdominal sepsis, perianal or perirectal sepsis, or in sepsis following aspiration of gastric contents), the addition of metronidazole 500–750 mg intravenously

every 8 hours, or clindamycin 600 mg intravenously 6 hourly, or penicillin 2 mega units intravenously 4–6 hourly, is warranted.

- If sepsis is thought to be related to central lines, IV vancomycin 500 mg 6 hourly should always be included in the regime.
- If *H. influenzae* is likely to be the incriminating organism, it is best to include a third-generation cephalosporin (if not used), or use cefuroxime acetate 1.5 g intravenously every 8 hours.
- Ordinarily antifungal therapy is not included initially in the standard regime except when there is strong clinical evidence, right from the outset, of a fungal infection. However, if an immunocompromised patient with sepsis or septic shock fails to improve within 48 hours on an antibacterial regime outlined above, antifungal treatment with amphotericin B or an Echinocandin is added to the therapy. In patients with cancer, in those immunosuppressed by antimitotic drugs, or in those immunosuppressed patients who have received broad-spectrum antibiotics for prolonged periods of time and who suddenly deteriorate, many would prefer to initiate antifungal therapy promptly. In patients with sepsis and severe granulocytopenia, who fail to improve on antibacterial broad-spectrum antibiotics, or those who improve initially but then suddenly deteriorate, a fungal infection is strongly suspect, and lyophilized amphotericin B or any other suitable antifungal agent should be added empirically to the therapeutic regime (see earlier section on PUO with neutropenia).
- In patients with cellular immune defects, antimicrobial therapy must consider coverage of *Listeria monocytogenes* (ampicillin 2 g every 4 hours and gentamicin). Fungal infections (chiefly *Candida* and *C. neoformans*) and viral infections (CMV and herpes virus) are also to be suspected in this situation.

There are no firm and objective guidelines regarding the duration of antibiotic treatment of sepsis in immunocompromised patients. Antibiotics should be continued till sepsis is well controlled—generally treatment lasts for at least 7–12 days, and often longer. If possible, the serum antibiotic concentration of all patients with sepsis, and, in particular septic shock should be monitored. Dose modifications may therefore be necessary, particularly in the presence of hepatic or renal dysfunction induced by the disease, by shock or by previous treatment.

The role of corticosteroids in sepsis has been discussed in the Chapter Sepsis and Septic Shock. Immunoglobulin infusions or infusions of complement or transfer factor to augment the immune response are of dubious clinical efficacy. However, the use of granulocyte colony stimulating factor (5–10 μg/kg per day) in such patients is often rewarded by an increase in the granulocyte count after a few days. A satisfactory granulocyte response may well turn the tide in the patient's favor.

Pneumonia and Pulmonary Infections

Infections in immunocompromised patients frequently take the form of pneumonia. In these patients, pneumonia very frequently results from the usual bacterial flora prevailing within the community. The commonest community-acquired pneumonia in India (as in other countries) is due to the *S. pneumoniae*. In older, particularly immunocompromised individuals, Gram-negative infections are frequent. In our country, as well as in all third-world countries where tuberculosis is common, a flare-up of this disease always needs to be considered. The diagnosis may not be easy as many of these patients produce little or no sputum for examination.

Immunocompromised patients, in contrast to patients who are immunocompetent, are however increasingly prone to opportunistic infections. In AIDS, pneumonia due to *Pneumocystis* is frequently observed when the CD4 lymphocyte count is less than 200/mm^3. *P. jirovecii* infection can also occur in lymphomas, leukemias, myeloproliferative disorders, organ transplant recipients, in patients on corticosteroid therapy and rarely in patients with rheumatoid disease on methotrexate therapy. Other opportunistic organisms causing pneumonia include the CMV and the herpes virus, *M. avium intracellulare*, protozoa, helminthes (Strongyloidosis) and fungi. Not uncommonly, more than one opportunistic organism is present in the same individual.

Finally, immunocompromised patients admitted to an ICU for noninfectious conditions (trauma and surgery) are especially prone to nosocomial pneumonia.

There are some noteworthy features in relation to pneumonia in immunocompromised patients—

- Pneumonias constitute a major cause of morbidity and mortality in diverse immunosuppressed populations and therefore pose a problem of enormous magnitude. In one large reported study of renal transplant patients, pneumonia occurred in 20% of patients and accounted for 50% of deaths.[3] Similarly in patients with lymphomas, pneumonia is the commonest infection causing death.[4] Interstitial pneumonia is reported to occur in 55% of bone marrow transplant recipients who survive for 30 days after transplantation, and carries a mortality of 60%.[5]
- In many patients, the symptoms are few, and there is a paucity of physical signs. In neutropenic patients, physical signs are virtually absent. An increase in the respiratory rate is probably the only important sign which may be observed. Radiological shadowing in neutropenic patients is barely noticeable and may even be absent due to the total lack of neutrophilic response in such patients.
- Pneumonias due to bacterial infections can be multilobar. Acute lung injury [acute respiratory distress syndrome (ARDS)] is more often observed in immunocompromised patients under the above circumstances. Similarly, multiple organ dysfunction, failure and death are more frequently observed.

17

Box 1: Noninfective pulmonary infiltrates or "shadows" in the immunocompromised host

- Pulmonary edema
- Pulmonary hemorrhage
- Acute respiratory distress syndrome
- Pulmonary embolism
- Drug-induced pulmonary disease
- Leukoagglutinin reaction
- Opportunistic neoplasms (lymphoproliferative disorders and Kaposi's sarcoma)
- Recurrence of a tumor, of a lymphoma, or of a leukemia in the lungs
- Immune-mediated disorders—
  - Acute rejection after lung transplant
  - Obliterative bronchiolitis
- Nonspecific inflammation

- A quick diagnosis allows specific therapy to be promptly instituted and improves patient survival. In renal transplant patients, a mortality of 21% was noted in those patients where a specific diagnosis was made within 5 days of the illness. In contrast, the mortality rate was 65% in patients who were diagnosed after 5 days of illness.[3]
- Each ICU must have a protocol or a plan of approach for dealing with an immunocompromised patient admitted with fever and pulmonary infiltrates. Good patient care in these patients necessitates a team approach which should however be orchestrated by a single individual in charge of patient care. It is unfortunate and sad that many microbiological and pathological laboratories in our country (outside large metropolitan cities) are ill-equipped to diagnose opportunistic infections, particularly *Pneumocystis,* viral infections and infections caused by rarer microbes—chiefly *Legionella*, *Mycoplasma* and *Nocardia*. Management protocols in third-world countries should therefore take into account the facilities available for investigations.
- Fever with pulmonary infiltrates in an immunocompromised individual is not always related to infection. It is vital to be aware of this fact. Noninfective causes of pulmonary "shadows" or infiltrates include pulmonary edema, pulmonary hemorrhage, pulmonary embolism, drug-induced pulmonary disease, and ARDS and opportunistic neoplasms (lymphoproliferative disorders, Kaposi's sarcoma). Other noninfective lesions include recurrence of underlying tumor, lymphoma, leukemia, within the lungs, immune-mediated disorders (acute rejection after lung transplant, obliterative bronchiolitis after lung transplant or after an allogenic stem-cell transplant), and nonspecific focal inflammation (Box 1).

Clinical Approach to Diagnosis of Fever with Pulmonary Infiltrates in Immunocompromised Patients

Knowledge of the background disease Patients with cell-mediated immune deficiency, e.g. HIV infection, prolonged corticosteroid therapy, Hodgkin's or other lymphomas, and those with organ transplants, are prone to infections by *M. tuberculosis*, *P. jirovecii*, CMV, other herpes viruses, *Cryptococcus*, *Nocardia* and *Legionella*. On the other hand, patients whose main defect is a severe granulocytopenia are prone to Gram-negative infections, staphylococcal and fungal infections (*Aspergillus, Mucor* and *Candida*).

In organ transplant patients, the time of onset after transplantation may be of diagnostic assistance. CMV pneumonias occur from 1 to 4 months after renal transplantation, but are relatively rare prior to or after this period.[3] Pneumonias occurring within the first 3–4 weeks after a transplant are almost never due to an opportunistic organism, but result from the usual bacterial pathogens causing post-operative pneumonias in surgical patients. Between 1 and 4 months after the transplant, besides the CMV, infections due to *Nocardia*, *Pneumocystis* and fungi should be kept in mind. After 4 months, patients who have normally functioning grafts, and who are on minimal immunosuppression, are prone to the usual community-acquired infections. Those with poorly functioning grafts, who require intensive immunosuppression, remain susceptible to the opportunistic infections stated above.

In the early part of the natural history of lymphomas, the patient is at greater risk for community-acquired pneumonias. As the disease progresses and particularly with repeated therapy, the patient is at greater risk for opportunistic pathogens.

Epidemiological clues should always be sought. In our country and in other third-world countries, depressed cell-mediated immunity is most likely to exacerbate or result in infection with *M. tuberculosis*. However, residence and exposure in areas endemic to fungi such as *Histoplasma capsulatum* or *Coccidioides immitis* could predispose to histoplasmosis or coccidioidomycosis.

Infiltrates due to noninfectious causes also have a predictable time for making their appearance. Patients treated for acute myeloblastic leukemia may develop interstitial pulmonary infiltrates. When these infiltrates occur within 4 days of a fall in the white blood cell count, they are suggestive of a leukemic cell lysis pneumopathy.[6] The mechanism of infiltrates and alveolar damage in this syndrome is perhaps related to the lysis of interstitial and alveolar blast cells. A pattern of pulmonary edema developing within minutes to hours of transfusion of blood or other blood products raises the possibility of a leukoagglutinin reaction.[6] On the other hand, pulmonary shadows (sometimes localized), may be related to pulmonary edema produced by overhydration, poor left ventricular function, or a capillary leak as in early acute lung injury (ARDS).

Bleomycin is the commonest drug responsible for interstitial infiltrates after the patient has received a cumulative dose of 150 mg of the drug. However, idiosyncratic reactions may occur with much smaller doses. Other antimitotic drugs, particularly methotrexate and busulfan, can also result in interstitial infiltrates.

Table 1: Differential diagnosis of fever and pulmonary infiltrates in the immunocompromised patient, based on radiological signs and onset of symptoms

Chest X-ray	*Symptoms*	
	Acute onset	*Subacute or Chronic onset*
Consolidation	• Bacterial • Thromboembolic • Hemorrhage	• Fungal • Nocardial • Tuberculosis
Peribronchial + alveolar shadowing; interstitial infiltrate	• Pulmonary edema • Leukoagglutinin reaction	• Viral • *P. jirovecii* • Radiation • Drug induced
Nodular infiltrate	• Bacterial • Pulmonary edema	• Tumor • Fungal • Nocardial • Tuberculosis

The mode of onset and the tempo of progression These often provide crucial clues in the diagnosis. Their value is enhanced if the above features are considered in association with radiological findings (Table 1). An acute onset over 24–48 hours is suggestive of a conventional bacterial infection, or certain noninfectious causes such as pulmonary edema, pulmonary hemorrhage, pulmonary embolism or a leukoagglutinin reaction. A subacute onset over a few days or weeks suggests tuberculosis, *Pneumocystis*, viral, fungal or *nocardial* infections. The same presentation may however also be observed with certain noninfectious causes such as drug-induced pneumonitis, radiation pneumonitis, or the recurrence of a tumor against the background of a mitotic disease.

Physical examination Physical examination may occasionally provide valuable clues. In sophisticated ICUs with high-technology equipment, physical examination tends to be perfunctory; this should never be so. Repeated clinical examination might reveal clues, which machines and elaborate investigations fail to detect. The features enumerated below are merely illustrative of the importance of a careful physical examination—

- Tachypnea in an immunocompromised patient, particularly in the absence of high fever is indicative of sepsis, pneumonia or acidosis. Physical signs in the chest may or may not be evident; an absence of signs on percussion or auscultation is often observed in these patients.
- Skin lesions are occasionally present in cryptococcal, nocardial and candidal infections. They take the form of minimally painful or asymptomatic macules, papules or nodules, which on biopsy provide the correct diagnosis, thereby obviating the need for invasive diagnostic procedures. Pyoderma gangrenosum is occasionally observed in infections with *P. aeruginosa*, and very rarely with other Gram-negative infections.
- A careful search for enlarged lymph glands can be rewarding. Lymphadenopathy strongly suggests a tuberculous infection in our country, either due to *M. tuberculosis* or in AIDS patients to a possible infection with *M. avium-intracellulare*. An underlying lymphoma, presenting with an obscure pneumonia, has been occasionally diagnosed following the biopsy of a nondescript clinically palpable lymph node.
- Ocular examination is important as ocular findings are common with disseminate CMV infection. The retina shows hemorrhages and yellowish-white exudates. Similar ocular findings have been noted in toxoplasmosis and occasionally in candidiasis, and aspergillosis.
- Examination of other systems is of crucial importance. Hepatosplenomegaly with lymphadenopathy may point to an underlying lymphoma or a myeloproliferative disorder. It is also commonly observed in disseminated hematogenous tuberculosis and toxoplasmosis.
- Neurological examination may reveal subtle symptoms and signs suggesting meningitis or a focal neurological lesion. Brain abscess is common in nocardial infection, cryptococcal infection and in disseminated disease due to *M. tuberculosis* (see Chapter Neurological Problems).
- Radiological Investigations in patients with pulmonary infiltrates generally do not allow a definitive etiological diagnosis to be made. Nevertheless, a study of serial chest X-rays, when combined with an analysis of the mode of onset and the progress of the disease, often help in limiting the diagnostic possibilities.

Focal or multifocal consolidation of short duration (less than 48 hours) seen on a chest X-ray is invariably due to an acute bacterial infection. Slowly progressive consolidation with a subacute or chronic history favors tuberculosis, nocardial or fungal infections.

Interstitial infiltrates spreading outwards from the hilar area and evolving in a subacute or chronic manner, suggest *Pneumocystis*, viral or drug-induced infiltration, or may be due to lymphangitic carcinomatosis. Acutely evolving interstitial infiltrates suggest pulmonary edema or a leukoagglutinin reaction.

Acute nodular localized alveolar consolidation or localized nodular infiltrates suggest pulmonary edema or bacterial bronchopneumonia. Nodular infiltrates which are subacute or chronic and slow in evolving could be tuberculosis, fungal or nocardial in etiology. Such infiltrates could also be due to the recurrence or spread of an original tumor.

These radiological observations are not sacrosanct, and as mentioned at the outset, an exact diagnosis can never be made by the mere description of shadows on a chest radiograph. The overall picture has to be considered.

It must be stressed that HRCT of the chest must always be done in immunocompromised patients with possible pneumonia. The CT generally gives much more information than a chest X-ray and may suggest a possible diagnosis not entertained on a mere viewing of the chest X-ray. For example,

Table 2: Likely respiratory pathogens in specific immunocompromised-host categories based upon presenting radiographic pattern

	Diffuse interstitial-alveolar	*Lobar-segmental*	*Reticulonodular*	*Discrete nodule*
Chemotherapy-induced granulocytopenia	Cytomegalovirus (CMV) (ALL)	Bacterial	-	Bacterial, *Aspergillus* Other mycelia
Bone marrow transplant	*P. jirovecii,* CMV, Respiratory syncytial virus (RSV), Influenza virus, Adenovirus	Bacterial, *Legionella* RSV Influenza virus	*Nocardia*	Other mycelia *Aspergillus* *Nocardia*
Solid organ transplant	CMV *P. jirovecii* Influeza	Bacterial Influenza virus	*Nocardia* *M. Tuberculosis*	*Aspergillus* Other mycelia
HIV-1	*P. jirovecii* CMV	Bacterial *Rhodococcus* *Cryptococcus*	*P. jirovecii* Histoplasmosis	Bacterial *Cryptococcus*

it may reveal cavitative lung disease or show features suggestive of *Aspergillus* infection, not evident on an X-ray of the chest. Table 2 gives the likely pathogens in specific immunocompromised states based on imaging (X-ray chest and HRCT chest) findings.

Management Protocol

This should be organized and planned depending on the facilities present in an ICU, and the degree of sophistication of the pathology and microbiology departments of the hospital. Routine investigations include a blood count, blood chemistry, blood culture, sputum examination (Gram stain and acid-fast stain), sputum culture, X-ray chest and often an HRCT chest. A Gram stain of the sputum at times provides a direction to appropriate therapy. In some patients, nebulization with hypertonic saline helps to obtain a satisfactory sputum sample (Flowchart 1).[7]

Empiric therapy should be started without awaiting results of blood and sputum tests. Therapy could be later changed, if the results so necessitate. The protocol we use in an acutely ill immunocompromised patient is as follows—

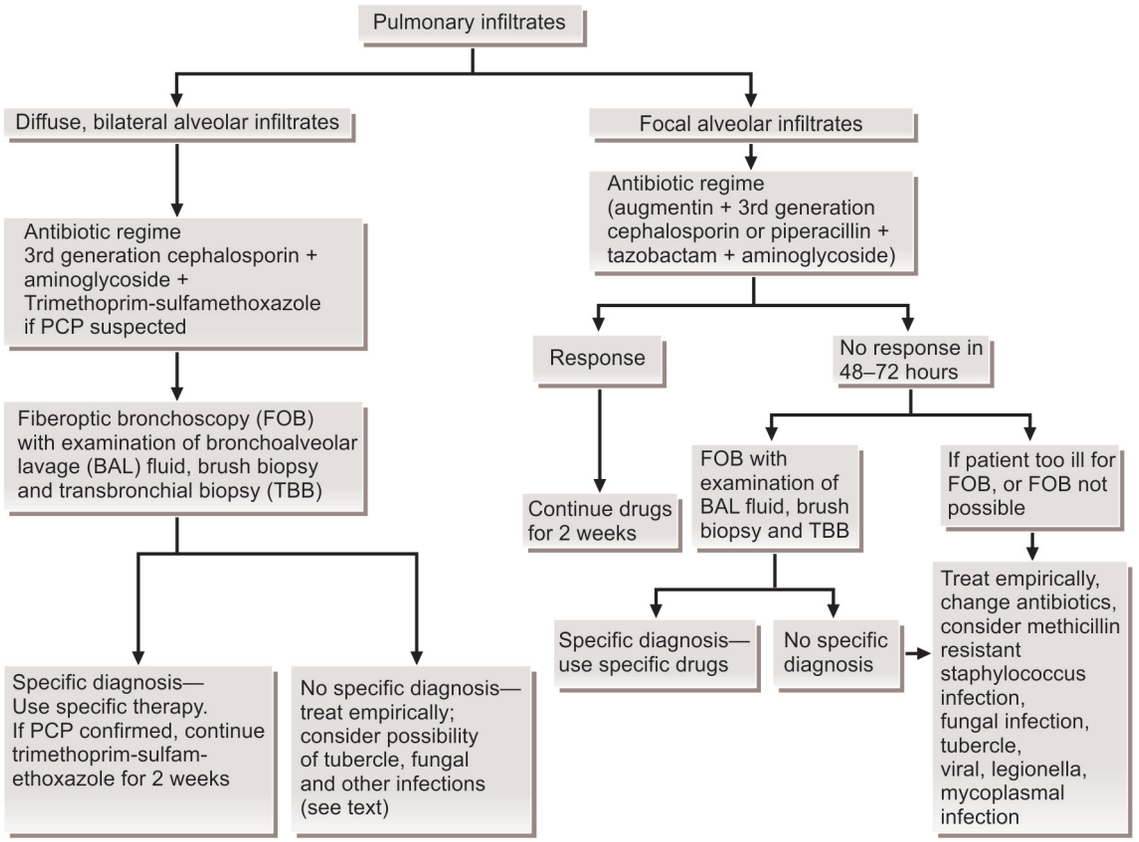
- If the patient presents with a focal alveolar infiltrate or consolidation, we use intravenous augmentin plus a third-generation cephalosporin, like ceftazidime plus an aminoglycoside, or alternatively use other broad-spectrum antibiotics that counter Gram-positive and Gram-negative infections, as outlined in the section on sepsis. The choice of the antibiotic regime depends on the possible nature of the organisms suspected in a given individual. Nosocomial pneumonias in immunocompromised patients should include a carbapenem like meropenem 1 g 8 hourly plus an aminoglycoside, in view of a marked increase in ESBL producing organisms. Many patients with *P. aeruginosa* infection are now resistant to carbapenems and other antibiotics. One is left with the use of Colistin with its loading dose (9 MIU) and maintenance dose of 2–3 million units IV 8 hourly as the only resort. The maintenance dose of Colistin must be adjusted according to the creatinine clearance of the patient. Since Colistin must never be administered alone, it is combined with a carbapenem which is given as a prolonged infusion. In pneumonia associated with severe neutropenia, particularly in those who have pleuritic pain, cough, hemoptysis and whose HRCT is compatible with an *Aspergillus* infection, we would add amphotericin B or voriconazole to the regime of broad-spectrum antibiotics on an empiric basis. If the patient responds to the above treatment, the antibiotic course is continued for a period of 2 weeks or even longer.

If the patient does not respond within 48–72 hours or if the disease progresses, it is best to do a bronchoalveolar lavage with a careful examination and culture of the lavage fluid. Whenever possible, brush biopsies of the involved areas by standard accepted techniques are recommended. A transbronchial biopsy of the lesion, if thought appropriate, can be done during the same procedure. The biopsy material is processed promptly for staining of the organisms, histopathology and cultures. The following etiological agents are diagnosed by these techniques—

- Gram-negative or Gram-positive infections.
- *M. tuberculosis* It is amazing how often this diagnosis would have been missed or would not have been seriously entertained if the above diagnostic procedure was not performed.
- Other rare infections, for example, *nocardial* infections.
- *P. jirovecii* infection; the organism can be identified in lavage and in biopsy material by suitable staining.
- Cytomegalovirus infection can be diagnosed by the presence of inclusion bodies in cells normally observed in this infection.
- Fungal infection, particularly *Aspergillus* infection. Aspergilli in the BAL fluid of an immunocompromised patient with "pneumonia" strongly suggests *Aspergillus* infection.
- Opportunistic *cryptococcal* infection and toxoplasmosis may be occasionally diagnosed on a transbronchial biopsy.

If a specific etiology is found by this procedure, the drugs used are, by and large, solely directed toward the eradication of the etiological agent.

Flowchart 1: Management protocol in acutely ill immunocompromised patients with fever and pulmonary infiltrates (see text for role of open lung biopsy and for details of management protocol)



If the patient is too ill for a bronchoalveolar lavage or a transbronchial fiberoptic bronchoscopy, or if the ICU cannot organize these procedures, or if the pathological and microbiological back-up is poor, further management should proceed on an empiric basis. For example, if amoxicillin + clavulinic acid, a third-generation cephalosporin and an aminoglycoside have been used initially with no effect, one could switch to piperacillin-tazobactam plus vancomycin or to a combination of meropenam plus vancomycin. Besides covering Gram-positive and Gram-negative infections, atypical organisms (e.g. *Legionella, Mycoplasma*) should be covered by azithromycin, and fungal infection, if suspected, by amphotericin B. Opportunistic infection may at times be impossibly difficult to diagnose.

In patients with a subacute onset, the possibility of tuberculous pneumonia should always be considered. The diagnosis is generally proven by demonstrating *Tubercle bacilli* in bronchial lavage specimens. Specific treatment consists of rifampicin 600 mg daily, isoniazid 300 mg daily, ethambutol 1 g daily, pyrazinamide 750 mg twice daily and streptomycin 1 g intramuscularly daily.

- If the patient shows diffuse bilateral alveolar, shadowing a third-generation cephalosporin or piperacillin-tazobactam, in combination with an aminoglycoside can be used. This regime may need to be modified depending on the likely Gram-positive or Gram-negative organism responsible for the infection in a given individual. *The sicker the patient, the greater should be the cover for possible invading organisms*. If the X-ray appearances and clinical background are compatible with *Pneumocystis* infection, trimethoprim-sulfamethoxazole combination needs to be given. This is followed by bronchial lavage, brush and transbronchial biopsies for possible diagnostic help. If this is not possible for reasons earlier outlined, or if the diagnostic procedure fails to provide a clue, further treatment remains empiric. Deterioration of the patient, should prompt the use of amphotericin B for *cryptococcal, Aspergillus,* or other rare fungal infections. If Legionnaires' disease is a clinical possibility, erythromycin is added. Disseminated tuberculosis should generally be evident by the demonstration of acid-fast bacilli in the samples obtained through a bronchial lavage.
- If the patient has bilateral pulmonary parahilar interstitial infiltrates, strongly suggestive of *Pneumocystis* infection, a trimethoprim-sulfamethoxazole combination is indicated, and this is followed up with bronchial lavage, bronchial brush biopsy and rarely a transbronchial biopsy, to prove the presence of *P. jirovecii*. If the diagnosis is confirmed, specific treatment is continued for 2 weeks. If unconfirmed, the above-mentioned treatment should still be continued and ganciclovir added for a possible CMV infection.

- The possibility that the shadows or lung infiltrates in the lung could be noninfective in nature should be kept in mind, particularly if investigations for an infective agent are persistently negative and the shadows persist in spite of antibiotic therapy.
- As mentioned in Table 1 earlier, a consideration of the specific nature of the immunocompromised state in a patient and the imaging findings help suggest the possible etiological agents likely to cause pneumonia.

Role of an Open Lung Biopsy

Many units in the West are aggressive in their approach, and perform an open lung biopsy within 24 hours, if the patient deteriorates, to obtain a specific diagnosis of the etiology of the pneumonia. We rarely perform open lung biopsies on our patients, as we feel that most of them are too ill to tolerate the procedure. Thoracoscopic lung biopsies are less traumatic than open lung biopsies. Lung biopsy is recommended under the following circumstances—

- When the patient is not critically ill, when the treatment directed toward the "pneumonia" has not provided definite benefit, and when diagnostic procedures carried out through a fibrotic bronchoscope have provided no yield.
- In subacute or chronic pulmonary infiltrates, the diagnosis of which is undetermined by the procedures mentioned above. The importance of establishing a diagnosis here is that it avoids unnecessary treatment with antibiotics for prolonged periods, this being definitely detrimental for the patient. Subacute or chronic infiltrates may be noninfectious in nature, and a thoracoscopic or an open lung biopsy helps to confirm this. At times, we have diagnosed chronic interstitial pneumonia which does not require any antibiotic treatment on an open lung biopsy. Above all, we have occasionally diagnosed infiltrates to be due to pulmonary tuberculosis, by doing an open lung biopsy in patients, whose clinical features and radiological findings were bizarre, and did not suggest pulmonary tuberculosis in any way.

Important Specific Pulmonary Infections in the Immunocompromised Patients

P. jirovecii pneumonia *P. carinii* (now termed *P. jirovecii*), which was earlier regarded as a protozoal parasite, is now regarded as a fungus; it is an important cause of pneumonia in immunocompromised individuals. It most frequently infects patients with AIDS; in fact, early in the HIV epidemic about 80% of patients with AIDS and pulmonary infiltrates had a PCP.[8] This is because *Pneumocystis* infection is the commonest in patients with severe cell-mediated immune deficiency, and AIDS is an example of the severest form of cellular immunity depression. However, with the widespread use of antiretroviral therapy and chemoprophylaxis against *P. jirovecii*, the incidence has fallen significantly. In an Indian autopsy study on 143 patients with AIDS, only 5% of lung pathologies were caused by *P. jirovecii*.[9] This is because AIDS patients in India, die of pulmonary tuberculosis, before they get a chance to acquire *Pneumocystis* infection (see subsequent Section on Pneumonia in AIDS). *P. jirovecii* is also seen in other diseases with depressed cell-mediated immunity; for example, lymphomas, in children with acute lymphoblastic leukemia, patients on high doses of corticosteroids, organ transplant recipients and allogenic stem-cell transplant patients.

In AIDS, the disease is often subacute or insidious in onset,[10] generally presenting with cough and bilateral perihilar infiltrates which slowly and progressively fan out into the periphery. As the disease progresses, it produces increasing breathlessness, but few physical signs. Hypoxia progressively increases so that the patient finally develops hypoxemic respiratory failure, and at this stage the patient usually gets admitted to an ICU. If the background of AIDS is known, the diagnosis is generally obvious; if AIDS has not been diagnosed, the diagnosis may be missed, if the clinician is unaware of its clinical and radiological features.

In diseases other than AIDS, *P. pneumonia* is more often an acute opportunistic infection, producing fever, increasing breathlessness and progressive interstitial infiltration fanning from the hilum to the periphery, and soon involving the greater part of both lungs. Death results from acute respiratory failure.

In the subacutely ill patients, nebulization of hypertonic saline[11] can give an yield of sputum positive for *P. carinii,* in more than 50–60% of patients. In the acutely ill patients in an intensive care setting, the diagnosis can be proven by bronchial lavage, brush biopsies or transbronchial biopsy as outlined earlier. Open lung biopsies are hardly ever necessary to establish a diagnosis.

Treatment The drug of choice is a trimethoprim-sulfamethoxazole (TMP/SMX) combination, the IV dose being trimethoprim 5 mg/kg and sulfamethoxazole 25 mg/kg given 6 hourly. The oral preparation double strength trimethoprim-sulfamethoxazole (TMP/SMX) in dose of 2 tablets thrice daily is better tolerated than the IV preparation. Adverse reactions are frequent[12] and over 50% of patients treated with this combination exhibit rashes, liver cell, renal dysfunction, leucopenia and thrombocytopenia. A recent study reported that TMP/SMX had an amiloride-like effect, thus partly accounting for the hyponatremia which is frequently associated with the use of these drugs.[13] Clindamycin (300 mg TDS/QDS) plus primaquine (15–30 mg OD) is a reasonable alternative and often one that is better tolerated. Other drugs used include nebulized and IV pentamidine (4 mg/kg IV OD), dapsone (100 mg OD) and atovaquone (750 mg orally thrice daily). Corticosteroids are beneficial as adjunctive therapy in patients with hypoxemic respiratory failure (PaO_2 <65 mm Hg).[14] Methyl prednisolone 40–60 mg administered once to four times a day in tapering doses over 21 days appears beneficial.

The prognosis for the first episode of *P. pneumonia,* if adequately treated, is good. Recovery occurs in 80–90% of patients.[15] Subsequent attacks carry a poorer prognosis.

Acute viral pneumonias requiring critical care The major viral pulmonary infection of concern in immunocompromised patients is the CMV infection. It can occur in any immunocompromised patient, but is particularly common in certain patient populations. It is most common after allogeneic bone marrow transplantation,[16] in organ transplant recipients and in patients with AIDS.

The clinical features are characterized by fever, nonproductive cough and increasing dyspnoea leading to a quickly progressive hypoxemic respiratory failure. A chest X-ray shows progressive interstitial pulmonary infiltrates, often indistinguishable from *P. pneumonia*. A miliary pattern on the chest X-ray is rarely observed in fulminant infections, leading to a quickly evolving arterial hypoxemia and death.

Multisystem involvement is often observed in fulminant infections, and when present, serves in most instances to distinguish CMV from *Pneumocystis* infection. Thus, liver cell dysfunction, leucopenia with atypical peripheral lymphocytes, lymphadenopathy, renal dysfunction probably due to virus-induced glomerulopathy, colitis and ocular changes may be observed. The frequency of CMV infection is undoubtedly underestimated, as diagnosis in critical care settings of developing countries is difficult. An important and rather peculiar feature of CMV infection is the ability of the CMV to further suppress cell-mediated immune responses in the host, thereby predisposing to further opportunistic infections. It is therefore not surprising that in AIDS, CMV infection often co-exists with mycobacterial, and also with *Pneumocystis* infections.[17]

A quick diagnosis of CMV pneumonia in a critically ill patient can be only suspected by the presence of inclusion bodies, within the cytoplasm of host cells in lung tissue obtained through transbronchial or open lung biopsies. A blood examination shows IgM antibodies against the CMV. A polymerase chain reaction (PCR) for CMV DNA is a crucial test; it demonstrates the presence of a significant viral load in CMV infection, even when the IgM antibody is negative.

Cytomegalovirus specific monoclonal antibodies are being studied to allow the diagnosis of CMV pneumonitis in tissues obtained from lung biopsies.

Gancyclovir in a dose of 5 mg/kg 12 hourly for 2–3 weeks is used as treatment. Its main toxic effect is myelosuppression.

Other acute viral pneumonias in immunocompromised patients Several other viral infections can produce acute life-threatening pulmonary infections in immunocompromised patients. Measles and varicella zoster viruses (VZV) may present as disseminated infections with a fulminant fatal pneumonia. Generally, there is no diagnostic difficulty in either case because of the characteristic skin rash in each disease.

Herpes simplex virus (HSV) rarely produces a hemorrhagic tracheobronchitis with a patchy pneumonia. The pathogen in most cases is due to an extension or aspiration of oral herpes simplex lesions, though in some cases, there is a hematogenous spread. Bronchoscopy shows hemorrhagic ulcerating lesions, within the bronchi covered with a white membrane. Material for specific cytological and virological studies may help establish a definite diagnosis. Therapy with IV acyclovir (5 mg/kg, 8 hourly) should be given in these patients. In the West, the incidence of herpes simplex viral infections in immunocompromised patients appears to be on the rise.

Nocardiosis This is an infection produced chiefly by *N. asteroides* in immunocompromised patients. It does not produce respiratory failure but presents in an intensive care setting as a pulmonary shadow of unknown etiology in an immunosuppressed patient admitted for an unrelated problem. The X-ray picture shows one or more shadows often circumscribed and sometimes cavitating. A review of nocardial infection in 160 patients who had undergone heart transplant provides a useful outline of the clinical profile of this disease.[18] Fever and dry cough are presenting features, but as mentioned above, an asymptomatic pulmonary shadow may be the first manifestation in 40% of patients. Though generally subacute in its natural history, in some instances, nocardial pulmonary infection in an immunosuppressed host may resemble an acute bacterial pneumonia.

Nocardial infection can disseminate particularly to the CNS. One or more abscess-like cavities in the lungs and the brain in an immunocompromised patient, should always suggest this diagnosis. Skin lesions occur in the form of nodules, which on biopsy show the presence of *N. asteroides.*

Diagnosis is difficult as *nocardia* is rarely present in sputum samples and cultures are frequently negative. This is one condition where a thoracoscopic or an open lung biopsy is indicated to establish a diagnosis. In two recent patients with nocardiosis, the diagnosis was arrived at by performing a CT-guided biopsy of the lesion in one patient, and by culture of material obtained through bronchial lavage in the other.

Treatment of nocardiosis is with sulfisoxazole (6–12 g/day) for a period of 3–6 months, extending to as long as a year in serious infections. Several authors have suggested that a trimethoprim-sulfamethoxazole combination may be the treatment of choice in nocardial infections.[19] This recommendation is based on a retrospective analysis of a small number of patients. We now use doxycycline 200 mg/day to start with, followed by 100 mg/day for 6 months to a year. Antibiotic sensitivity tests may be of help, if the organism is grown on culture. Anecdotal reports claim success with a number of other drugs, minocycline, cycloserine, erythromycin and ampicillin.

Acute fungal pulmonary infections Fungal infections are being increasingly recognized in immunocompromised patients and invasive fatal pulmonary infections due to *Aspergillus* are probably the commonest of these fungal infections. In AIDS patients however *cryptococcal* lung disease appears to be significantly more common, but rarely leads to respiratory failure. Although disseminated candidiasis is a frequent opportunistic infection in immunocompromised patients in an intensive care setting, isolated or primary

candida pneumonia is rare.[7] Infection caused by the *Mucor* species (mucormycosis) should be kept in mind in immunocompromised patients (particularly in diabetics or those on corticosteroids) who have a maxillary sinusitis, or who have necrotic eschars over the sinuses or within the nasal cavity with orbital swelling and conjunctival edema. *Mucor* tends to invade vessels leading to ischemic necrosis of tissue supplied by these vessels.

Invasive rapidly spreading *Aspergillus* pneumonia almost exclusively occurs in severely immunocompromised and myelosuppressed patients.[7] Severe leucopenia and, in particular, marked granulocytopenia is a major risk factor in the evolution of invasive pulmonary aspergillosis. Patients with acute leukemia develop invasive aspergillosis as a complication 20 times more frequently than patients with lymphomas or recipients of organ transplants.[7] In renal transplant patients, the risk of invasive pulmonary aspergillosis (IPA) increases with the use of high doses of corticosteroids.

Reports from the West continue to stress the importance of acute critical illnesses produced by invasive aspergillosis in patients with neoplastic disease and in heart transplant patients.[7] The spectrum of background diseases predisposing to invasive aspergillosis now includes patients with subacute hepatic necrosis treated with corticosteroids and IV antibiotics.[20] We are fortunate in that the incidence of IPA is low as compared to the West. Perhaps the frequency and the epidemiology of *Aspergillus* infections is governed to an extent by the presence of airborne *Aspergillus* in a particular eco-environment. Outbreaks of this infection have thus been related to the increased presence of this organism in the air, related to construction or to inadequate air conditioning systems.[21-23]

Fever, nonproductive cough, hemoptysis, pleuritic chest pain and a quick deterioration in the general condition of the patient is observed with IPA.

About 10% of immunocompromised patients, may present with a PUO with an X-ray chest which is normal. CT of the chest in these patients may demonstrate nodular infiltrates compatible with IPA.

Invasive pulmonary aspergillosis is sometimes suspected on CT findings in the chest. These include—

- A "halo sign" which is an area of attenuated shadowing surrounding a nodule or an area of consolidation.
- A "crescent sign" which relates to a partially formed cavity due to infarcted lung tissue.

The halo sign is neither very sensitive nor specific, for many molds other than *Aspergillus* (e.g. *fusarium*) may cause a similar pattern on a CT. Radiographic appearances vary from nodular infiltrates to dense consolidation. Because of the angioinvasive nature of the fungus, wedge shaped pleural-based infarct may be observed, which may later cavitate. A CT is mandatory as it reveals lesions not seen on an X-ray chest.

Chronic necrotizing pulmonary aspergillosis (CNPA), producing a critical illness has been reported in insulin dependent diabetics, in patients on a modest dose of corticosteroids, or in patients following radiotherapy to the lungs.

Diagnosis of invasive aspergillosis is difficult. Sputum is rarely present and if present is rarely positive. Sputum cultures take a long time for growth of *Aspergillus* and in critically ill patients, it is wrong to await reports when clinical suspicion is strong. Presence of *Aspergilli* in the BAL fluid in an immunocompromised patient is indicative of Aspergillosis. An HRCT of the chest is far more sensitive in the diagnosis of IPA than an X-ray chest, a sputum examination or a bronchoscopic examination. A transbroncial biopsy is positive for *Aspergillus* in only 50% of patients with invasive disease.[24] An open lung biopsy is diagnostic, but is not performed often, because of the poor condition of the patient. Empiric treatment is both indicated and justified in such situations.

Noninvasive tests include—

- Detection of galactomannan or glucan cell wall antigen on BAL specimen obtained through a fiberoptic bronchoscope or in the blood.
- PCR for *Aspergillus* DNA from the blood. Though highly sensitive, the galactomannan test may give false positive results in patients receiving piperacillin-tazobactam.

Pneumonia in AIDS

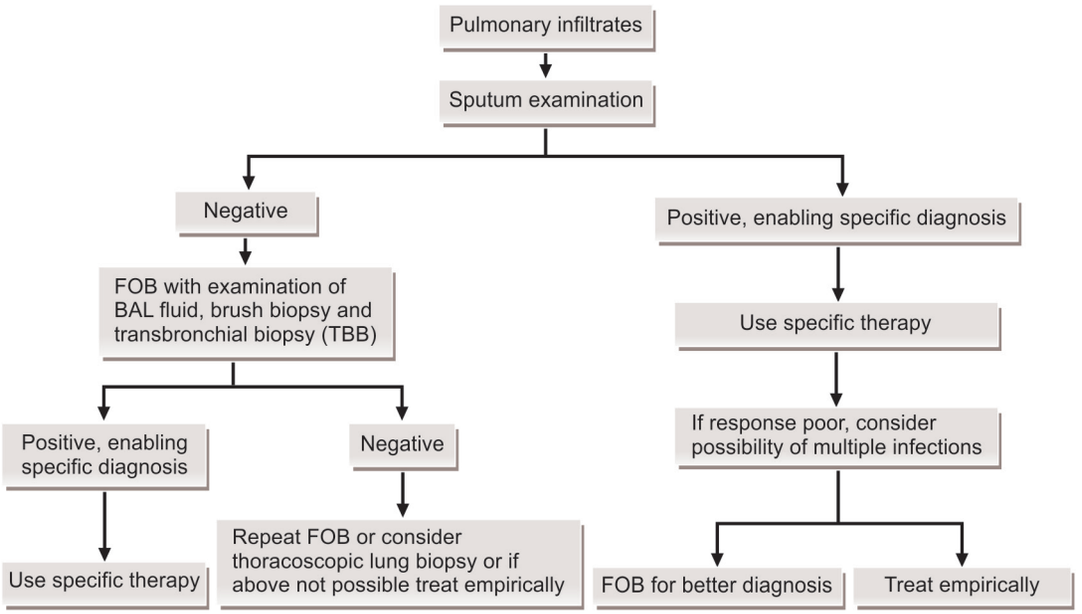
The principles enunciated above in relation to pneumonia in immunosuppressed individuals apply to patients with AIDS as well.

A few points however need to be stressed in relation to these patients—

- There are some differences in the frequency of opportunistic pathogens in this syndrome. Acute disseminated tuberculosis (including lung involvement), is the major opportunistic infection complicating the HIV epidemic worldwide.[25] A study by Selwyn et al. showed a 7.6% incidence of tuberculosis among anergic high-risk HIV-seropositive individuals.[26] It is a general belief that *Pneumocystis* infection is uncommon in India. This is not so; it occurs later than tuberculosis in the natural history of HIV infection. The apparent infrequency of *P. jirovecii* infection in patients with AIDS in India is because these patients are killed by the tubercle bacillus before the CD4 lymphocyte count drops to a level (<200/mm^3) which predisposes them to *P. jirovecii* infection. Also, the latter infection is difficult to prove in units where microbiological and bronchoscopy facilities are inadequate.

  An autopsy study of 143 patients with AIDS from Mumbai in 2001,[9] revealed a pulmonary pathology in 88% of cases. The lesions identified were tuberculosis in 59%, bacterial pneumonias in 18%, CMV infection in 7%, cryptococcal infection in 6%, *Pneumocystis* infection in 5%, aspergillosis in 3%, toxoplasmosis in 1%, Kaposi's sarcoma in 1% and squamous cell carcinoma in 1%. Two or more infections were found in 13%.

Flowchart 2: Algorithm for the diagnostic evaluation of pulmonary infiltrates in patients with AIDS



Pulmonary infiltrates
Sputum examination
Negative
Positive, enabling specific diagnosis
FOB with examination of BAL fluid, brush biopsy and transbronchial biopsy (TBB)
Use specific therapy
If response poor, consider possibility of multiple infections
Positive, enabling specific diagnosis
Negative
Use specific therapy
Repeat FOB or consider thoracoscopic lung biopsy or if above not possible treat empirically
FOB for better diagnosis
Treat empirically

- The clinical features of pulmonary infections in AIDS may be even more subtle than in other immunocompromised patients. This is so with all infections but is particularly observed with *Pneumocystis* infection (which is generally subacute), disseminated tuberculosis and fungal infections.
- Diagnostic procedures like examination of bronchoalveolar lavage fluid or the use of transbronchial biopsy, yield better or more definite results in diagnosing the etiology of acute pulmonary infiltrates in AIDS as compared to other immunocompromised populations.

A plan for diagnostic evaluation of pulmonary infiltrates follows the same principles as in other immunocompromised patients and is briefly illustrated below in Flowchart 2.

Specific antibiotic therapy (with the dose and duration of treatment) for organisms commonly encountered in immunocompromised patients is listed in Table 3.

Disseminated Tuberculosis

This is an extremely important cause of a critical illness demanding intensive care in our country, and probably in all developing countries where tuberculosis is rampant. It occurs chiefly in patients whose cell-mediated immune response is suppressed or compromised. We have observed its frequent occurrence in AIDS, and in patients on chemotherapy or corticosteroids. The combination of chemotherapy and corticosteroids in high doses, given over a prolonged period, is a potent risk factor for hematogenous disseminated tuberculosis.

The clinical features, diagnostic methods, complications and management are described in detail in the Section Fever and Acute Infections in a Critical Care Setting.

Central Nervous System Infections

Immunosuppressed patients have an increased incidence of CNS infections necessitating critical care in an ICU.

Meningitis and brain abscesses are both important complications and their diagnosis should be quick. Meningeal signs are almost never as florid as in patients with a normal immune status. In fact, they may be subtle and it is important to examine the CSF through a lumbar puncture even on a mere suspicion of possible meningitis. If a brain abscess is suspected because of focal signs or because of evidence of increased intracranial pressure, a CT scan of the head with contrast study should be done prior to a spinal tap. Generally, however, in such patients a spinal tap is best avoided particularly if the lesion is subtentorial or there is increased intracranial pressure.

The choice of therapy in pyogenic meningitis depends on the organisms seen on Gram staining of the CSF. Treatment should start promptly, the choice of empiric therapy being based on an evaluation of the clinical background of the individual patient. If the nature of the immunologic defect is known, therapy is easier to plan. For neutropenic patients in whom Gram-negative bacillary infection is a strong possibility, a combination of ceftazidime 2 g intravenously 6 hourly is used. An alternative regime used, as in patients with Gram-negative sepsis, is a combination of meropenem with an aminoglycoside. If a coccal infection is suspected, ampicillin 2 g 4 hourly should be added to the above regime. On the other hand, if these patients have intracranial foreign bodies such as an ommaya reservoir or a shunt, or have undergone a recent neurosurgical procedure, vancomycin 500 mg intravenously 6 hourly should be added.

Table 3: Specific antibiotic therapy for commonly encountered organisms in immunocompromised patients

Organism	*Drug and dose*	*Average duration of treatment*
1. Viruses—		
• Herpes Simplex	Acyclovir 5 mg/kg q8 h IV	7–14 days
	Acyclovir 10 mg/kg IV q8 h (meningitis/encephalitis)	10–14 days
• Herpes Zoster	Acyclovir 10 mg/kg q8 h IV	7–14 days
• CMV	Induction: Ganciclovir 5 mg/kg q12 h IV	14 days (induction)
	Maintenance: Ganciclovir 5 mg/kg (IV) q24 h OR 1 gm (PO) q8 h	3–4 weeks (maintenance)
2. Protozoa—		
• Toxoplasma gondii	Pyrimethamine 200 mg (PO) single dose	
	Followed by 50 mg (<60 kg) to 75 mg (>60 kg)	for 6–8 weeks
	daily orally + sulfadiazine 1 gm q6 h OR	
	Clindamycin 600 mg q6 h PO/IV	
	(up to 1200 mg IV q6 h)	
3. Fungi—		
• Candida species	Caspofungin: 70 mg load then 50 mg daily	Continue till 2 weeks after Blood cultures are negative
	Micafungin 100 mg daily	
	Anidulafungin 200 mg load, then 100 mg daily	
	Liposomal Amphotericin B 3–5 mg/kg daily	
• Aspergillus species	Loading dose: Voriconazole 6 mg/kg IV q12 h	
	Maintenance dose: 4 mg/kg q12 h	
• Cryptococcus neoformans	Induction phase—Amphotericin B deoxycholate 0.7 mg/kg q24 h IV +/- 5-flucytosine 25 mg/kg Orally q6 h	2 weeks
	Consolidation phase: Fluconazole 400 mg (PO) q24 h	8 weeks or until CSF cultures are sterile
	Chronic maintenance therapy: Fluconazole 200 mg (PO)	
	For secondary prophylaxis q24 h	
• P. jirovecii	Trimethoprim 5 mg/kg q6 h IV	21 days
	+ sulfamethoxazole 25 mg/kg q6 h IV	

Note: For Candida species, Fluconazole can be used in less critically ill patients and those who have no recent azole exposure. Fluconazole in such cases is used as loading dose of 800 mg (12 mg/kg), and then 400 mg (6 mg/kg).

Meningitis related to humoral or complement deficiencies is often due to *S. pneumoniae* or *H. influenzae*. Therapeutic regimes should include ceftriaxone 2 g intravenously every 12 hours and vancomycin 30–60 mg/kg 8 hourly. *Listeria monocytogenes* is a rare cause of acute meningitis in patients with cell-mediated immune deficiencies. Therapy for this should include ampicillin 2 g intravenously 4 hourly.

Tuberculous meningitis may occur in immunocompromised patients either by itself, or as a part of disseminated hematogenous disease. The clinical picture may be subacute, or may take the form of a fulminating meningo-encephalitis. Increase in cerebrospinal fluid (CSF) lymphocytes, raised proteins and a lowered CSF sugar level suggest the diagnosis. Acid-fast bacilli are almost never found in the CSF.

Therapy of inflammatory space-occupying lesions must necessarily be empiric before a definitive diagnosis (by an invasive procedure) is made. Pyogenic abscesses are best treated with massive doses of penicillin or ampicillin. Vancomycin should be added to cover a staphylococcal infection. In leucopenic patients, possible Gram-negative infections should be covered by ceftazidime and an aminoglycoside, or piperacillin + tazobactum together with and amikacin.

Tuberculomas and tuberculous abscesses, sometimes multiple, are common in our country and in all third-world countries where the incidence of tuberculosis is high. The CT findings with contrast studies are often distinctive enough to suggest a strong possibility of a tuberculous abscess. Specific treatment includes the use of rifamycin, isoniazid, pyrazinamide,

ethambutol and streptomycin in the doses outlined earlier. Treatment should continue for 9 months to a year.

In patients with a cellular immune defect, a mass lesion may be due to *Toxoplasma* infection. This requires the use of pyrimethamine 25–75 mg orally daily and sulfadiazine 1–2 g orally every 6 hours with leucovorin calcium 10 mg intravenously daily. If toxoplasmosis is proven to be the cause of a mass lesion, all the three drugs mentioned above should be continued for at least 6 weeks, and a maintenance regime with a lower dose of these drugs should be continued life-long in patients with AIDS. Dexamethasone 4 mg 6 hourly intravenously should be used only when mass lesions are associated with cerebral edema and with increased intracranial pressure.

Mass lesions may be due to other disseminated fungal infections. Definitive diagnosis can only be made by invasive procedures like a brain biopsy.

In patients with AIDS, inflammatory mass lesions described above need to be distinguished from tumors, particularly lymphomas, and viral infections, viz. the mass lesions produced by the HSV. The clinical background, the natural history of the disease and the CT findings help in the diagnosis. Definitive diagnosis more often than not, can only be made by a brain biopsy.

Disseminated Presentation

Involvement of two or more organ systems may well be present in infections occurring in immunocompromised patients.

- The lungs and the CNS can both be involved by either *M. tuberculosis*, *Nocardia, Aspergillus* and other mycelia and cryptococcal infections. Pyogenic abscesses can involve both the lung and the brain.
- The lung and mucocutaneous lesions occur with *Aspergillus* and in histoplasmosis (areas endemic to the fungus).
- *Multiple organ systems* Lungs, skin, joints, ocular, liver and spleen involvement can occur with invasive candidiasis. Patients who present with a single organ involvement may after a lapse of time may develop involvement of one or more other organ systems.

INFECTIONS IN PATIENTS WITH AIDS[7]

These patients form a subset of the most severely immunocompromised patients. The principles in relation to infective complications and their management outlined earlier are obviously applicable to these patients as well. The features characterizing pulmonary infiltrates in AIDS have already been briefly dealt with. Sepsis however can originate from almost any other site. The oral cavity, CNS, GI system, urinary system and breached surfaces of skin or mucosa are other important sites of infection in these patients. Great care should be taken to evaluate every possible source of infection; sepsis arising from indwelling catheters or central venous lines assumes special importance.

Fungal esophagitis, fungal (candidal) ulcers involving the lower esophagus and stomach, bleeding from the GI tract, perianal abscesses, perforated diverticulitis or other acute abdominal catastrophes may pose problems in diagnosis and management. Symptoms may be even more insidious than in other subsets of immunocompromised patients. In our country, tuberculosis, *salmonella* infections and overwhelming parasitic infections, head the list of infectious complications in this group of patients. Patients with AIDS form the only group of patients, in our country, in whom disseminated fungal infections (particularly cryptococcal and candidal infections) are quite common. All these infections should be assiduously searched for, investigated and treated. Not uncommonly, fungal, viral and parasitic infections in AIDS may be controlled during the acute stage but cannot be cured. Long-term suppressive therapy is needed to keep them under control, as they often flare up and cause acute illness if suppressive therapy is omitted, or if further deterioration occurs in the immune status of the patient. Infections in AIDS are usually multiple, often recurrent, with multiple organisms involving different sites. They are more severe; more disseminated, and elicit an even poorer tissue and body response as compared to patients immunocompromised due to other causes. They are often characterized by a very high density of organisms, a factor responsible for the poor results of therapy .

Finally, as already stressed earlier, any critical illness in a patient with AIDS may be due to tumors; in our country, lymphomas are probably observed with the same frequency as in the West; Kaposi's sarcoma, however, is comparatively uncommon.

Table 4 gives the list of common opportunistic infections recognized to be associated with HIV infection.

Table 4: Common opportunistic infections associated with HIV infection

	Clinical manifestations	
Organism	*Common*	*Infrequent*
1. Protozoa—		
• Toxoplasma	Encephalitis, retinochoroiditis	Pneumonia, dissemination
• Cryptosporidium	Enteritis	Cholangitis, bronchopleural lesions
• Isospora belli	Enteritis	
2. Fungi—		
• *P. jirovecii*	Pneumonia	Otitis, dissemination
• Candida spp.	Stomatitis, esophagitis	Proctitis, vaginitis, dissemination
• Cryptococcus neoformans	Meningitis, disseminated disease	Pneumonitis, skin lesions
• Histoplasma	Disseminated disease	
3. Nocardia	Lung abscess	Dissemination
4. Bacteria—		
• M. tuberculosis	Pneumonia, dissemination	Meningitis
• Atypical mycobacteria	Dissemination	Pneumonia, diarrhea
• Salmonella	Diarrhea, sepsis	
• *H. influenzae*	Upper respiratory infection	Pneumonia, sepsis
5. Viruses—		
• Cytomegalovirus	Retino-choroiditis, pneumonia, colitis	Adrenal necrosis, hepatitis, encephalitis, myelitis
• Herpes simplex	Mucocutaneous (mouth, digits, rectum)	Pneumonia, encephalitis
• Herpes zoster	Dermatomal skin lesions	Encephalitis, disseminated skin lesions
• Epstein-Barr	Hairy cell leukoplakia	
6. Helminth—		
• Strongyloides	Hyperinfection syndrome, bronchopneumonia	Dissemination

CHAPTER 64

Intensive Care Management of Polytrauma

NS Laud *MS (Orth). Retired Professor and Head, Department of Orthopedic Surgery and Chief Traumatology, LTM Medical College and LTMG Hospital, Mumbai, Maharashtra, India, Consultant Orthopedic Surgeon, Breach Candy Hospital, Mumbai, Maharashtra, India, with* ***FE Udwadia***

GENERAL CONSIDERATIONS

Polytrauma is a symptom complex with profound patho-metabolic changes.

The incidence of polytrauma is on the rise due to rapid industrialization and urbanization and the need for mechanized transport. Even in rural areas, its impact is seen due to the increased use of motorized equipment.

International data reveals not only an increasing incidence, but also a high early mortality in polytrauma. Violent trauma and road traffic injuries kill more than 2.5 million people in the world every year. According to the World Health Organization, there were 1.6 million violent deaths and 1.2 million deaths from traffic injuries[1,2] for a combined mortality of 48 deaths per 100,000 per year.

Most trauma deaths occur at the scene or in the first hour after trauma. In Western countries, 34–50% of these early deaths occur in hospitals.[3] Many of these deaths are preventable. With adequate prehospital care, with special regard to quick transportation to hospital, maintenance of a patent airway, breathing, circulation by paramedics, the mortality is significantly reduced. However, errors made in the in-hospital period of care are responsible for one-third to two-thirds of the deaths reported by various authors.[3] Of these, intensive care unit errors are reported to be among the most frequent and significant.

India is one of the ten most industrialized nations in the world. While India's vehicle population is less than 5% of the world, it accounts for the highest incidence of accidents in the world. More than 80,000 people lose their lives in accidents every year and it is estimated that about ten times that number are admitted in hospitals with injuries. The analysis from one of the "A" level trauma centers indicates a mortality between 19% and 23%. At the LTMG Hospital, Mumbai, which is one of the leading trauma centers, early intensive care with the participation of multispecialty residents, adequate monitoring, and treatment based on protocols, reduced the mortality of polytrauma from 23% to 16%. Further analysis of the patients salvaged indicated that mortality was highest in those arriving in the hospital after 24 hours and in those with multiple injuries brought to the hospital without adequate care during transportation in the first 6 hours.

These observations indicate that pre-hospital care has a significant role in the management of polytrauma. In most developing countries, pre-hospital care is non-existent. Patients are almost always transferred without any treatment, resulting in asphyxia, hemorrhage and shock.

PATHOPHYSIOLOGY OF TRAUMA VICTIMS

The human body is a superbly balanced mechanism having multiple self-restoring safeguards which are activated when an injury occurs. It is vital to understand the pathophysiology of the human response to trauma, if we wish to reduce the morbidity and mortality of the victim.

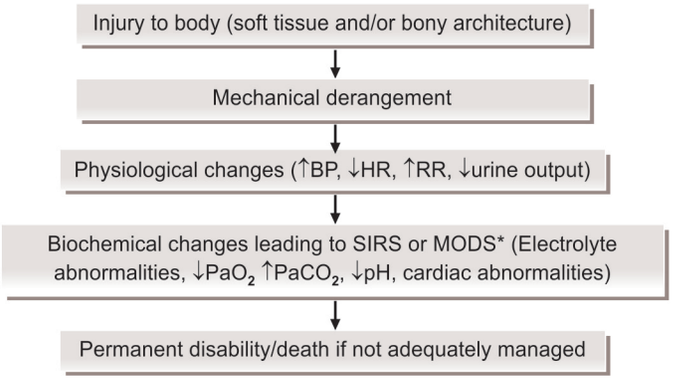
Flowchart 1 summarizes the various changes, and gives an idea of various levels at which one can intervene to interrupt the natural progression leading to death/permanent disability.

Physiological Response of the Body

The "fight or flight" sympathetic response is activated as a result of any trauma. It helps to counter blood loss, alters pulmonary/cardiac functions, and helps maintain viability of vital organs.

Tachycardia, tachypnea, peripheral vasoconstriction and selective shutdown of skeletal muscle microcirculation help

Flowchart 1: Pathophysiology of trauma



Injury to body (soft tissue and/or bony architecture)
Mechanical derangement
Physiological changes (↑BP, ↓HR, ↑RR, ↓urine output)
Biochemical changes leading to SIRS or MODS* (Electrolyte abnormalities, ↓PaO_2 ↑$PaCO_2$, ↓pH, cardiac abnormalities)
Permanent disability/death if not adequately managed

*SIRS—Systemic inflammatory response symdrome
MODS—Multiple organ dysfunction syndrome

in keeping the kidneys, brain and heart adequately supplied with oxygenated blood. The reduced blood supply to skeletal muscle induces anaerobic metabolism and causes metabolic acidosis, which, in turn, stimulates the respiratory centers leading to hyperventilation.

Increased catecholamines, products of the activated complement system, and the liberation of cytokines and other inflammatory mediators by host cells result in widespread damage to the endothelial lining of the microcirculation in various organ systems. There is also probably widespread impairment of cell function in various organs. The end result is multiple organ system failure. Involvement of the lungs is frequent and results in acute lung injury [acute respiratory distress syndrome (ARDS)]. Renal and other systems also show progressive dysfunction. Fat embolism following upon multiple long bones and pelvic fractures can worsen organ dysfunction, with particular reference to the lungs. The presence of an associated head injury or chest injury can depress the respiratory drive, physically impair ventilation and worsen the problems in relation to breathing and gas exchange.

The effect of altered oxygenation, altered acid-base balance and electrolytes can lead to cardiac function abnormalities. Associated chest trauma or direct injury to thoracic viscera results in an added insult to the already stressed circulatory system; this may further lead to hypotension with reduced cerebral and renal perfusion.

Reduced renal perfusion results in electrolyte imbalance; if renal perfusion is significantly low for a prolonged period, it can cause acute tubular necrosis. This situation can develop quite early in an acutely injured person, even though there is no direct renal injury to begin with. Crushing of muscles, development of the compartment syndrome and myonecrosis, severe infection and sepsis are other concomitant causes which can lead to acute renal shutdown. Unless rapid and early precautions are taken in these situations, it is easy to lose an otherwise stable patient.

Presence of major bone fractures causing severe pain, limited mobility and other complications, like fat embolism, injury to vessels or viscera, are important factors which contribute to increased mortality and morbidity.

The overall response of the human body to major stress is catabolic. The effect of this becomes more apparent if the time lag between severe injury and active intervention progressively increases. Absence of prompt critical care in severe trauma results in the human body being trapped in a self-propagating vicious cycle of an increasingly severe systemic inflammatory response, that finally culminates in death. Hence as providers of trauma care, our actions must be *urgent and on all fronts.* This is the precise reason why the patient with polytrauma warrants *intensive trauma care.*

T_1-T_2-T_3 CONCEPT OF TRAUMA CARE

The events from the time of accident to recovery can be chronologically divided into three time spans, denoted as T_1, T_2 and T_3 (Fig. 1).

T_1 is the time of accident which is very short and at the end of which the mechanical damage to the body is complete. Consequently, no further mechanical damage can occur till the point of intervention. The physiological and biological changes are often minimal during this period. A small percentage of patients having injuries incompatible with life (e.g. cerebral lacerations, open or penetrating cardiac injuries, multiple injuries or fractures with severe internal/external bleeding) die during this period. These constitute the *First Peak* of trauma deaths. There is no way of salvaging these patients; the only way to reduce or eliminate this first peak is by preventive safety measures taken in industries or on roads to reduce the incidence of accidents.

T_2 is the period from the point of accident to the point of intervention. This is the time when the patient is literally left to nature for achieving homeostasis. The longer this period, the lesser the chances of a successful outcome. The aim of the *Golden Hour Project,* which was started in cities like Mumbai, was to reduce this T_2 period to a minimum. Intervention within the first 60 minutes of an accident significantly improved the survival rate. A network of co-ordinated ambulances stationed at strategic points and working in unison with the local general practitioners and health workers transported any trauma victim to the hospital within 1 hour of the accident. A central office which regulated the flow of patients to various trauma care centers helped in avoiding bottlenecks in the traffic. Many deaths are thus prevented by the institution of prompt intervention.

T_3 is the intervention-recovery period. The duration of T_3 depends on the efficiency of the trauma care system. Delayed morbidity and mortality can occur in this period.

The most effective overall treatment of trauma victims is only possible if the modular concept of trauma care is adopted (Fig. 2). This includes Types A, B and C level trauma centers, with Type A being the most advanced with specialized units involving neurosurgery, reconstructive surgery, plastic

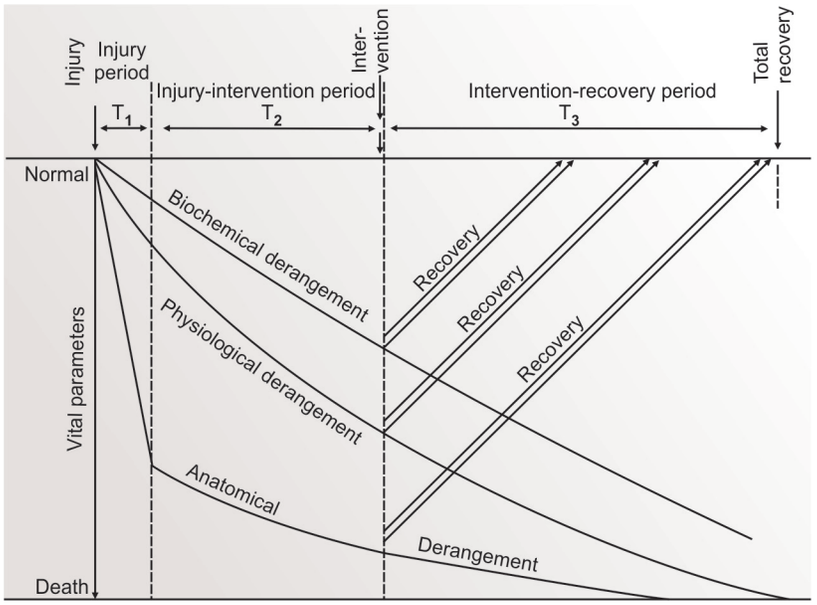


Fig. 1: The injury-intervention-recovery graph (a qualitative representation)

surgery, etc. Type C is the most basic or core unit which can provide the basic trauma intensive care for initial stabilization and emergency primary intervention. After stabilization, the patient can then be shifted to a more advanced unit for specialized treatment and/or rehabilitation.

WHAT CONSTITUTES INTENSIVE TRAUMA CARE

Aim To reduce mortality and long-term morbidity.

Conceptually, it is basically divided into two: (1) pre-hospital care and (2) hospital care.

Pre-hospital Care

The previous concept of 'pick and run' or 'stabilize and transport' has now been replaced by a new concept of evacuation and salvage by paramedics. It essentially consists of: (a) maintaining airway and circulation, (b) stabilizing the neck with a cervical collar, (c) splinting of fractures, (d) transportation of patients on a supine flat board anticipating spinal injury, and (e) covering open wounds with sterile dressings with gentle manual pressure to prevent blood loss and elevating the lower limbs in the presence of shock. The new trauma ambulances are manned by emergency medical officers and emergency technicians whose job is to initiate resuscitation and maintain the patient's basic life support, as also to communicate during transportation with hospital care units. These paramedics assess the severity of injury and transport patients to a specific center for initial and further management. This concept reduces the initiation time of T_2 concept as also the load on A-level trauma centers. It also helps to transport patients to appropriate centers.

Intensive Care Management[4,5]

The first 60 minutes are the "Golden Hour" for trauma victims.

Primary Survey

The primary survey is remembered as the A B C D E of trauma. Primary assessment of injury and resuscitation should be carried out simultaneously.

Airway

It is vital to look out for any obstruction to the airway. This could result from foreign bodies, facial fractures, bleeding or secretions. Snoring or gurgling sounds indicate an upper airway obstruction due to falling back of the tongue, or blood or vomitus in the oral cavity. At times, the patency of the airway may be compromised because of head injury or intoxication (notably alcohol or narcotics). The mouth should be cleared of all debris and an oropharyngeal airway inserted. A patient who verbalizes without stridor or hoarseness usually has a patent airway. It is however important to realize that airway compromise can come on later. This should be promptly recognized and the airway properly secured as an immediate intervention.

In many trauma patients, the airway can only be secured by endotracheal intubation with a cuffed endotracheal tube. It not only keeps the airway patent, but also guards the tracheobronchial tree from aspiration of blood or vomitus in unconscious patients. *One should always bear in mind the possibility of a cervical spine fracture, and the neck should therefore be kept in the neutral position to avoid injury to the spinal cord during intubation.* A nasotracheal intubation may be necessary in these patients. Rarely a tracheostomy may be necessary, particularly in patients with faciomaxillary injuries or fracture of the cervical spine.

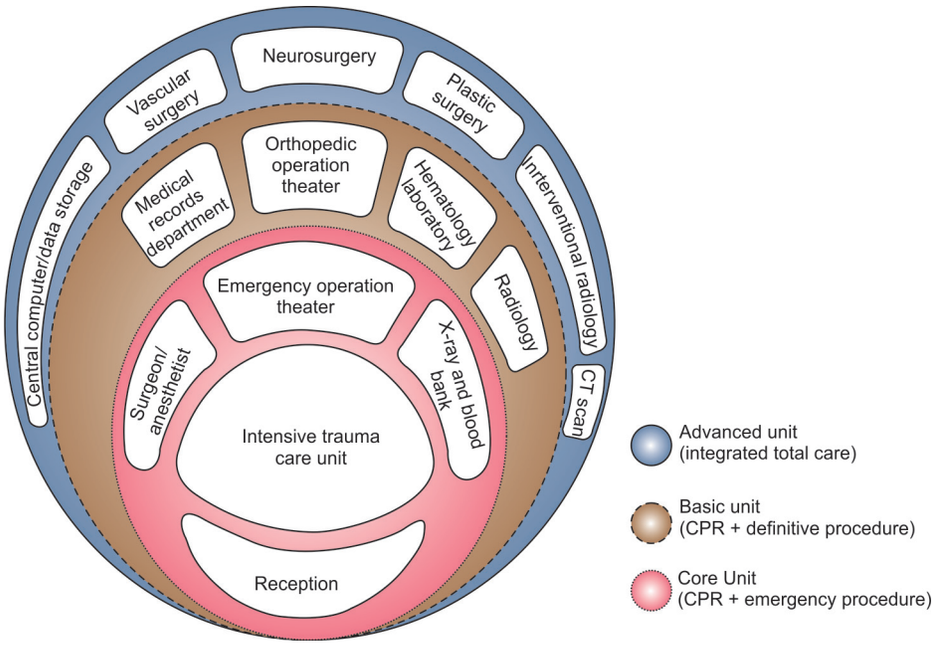

Fig. 2: Modular system of trauma units

Trauma victims may have a laryngeal, tracheal or bronchial disruption. This usually follows crush injuries and is to be suspected in the presence of hemoptysis, surgical emphysema and pneumothorax. Urgent surgical repair becomes necessary to allow preservation of airway integrity.

Breathing and Ventilation

A quick but careful clinical examination helps. Diminished chest excursions may be due to: intracranial injury, pain related to fractured ribs, or a pneumothorax or hemothorax. A massive atelectasis of the lung may produce similar physical signs. Diminished or absent breath sounds on either side might be related to hemothorax, pneumothorax, massive atelectasis or pulmonary contusion. Deviation of the trachea to the opposite side is seen with a pneumothorax, hemothorax or to a large hematoma in the neck. A careful look for obvious fracture of ribs and the presence of a flail chest is important. There are two important points to note while assessing breathing and ventilation—

1. It may be difficult to distinguish airway compromise from ventilatory failure in some patients.
2. A patient presenting with dyspnea may have several causes for it. Massive pulmonary contusions are one of the important causes.

High flow oxygen is used for all patients. If breathing and ventilation are seen to be jeopardized, bag mask ventilation using 100% oxygen should be promptly started to achieve good oxygenation. If for whatever reason ventilation is unsatisfactory, intubation with mechanical ventilatory support should be given. It should be kept in mind that positive pressure ventilation would worsen a pneumothorax if that is present. A pneumothorax and/or a hemothorax need to be promptly drained to allow effective ventilation. It is important to achieve an O_2 saturation of well over 90%.

Circulation and Control of Hemorrhage

Blood volume and cardiac output The clinical features of blood loss and poor perfusion are easily recognized. A fast thready pulse, hypotension, pale ashen skin, poor capillary refill, sweating, increasing mental obtundation, and little or no urinary output are the classic features of hemorrhagic shock.

Bleeding External bleeding is obvious and should be stopped by pressure or by ligation of the bleeding vessel, if possible. Occult bleeding should always be suspected if there are signs of shock without external blood loss. Common sites of internal bleeding are—

- *Intra-abdominal* This may be present without any evidence of laceration or external injury. Injuries to the liver, laceration or rupture of the spleen, large retroperitoneal hematomas should be kept in mind. Distension of the abdomen and generalized or localized tenderness should be looked out for. An ultrasound-guided abdominal paracentesis may confirm the presence of blood in the peritoneal cavity. A four-quadrant abdominal paracentesis is often adviced when there is a strong suspicion of an intra-abdominal bleed.
- *Chest* The presence of rib fractures dullness on percussion and diminished breath sounds lend suspicion to the presence of pleural effusion. A chest X-ray can confirm fluid within the pleural space.
- *Fractures of the pelvic and/or long bones such as the femur* A fracture of the femur can lead to loss of as much as one or two units of blood within the tissues and muscles of the thigh.

Points to remember with regard to circulatory shock from blood loss and hypovolemia are listed as follows—

- Elderly patients decompensate rapidly; marked tachycardia may be absent. Young patients have more reserve and may not show signs of shock unless markedly volume depleted.
- Patients on β-blockers may not show tachycardia.
- Internal bleeding may be present from *multiple sites* in trauma victims who are in shock due to blood loss.
- Important complications following trauma producing severe shock and mimicking hemorrhagic shock are tension pneumothorax and cardiac tamponade. These complications may also well exist side-by-side with hemorrhagic shock. Finally, severe contusions of the heart can effectively reduce cardiac function and output resulting in the picture of cardiogenic shock.

Circulatory shock should be managed on a war footing. Two large bore intravenous lines should be inserted in two peripheral veins one above and the other below the diaphragm to allow volume replacement. If a peripheral vein is inaccessible, a large single lumen catheter is inserted into a central vein through which fluid is administered. One to two liters of Ringer's lactate solution are administered promptly, and this usually restores the normal pulse and blood pressure if the blood loss is less than 15% and there is no persistent bleeding. If 2 L of Ringer's lactate solution fail to restore blood volume and the patient remains hemodynamically unstable, 2 more liters are infused and blood transfusions are also given. If hypotension persists despite infusion of 4 L of Ringer's lactate, colloids and blood, the blood loss is likely to be greater than 40%. If the patient needs surgery, resuscitation is continued in the operation theater.

Efficacy of volume replacement is gauged chiefly on clinical grounds—significant improvement in pulse rate, blood pressure, skin color, capillary refill, mental state and urine output. Metabolic acidosis is corrected following volume resuscitation and the blood lactate levels return to normal or near normal.

Disability or Neurological Status

A rapid neurological examination is important. The following features should be carefully looked out for—

- Glasgow Coma Score (3–15)—
  - Eye opening 1–4.
  - Motor response 1–6.
  - Verbal response 1–5.
- Pupillary size and reactivity.
- Presence of lateralizing signs.
- Presence of possible spinal injury and, if so, at what level.

It is important to note that a lucid interval may be present before an intracranial lesion manifests itself clinically.

Exposure/Environmental Control

It is important to remove all clothing to allow a full examination and a thorough inspection of injuries. After this has been done, the patient should be well covered; hypothermia should be avoided and, if present, countered by a warmer blanket. Hypothermia worsens bleeding and outcomes in trauma.

Adjuncts to the Primary Survey

Certain interventions and procedures are necessary during the evaluation and resuscitation of the trauma patient. These are performed during the primary survey or immediately after. These include—

- *Continuous electrocardiography (ECG) monitoring* A full ECG is done to start with and subsequently if there is any arrhythmia or ST segment changes.
- *Pulse oximetry* The O_2 saturation is kept greater than 90%.
- Insertion of a urinary catheter to assess urine output. It is important to assess for urethral injury by noting any bruising of the perineum or bleeding through the urethral meatus before attempting to insert a catheter.
- *Insertion of a nasogastric tube* Stomach contents should be aspirated to prevent risk of aspiration pneumonia.
- Arterial line for continuous blood pressure monitoring.
- Urgent X-ray of the chest, pelvic films, if there is a blunt trauma or a penetrating wound to the abdomen. Other imaging studies are done as determined by the clinical situation and the nature of the trauma. An X-ray of the cervical spine is important.

Secondary Survey

After a primary survey is complete and resuscitation started, a very careful secondary survey is carried out with detailed, careful examination of all different body areas.

It is important to ask from relatives or friends any history of drug allergy, any medication the trauma victim has been taking, a history of past illness and the time of the last meal before trauma. Details of the nature of trauma or accident should also be elicited.

Clinical examination of different areas should start with the head and systemically proceed downwards.

Head

Head should be carefully examined for lacerations, hematomas, eye injuries and vision.

Maxillofacial Area

Maxillofacial injuries should be carefully looked for facial nerve injuries and intraoral mandible fracture, in particular.

Neck

The neck should be examined for crepitus, hematomas, tracheal shift and tenderness over the cervical spine. The venous pressure should be assessed clinically.

Chest and Heart

A careful examination of the chest should be performed. Evidence for fracture of ribs and sternum, lacerations

over the chest and the presence of crepitus should be sought. Abnormalities in chest expansion, percussion and auscultatory findings should be noted. A special look for the presence of pericardial effusion or cardiac tamponade is necessary. The heart should be carefully auscultated for a gallop. Crepitations over the lungs signify retained secretions or pulmonary edema. A noteworthy cause of pulmonary edema is left ventricular failure following upon contusion of the heart. An echocardiogram will help gauge systolic and diastolic cardiac function.

Arrhythmias need prompt treatment. The occurrence of ventricular tachycardia causing hemodynamic instability or ventricular fibrilation at any point in time will require DC defibrilation, starting with a DC shock of 200 J, and increasing, if necessary, to 300 J. Cardiopulmonary resuscitation is unquestionably of prime importance and of immediate priority in trauma patients who require it (for details see Chapter Cardiopulmonary Resuscitation and Cerebral Preservation in Adults).

Abdomen

One should look for evidence of bruising, laceration, distension, tenderness, discoloration, suggesting underlying hematoma, and for the presence or absence of bowel sounds. A USG of the abdomen may provide valuable information.

Perineum

A search should be made for hematomas, tenderness on palpation, vaginal tears, rectal bleeding and bleeding from the urethral meatus.

Limbs

Examiner should look out for deformity, crepitus on movement, distal pulses, hematomas and any possible injury to nerves and vessels.

Central Nervous System

A detailed neurological examination should be performed to determine if there are lateralizing signs or if there is evidence to suggest injury to the brainstem. In spinal cord injuries, the level of the lesion should be determined, if possible, on clinical examination.

Tertiary Survey

It is crucial for intensivists in the ICU to perform a continual reassessment as outlined in the secondary survey. The response to resuscitation measures is carefully assessed, and complications arising subsequently promptly identified and treated.

Major complications to be watched out for and appropriately treated are infections related to trauma, nosocomial infections, pneumonia, sepsis, ARDS, renal dysfunction and the multiple organ dysfunction syndrome. Metabolic disturbances include fluid and electrolyte disturbances as also acid-base disturbances.

MAJOR IMMEDIATE LIFE-THREATENING COMPLICATIONS

Cardiac Tamponade

Cardiac tamponade is generally observed after blunt injury or crush injuries to the chest, in patients with a fracture of the sternum, fracture of the ribs and in patients with a flail chest. Any intrathoracic injury in a trauma patient should prompt the intensivist to look out for a possible cardiac tamponade.

Cardiac tamponade is typically characterized by tachycardia, an increase in central venous pressure, hypotension and the clinical features of shock. The central venous pressure is however not always sufficiently raised and may even be normal if there is associated hypovolemia. Echocardiography helps in the diagnosis. An X-ray of the chest may show an enlarged cardiac silhouette with a widened mediastinum.

Pericardiocentesis relieves the tamponade; this may have to be repeated. Surgical drainage through a pericardial window is the treatment of choice (see Critical Care in Relation to Cardiovascular System).

Tension Pneumothorax

This is a frequent life-threatening emergency in trauma patients. It should always be looked for. The presentation is with breathlessness, respiratory distress, absent breath sounds over the affected side, shift of the mediastinum to the opposite side and features of shock—tachycardia, hypotension and hypoxia. In a dire emergency, a needle decompression (through the second intercostal space in the midclavicular line) of the pneumothorax should be done. A chest tube drain connected to an underwater seal can then follow.

Massive Hemothorax

Massive hemothorax presents as hemorrhagic shock. A dull percussion note over the hemothorax with diminished or absent breath sounds is noticed. An X-ray chest shows massive intrapleural opacity. A CT chest (if the patient is stable) confirms the diagnosis.

Resuscitation with fluid and blood replacement, together with chest tube drainage, is promptly done. Surgery is often needed to identify and stop the source of bleed.

Contusion of the Heart

A severe contusion of the heart leads to hypotension, and tachycardia despite adequate fluid replacement. Arrhythmias may be the presenting feature. It should be noted that the estimation of cardiac enzymes (creatinine phosphokinase and troponin) has no proven value in the diagnosis of cardiac contusion following blunt injury. Echocardiography shows impaired wall motion over the area of contusion. ECG shows ST-T changes which may be indistinguishable from those seen in myocardial infarction. Treatment is largely supportive, chiefly with the use of inotropic drugs.

Flail Chest

A flail chest is obvious on clinical examination. If not promptly treated, it leads to progressive hypoxia or to hypoxic and hypercapnic respiratory failure, to atelectasis of segments or even a lobe and retained secretions within the chest.

An X-ray of the chest and, if possible, a CT of the chest allows a detailed evaluation of the injuries to ribs and/or sternum.

Treatment consists of adequate pain relief, bronchial toilet and endotracheal intubation with ventilator support till the chest stabilizes. Non-invasive ventilator support often suffices if the degree of injury is not marked.

Injuries to the Liver, Spleen, Gut and Pelvis

Injuries to the liver, spleen lead to profuse intra-abdominal hemorrhage causing hemorrhagic shock and abdominal distension. A peritoneal aspirate draws frank blood. Injury to the pelvis and pelvic bones produces a similar picture. A laparotomy with removal of the spleen if there is a rupture or severe laceration, and careful surgical attention to a lacerated liver are life-saving. It is important to stabilize the pelvis in the presence of pelvic fractures to reduce venous oozing. Perforation or a tear in the gut is a cause for distension, with signs of peritonitis.

Head Injury

This has been dealt with in the Chapter "Neurological Problems".

Cervical Cord Injury[6]

It is vital to exclude cervical cord injury in a traumatic victim. Till such time as this is determined, the head is kept in a neutral position. Neurosurgical advice and the advice of a spinal surgeon should be taken promptly for diagnosis and management.

ROLE OF MECHANICAL VENTILATION IN TRAUMA PATIENTS

Indications[2]

Ventilator support is mandatory for patients with head injury, chest injury (flail chest with pulmonary contusion), high cervical cord injury, acute lung injury (ARDS), sepsis syndrome and severe pneumonia. Elective mechanical ventilation is also indicated: (i) in patients with blood loss greater than 40% of estimated blood volume, hematocrit less than 30% and hemodynamic instability (low blood pressure, tachycardia, reduced urine output and other features of shock); (ii) in patients with an injury severity score greater than 30; (iii) in patients with multiple fractures (polytrauma); and (iv) in some patients with head injury to control intracranial pressure, and thereby reduce mortality and morbidity.

Ventilator support should not be delayed till a point in time when the patient is in severe respiratory distress or is obviously cyanosed. The indications for initiating ventilatory support are based on clinical assessment and results of arterial blood gases. Indications, together with details on management of ventilatory support, have been dealt with in the Chapter Mechanical Ventilation in the Critically Ill.

Weaning from Mechanical Ventilation[3]

Every effort should be made to discontinue ventilatory support as soon as the patient is hemodynamically stable and is able to resume and sustain spontaneous ventilation. Weaning criteria have been discussed in the Chapter Mechanical Ventilation in the Critically Ill.

RE-EVALUATION AND CONTINUOUS RE-ASSESSMENT

Re-evaluation and re-assessment is vital all through the patient's stay in the ICU. It enables the intensivist to detect complications—as, for example, renewed bleeding, complicating infection, sepsis and ARDS. At times, re-surgery or reconstructive procedures are necessary within 48–72 hours of the primary treatment. Delayed deaths or complications due to lack of adequate or infrequent follow-up will lead to loss of human life, and will negate the effort and expenditure spent on initial pick-up and stabilization.

APPROACH TO SKELETAL INJURIES IN POLYTRAUMA PATIENTS

Multiple fractures are often observed in polytrauma patients and, at times, may dominate the clinical picture. The timing of surgical interference with regard to skeletal injuries as also the nature and extent of surgery that should be performed have been subjects of continuing discussion. Current opinion on this subject is embodied in the concept of damage control; this concept plays an important role in the early care of polytrauma patients with severe skeletal injury. The patients are essentially categorized into four groups—

1. Stable patients after initial resuscitation, stabilized visceral injury with maintenance of basic parameters.
2. Borderline patients, well resuscitated after major chest or abdominal injury and major skeletal fractures.
3. Unstable patients with major skeletal injury and visceral injury after initial management.
4. Severely ill polytraumatized patients who are extremely unstable.

"Damage control" concept indicates the following approach. In groups I and II, early skeletal fixation can be advocated. The operation should be done as early as possible, and the preference is for minimally invasive surgery, e.g. use of external skeletal stabilization in injury to the pelvis and closed intramedullary nailing using unreamed

nails in proximal fractures. However, in Groups III and IV, the damage control operation concept envisages a stagewise approach.

Stage I. Management in the emergency room and lifesaving operations like exploration of visceral injury to control hemorrhage and external skeletal stabilization of pelvic or proximal fractures.

Stage II. Shift to ICU for intensive monitoring and further stabilization till the metabolic response to trauma is assessed and the patient's parameters return to normal, indicating a reduction in the proinflammatory response. Urgent surgery is required for head and brain injuries, for fractures with severe soft tissue injuries, visceral injuries and spinal cord injuries.

Stage III. Definitive reconstruction of the chest or abdominal trauma or definitive osteosynthesis using plate, intramedullary nail or screws is usually carried out between 7 and 10 days.

The incidence of infection following temporary external skeletal fixation, with conversion to internal fixation within 1–2 weeks is the same as that observed with primary intramedullary nailing.[7] Damage control orthopedic surgery has helped in early total stabilization of the patient, reduction in the need for ventilatory support, better pain relief and prevention of ARDS. Pain relief following definitive skeletal stabilization and very early mobilization of the injured limb or limbs reduce the chances of postimmobilization muscle atrophy and helps the patient attain a positive nitrogen balance. There is also a dramatic improvement in the functional and psychosomatic state of the patient. The advent of minimally invasive surgery and new implants has dramatically reduced the duration of hospital stay, has enabled early ambulation and has resulted in a reduction in secondary complications.

Prevention of Infection

Trauma patients have a reduced capacity to fight infections, as the immune system is depressed under these conditions. The body is in a catabolic state following injury and subsequent surgical intervention. The use of steroids further reduces the capacity of the body to fight infection. Blood transfusions, presence of intravenous lines, central line catheters, urinary catheters, and endotracheal or tracheostomy tubes are all potential sources of sepsis.

The bedridden patient is also more prone to develop bedsores and basal hypostatic pneumonia. These factors all predispose to the development of overt or occult infection in polytrauma patients. Open fractures and compound injuries further aggravate the problem. If infection occurs in these critically ill patients, it can rapidly push them downhill; prophylactic antibiotics are thus preferable. They should cover both Gram-positive as well as Gram-negative organisms, and also anaerobes. A combination of ampicillin with an aminoglycoside and metronidazole is usually used. Use of more specific antibiotics after culture and specific testing for antibiotic sensitivity is preferable, and can be instituted at a later date. If a specific infection is identified (e.g. urinary tract infection or bone infection), a more specific antibiotic having better penetration in these systems can be used. General aseptic measures and limiting of traffic in the intensive care trauma unit will help in reducing the incidence of these infections. Early mobilization of the patient by fixing bony injuries surgically will go a long way in improving the general condition of the patient, and will thereby reduce the incidence of deep vein thrombosis, basal atelectasis, pneumonia and bed sores.

Nutritional Support

It cannot be overstressed that good nutrition is essential for survival in severe trauma victims. The importance of this is sadly ignored in many units in our country, resulting in a high morbidity and mortality. Enteral feeding is the best way of ensuring proper nutrition to a patient. However many situations preclude the use of the enteral route, and force the physician to resort to the parenteral route (see Chapter Nutritional Support in the Critically Ill Adult).

Pain Relief in the Trauma Victim[8]

This is an important feature in the care of critically ill trauma patients. Various methods are used for pain relief, which are as follows—

- Patient-controlled analgesia.[9] A pump containing a maximally allowed total dose of an analgesic (usually narcotics like morphine or pethidine) is set up. The patient has a push button which when pressed will inject a small amount of the drug intravenously. A lag time is adjusted between two successive injections to prevent a patient from overdosing himself by repeated use of the device. This is a very good system as the patient can himself decide when he requires relief from pain.[8,10]
- Continuous analgesic intravenous infusion of small doses of morphine (0.1 mg/minute) provides effective pain relief in most cases. Alternatively, 30 mg pentazocine together with 50 mg pethidine is added to 500 mL of 5% dextrose/N saline and given intravenously as a slow infusion over 5–6 hours. This drip can be repeated after 12 hours depending on the patient's needs.
- Oral analgesics can be given if the patient can tolerate them.
- Regional blocks to anesthetize the painful area (e.g. intercostal blocks in rib fractures where breathing is impaired due to pain) are also used to relieve pain.
- The placement of an epidural catheter with continuous patient-controlled/physician-controlled epidural injections of appropriate analgesics is being increasingly used in the ICU. In our set-up, we commonly use buprenorphine 150 μg, diluted in 10–20 mL of normal saline administered slowly. This provides highly effective pain relief, the analgesic effect lasting for approximately

12–16 hours. Morphine or pethidine may also be used via the epidural route. In acute cases, pain relief should consist of a combination of analgesics. Non-narcotics like diclofenac sodium can be combined with narcotics like morphine, pethidine or their derivatives. In cases of head injury, where the level of consciousness needs to be assessed, narcotic analgesics should be avoided. Effective pain relief reduces the patient's anxiety and helps in controlling excessive sympathetic outflow.

Splinting of fractures, use of pinless fixators to stabilize broken limbs and subsequent early stabilization, all go a long way in effective pain relief.[8,10]

General Nursing Care and Physiotherapy

Specific care to prevent bedsores is necessary in debilitated patients. Special foam mattresses, alternately inflating-deflating air beds and waterbeds are various ways of solving dependent skin pressure problems. Log rolling of the patient, active movements and keeping the dependent pressure-bearing skin points dry are also important. Deep breathing exercises and chest physiotherapy are essential in most patients. Passive mobilization of all joints, splinting of joints in their functional position in order to prevent contractures and active movements to prevent muscle wasting are also necessary. Care of the eyes and mouth (especially in unconscious patients) also constitutes an important aspect of general nursing in a severely traumatized victim.

Long-term Rehabilitation

This should be planned and discussed with the patient, keeping in mind his realistic functional outcome as soon as possible. This will allow the patient to mentally accept his disability, and will give him a psychological boost to try for maximum possible recovery.

CHAPTER 65

Management of Critically Ill Burns Patients

SM Keswani MS, M.Ch. Consultant Plastic and Cosmetic Surgeon, Breach Candy Hospital and National Burns Centre, Airoli, Mumbai, Maharashtra, India, with **FE Udwadia**

GENERAL CONSIDERATIONS

It is now universally accepted that burns are essentially a medical problem, at least in the initial stages. The alterations in circulatory hemodynamics, renal function, cardiorespiratory physiology, the gastrointestinal (GI) and the hematopoietic systems, all require the attention of a team of specialists. Thus a team approach is required for the management of major burns.

In India, burns are the second most common cause of injury after road accidents. Women and children are involved in 80% of burn accidents; the majority of women who get burnt are between the ages of 15 and 20 years. Around 75% of burns occur at home.[1] Burn accidents occur throughout the year, but are commoner during the cold season. This is largely because the cold season is generally windy; it is the wind which fans a fire causing more extensive burns. During the festive season of Diwali (the festival of lights), when firecrackers are widely used, burn accidents tend to increase in number. Suicidal and homicidal burns account for approximately 5% of all burn accidents, particularly in young women. The majority of burns occur in the homes of the poor, which usually are small and at ground level. Here it is easy for the victim to rush out and seek help, and respiratory injury is uncommon. The loosely wrapped *saree* is ideal for burning; the thighs and legs which are the best skin donor areas get damaged in *saree* burns. It is an often repeated myth that the Indian burns patient is anemic and hypoproteinemic. They become so after the burns due to inadequate management.

Burns involving 70–80% of body surface area have a 100% mortality. In good burns centers, the mortality rate is now less than 50%.[2] There have been two major advances responsible for the sharp reduction in the mortality of severe burns—

- The first is the quick removal of burnt tissue prior to the onset of infection, and covering of the wound with available autoskin grafts and skin substitutes. Unfortunately, in poor developing countries like India, facilities and infrastructure for prompt surgery in severe burns exist only in very few centers. Mortality in extensive burns thus continues to be forbiddingly high.
- The second is the improvement in the critical care of burns patients, which enables the prevention of multiple organ failure during the period of resuscitation, surgical excision of the burns, and the healing process.[2]

The occurence of multiple organ failure carries a forbiddingly high mortality (>80-90%) and its treatment in the presence of burnt tissue is impossibly difficult, chiefly because the presence of remaining burnt tissue perpetuates and worsens organ system dysfunction. Although the critical care of burns patients has improved in the large centers of India, much more needs to be done in the country for better care. The leading cause of death from burns in poor countries is still sepsis and its complications, whereas in the West, the leading cause of death is now respiratory failure.

PATHOPHYSIOLOGY OF THE BURN WOUND

Skin is damaged by the total quantity of heat applied to it, i.e. the intensity of the heat and the duration of time the heat is in contact with the tissue.

Jackson described three concentric zones of burn injury.[3,4] These zones are illustrated in Figure 1.

The central "Zone of Coagulation" represents the area of maximum damage, and consists of protein coagulation of the tissues including the blood vessels. Blood flow through the affected arterial and venous channels ceases, resulting in a state of irreversible tissue death.

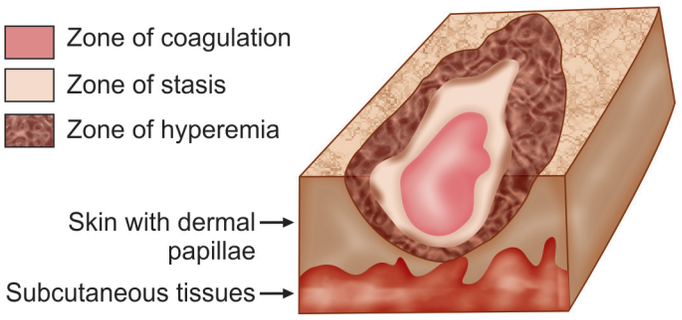

Fig. 1: The three concentric zones of burn injury as described by Jackson
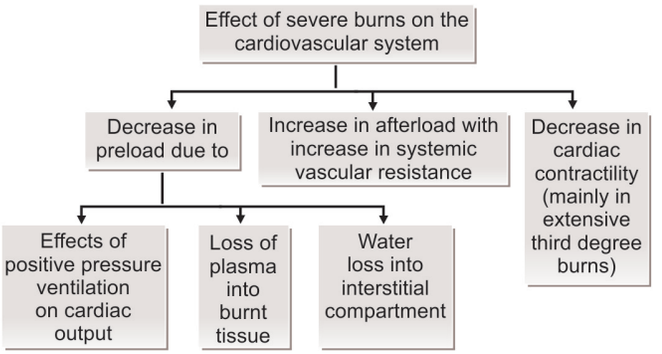
Source: Zawacki BE. Reversal of capillary stasis and prevention of necrosis in burns. Ann Surg. 1974;180(1):98-102.

Flowchart 1: Cardiovascular response to severe burn injury



Effect of severe burns on the cardiovascular system
Decrease in preload due to
Increase in afterload with increase in systemic vascular resistance
Decrease in cardiac contractility (mainly in extensive third degree burns)
Effects of positive pressure ventilation on cardiac output
Loss of plasma into burnt tissue
Water loss into interstitial compartment

This central zone is surrounded by a zone of less damaged tissue, known as the "Zone of Stasis". The blood flow through this zone is completely slowed down, and tissues are starved of oxygen and nutrients. If left unprotected as with exposure treatment, this zone becomes dried up, desiccated, infected and the cells become irreversibly dead. If managed properly, the damage may be reversed and the "Zone of Stasis" comes back to life. The aim of modern burns management is to prevent this "Zone of Stasis" from getting dried up or infected. This can be achieved by the application of autografts, homografts, xenografts (other animal skin), synthetic skins, cultured skins or potato peel bandages.[5] The burn wound must be kept moist, and should not become infected. Wound healing must not be disturbed by traumatic dressings.

Surrounding both these zones is the zone of least damage, the "Zone of Hyperemia". In this zone, the cells are hyperemic, and heal spontaneously if provided with adequate care.

SYSTEMIC RESPONSE TO BURN INJURY[6]

Cardiovascular System

The initial response to burn injury is decreased cardiac output and increased systemic vascular resistance (Flowchart 1). This is proportionate to the size of the burn and the severity of hypovolemia that may be allowed to occur. If corrected rapidly, the process may be reversed, the cardiac output increases and the peripheral vascular resistance decreases. During the second 24 hours post-burn period, the post-burn capillary hyperpermeability decreases, the extravasated fluid from the interstitial compartment returns to the vascular compartment, the volume deficit is corrected, and the cardiac output increases to above normal levels. It has been shown that the increase in blood flow is more in the burnt tissue than elsewhere, thus optimizing wound healing.

Respiratory System

Pulmonary complications are an important cause of morbidity and mortality, particularly in the West. Thermal injury in a closed environment causes pulmonary inhalation injury that can seriously damage the upper airways, larynx, trachea, bronchial tree and the pulmonary parenchyma. In addition, intoxication can result from inhalation of combustion products; the most important of these are carbon monoxide (CO) and cyanide. The physiopathology of pulmonary changes in severe burns is due to many factors. These include thermal inhalation injury, chemical irritation by smoke and other chemicals, secondary infection, the occurrence of acute lung injury (ARDS), fluid overloading and pulmonary embolism.

Physiological changes occur in the respiratory tract after every major burn injury. The respiratory rate and tidal volume increase in direct proportion to the size of the burn. With the large volume of resuscitation fluids infused, the chest wall edema increases considerably, and if treated by exposure, any burn on the thorax forms a tough constrictive eschar, which restricts movements of the thoracic cage. This requires correction with urgent escharotomy. However, it may be mentioned at this stage that the use of potato peel bandages keeps the burn wound supple, and has obviated the need for escharotomy in any patient, except when the patient reaches the burn center late with already established, constricting eschars.

By the 3rd to 5th day post-burn, the extravascular fluid gets reabsorbed, and if the patient has been overinfused, pulmonary edema progressing to acute lung injury (ARDS) may result. Hence, infusion of fluids during the initial resuscitation period has to be carefully calculated so as to maintain a normal blood volume, as also adequate tissue perfusion and renal perfusion.

Arterial hypoxia (a fall in PaO_2) may occur at the very start in severe burns. In other cases, arterial hypoxemia and hypercapnia become manifest 8–14 days following the burns. Ventilation-perfusion inequalities, increase in the right to left shunt within the lungs, and inadequate ventilation in relation to metabolic needs are responsible for these blood gas changes.

Renal System

With the onset of hypovolemia following burns, the renal blood flow and glomerular filtration rate are both considerably reduced. If not corrected early, this may result in acute tubular necrosis and renal shutdown. Early and adequate correction of hypovolemia is hence essential in the treatment

of burns. Forty-eight hours following burns, when resorption of the extravasated fluid takes place, diuresis occurs.

Gastrointestinal System

Acute ulceration of the stomach or duodenum (Curling's ulcer) occurs in about 11% of burns population. Multiple acute erosions may also occur and can cause severe GI bleeds. Post-burn hypovolemia is also accompanied by reduction of GI tract blood flow which manifests as ileus. If hypovolemia is not allowed to supervene, this is rapidly corrected and ileus does not occur. Ileus causes gastric and intestinal distension and stasis with an increasing likelihood of translocation of intestinal bacteria. Contrary to earlier practice, early post-burn feeding is now encouraged not only to provide nutrition through the natural pathway but also to preserve the integrity of the gut and to offset the complications which may ensue from bacterial translocation.

Central Nervous System

Specific neurologic changes following burn injury have not been described. Restlessness, disorientation and fits are observed and indicate cerebral hypoxia, cerebral edema, fluid and electrolyte imbalance or sepsis. These should be investigated and corrected early.

Hematopoietic System

The red cells circulating in the burnt area are promptly coagulated. But many more are significantly damaged and become nonviable soon afterwards. In major burns this is often marked by the loss of fluid from the intravascular compartment, which results in severe hemoconcentration and an increased packed cell volume. It is only after the resorption of the extravasated fluid that the reduction in red cell mass becomes manifest. The loss of red cells may be as high as 10% of the total red cell mass per day in major burns. Constant and regular monitoring of the blood count is, therefore, essential in all burns.

Changes in white cell count occur according to the level of infection in the body. A reduction in platelet count is one of the earliest signs of impending sepsis. Transfusion of platelet concentrates as and when necessary and the use of appropriate antibiotics is indicated.

Coagulopathies may occur in the resuscitation phase. Disseminated intravascular coagulopathy is associated with reduction of various clotting factors including prothrombin, factors V, VIII and IX. Thrombocytopenia and thrombocytopathy necessitating platelet transfusions may be observed. A hypercoagulable state may occur 2–4 weeks after a severe burn injury.

Immunologic Effects

The host immune response is suppressed in severe burn injuries. Complement and immunoglobulin levels are initially depressed, and chemotaxis is initiated by the presence of a plasma inhibitor. Patients with burns are excessively prone to nosocomial infections, and in spite of the use of topical and systemic antibiotics, sepsis remains a major killer, particularly in poor developing countries.

Metabolic Effects

Increase in the metabolic rate with a markedly negative nitrogen balance is greater than in any other form of trauma. There is an increase in oxygen consumption and in carbon dioxide production. The stress response is mediated by catecholamines, other anti-insulin hormones, and is often associated with glucose intolerance in the early post-burn period. Insulin resistance may be observed over a prolonged period of time. Hypermetabolism increases with sepsis, cooling and pain, and control of the above-mentioned factors plays an important role in management.

First Aid

Burn injury is caused by heat. Even after the flames are extinguished, the residual heat trapped in the skin continues to damage the tissues. A burning sensation indicates the presence of heat in the tissues. Cold water (not ice cold) should be poured over the burnt area till the burning sensation has subsided. This may take up to 6 hours. Cooling the burnt area reduces both the area and depth of burn. It is the easiest way to reduce the burn damage to the tissues, and to reduce the pain. Analgesics and sedatives should be avoided, as the restlessness seen after burn injury is often due to cerebral hypoxia; sedation may actually accentuate the cerebral hypoxia, thereby increasing the restlessness. In chemical burns, the chemicals over the body should be washed away with copious amounts of water.

Transport

Loss of blood volume starts immediately following burn injury. It is most severe during the first 8 hours. In burns higher than 30% of total body surface area, the leakage of plasma occurs all over the body. This fluid volume deficit must be replaced as early as possible. While in transport, fluid replacement should be actively undertaken if the time taken to reach a burn center will take more than 1 hour.

Assessment of Burn Severity

The area of burns is estimated by the simple Wallace's "Rule of Nine" (Fig. 2). A more accurate and better method is the estimation by Lund and Browder's chart (Fig. 3).[7] Burns of over 10% body surface area in a child and over 15% body surface area in an adult can cause hypovolemic shock and hence should not to be taken lightly. Burns of over 30% of the body surface area are very serious.

Burn severity also varies with the depth of burn (Fig. 4). Burns which damage the full thickness of the skin are considered full thickness burns. When the depth of the burn is not complete, it is known as a partial thickness burn. Partial thickness burns heal by regeneration from the residual skin elements, if managed properly. Full thickness

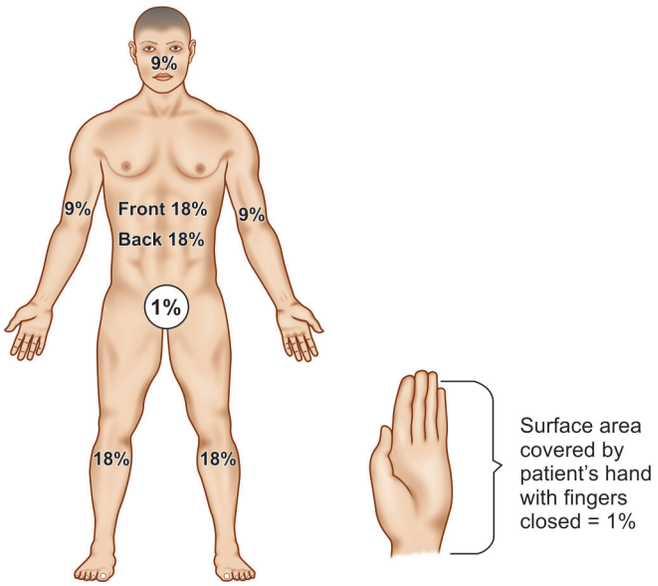


Fig. 2: Estimation of surface area by the Wallace's Rule of Nine

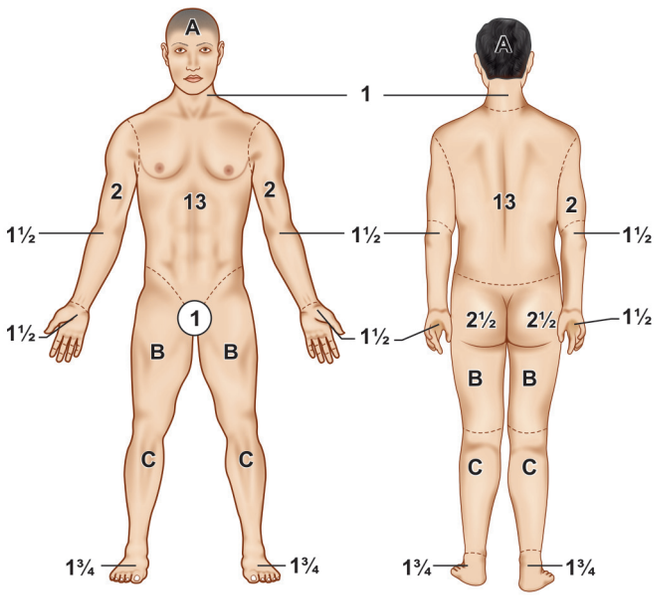

Area	Age	0	1	5	10	15	Adult
A = ½ of one thigh		9½	8½	6½	5½	4½	3½
B = ½ of one thigh		2¾	3¼	4	4½	4½	4¾
C = ½ of one leg		2½	2½	2¾	3	3¼	3½

Fig. 3: Estimation of extent of burns (%) by Lund and Browder's Chart[7]

burns always require a skin graft to heal. They are therefore more difficult to manage.

The depth of the burn is also dependent on the degree and duration of heat applied to the tissues (Table 1).[8,9]

IMMEDIATE MANAGEMENT

Hemodynamic changes outlined earlier occur rapidly following burns. These have to be anticipated and managed

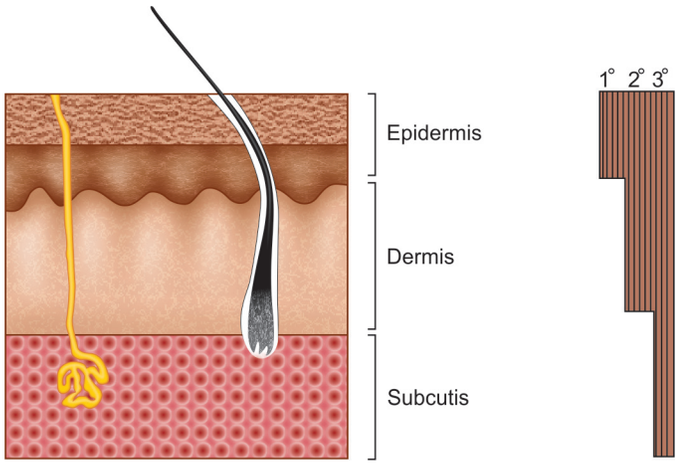

Fig. 4: Classification of burns according to the depth of injury

Table 1: Production of full thickness burns depends on degree and duration of heat applied to skin[8,9]

Temperature (°C)	*Time*
At 44	In 6 hours
At 59	In 60 seconds
At 62	In 30 seconds
At 65	In 20 seconds
At 70	In 10 seconds

appropriately. Burn patients have massive evaporative heat loss and hence need treatment in a room with increased temperature. Air conditioning, i.e. cooling of the atmospheric temperature, is contraindicated. The burnt skin exposes the underlying tissues to infection, and such patients need strict aseptic management. A well-equipped burn center staffed by specially trained personnel is an essential requirement for the management of these critically ill patients.

Management is best considered during the resuscitation phase (0–36 to 48 hours), the postresuscitation phase (36–48 hours to 5 days), and the phase of inflammation and infection (6 days to period of wound healing).

RESUSCITATIVE AND IMMEDIATE POSTRESUSCITATIVE MANAGEMENT[8]

The principles of therapy are—

- Fluid replacement and cardiovascular support to ensure maximum hemodynamic stability.
- Care of the airways and pulmonary support, as and when this becomes necessary.
- Correction of electrolyte and acid-base disturbances.
- Nutritional support.
- Care of the burn wound.
- Symptomatic treatment of pain and the use of antacids.

Fluid Resuscitation and Cardiovascular Support[6,10]

Several formulae are available and have strong proponents. The Parkland formula of Baxter is simple, practical and efficacious, has been adopted in most burn centers, and is currently the standard against which new formulae must be compared.[11]

First 24 Hours

Ringer Lactate solution, 4 mL/kg body weight per percent burn, is administered. The total burn area is used in the calculation. Half of the calculated amount is given in the first 8 hours. The urine output should be approximately 0.5–1.0 mL/kg per hour.

Second 24 Hours

Five percent dextrose and ringer lactate 0.5 mL/kg per percent burn are used. Colloids are administered after the first 24 hours by which time the capillary leak is generally sealed. Some units favor the earlier use of colloids, administering them after the first 6 hours. The amount of colloid administered depends on the degree of burns 0.25–0.5 mL/kg per percent of burn, or 20–60% of calculated plasma volume. Albumin is often preferred; the only drawback is that it is very expensive. Fresh frozen plasma, dextravan, hemaccel or lomodex may also be used. Colloids and crystalloids must be infused at a constant rate. The sodium requirement is about 0.5 mmoL/kg per percent burns.

As mentioned earlier, various formulae have been recommended for fluid resuscitation and the use of colloids in the first 48 hours post-burn resuscitation period. These should serve merely as rough guidelines, and fluid adjustments should be titrated against patient response. Fluid resuscitation can be considered appropriate if tissue perfusion is adequate. In a young patient, a pulse rate less than or equal to 120/minute, a systolic blood pressure more than or equal to 100 mm Hg, a mean arterial blood pressure of about 85 mm Hg, a urine output of at least 0.7–1 mL/kg, and absence of base deficit are parameters generally associated with adequate perfusion.

Renal and splanchnic blood flow are often selectively decreased during the first 24–48 hours after burns, and there is an increase in the secretion of aldosterone and antidiuretic hormone. We often use low dose dopamine (2 μg/kg per minute) to maintain the urine output, rather than pushing excessive intravenous fluids, when other parameters of adequate perfusion have been satisfied.

Fluid Replacement during the Post-resuscitative Phase (36–48 Hours to 5 Days)

This period is characterized by major fluid shifts. In deep burns, there is a continued loss of plasma into the burnt tissue. In superficial burns, there is a leak of plasma from the wound surface. The higher the capillary filtration pressure, the greater is the loss (Box 1). In addition, there is significant evaporative water loss from the wound surface. Five percent dextrose, alternating with dextrose saline is used to replace both loss of fluid from the burns, and evaporative loss from the wound surface. Hourly losses can be estimated from the formula—

Box 1: Fluid replacement in the post-resuscitative phase of burn injury (36–48 hours to 5 days)

- Replace evaporative water losses from wound surface and plasma loss into burn tissue with 5% dextrose alternating with dextrose saline
- Correct protein losses by albumin infusions, maintaining serum albumin >2.5 g/dL
- Correct anemia by packed cell infusions, maintaining hematocrit >30%

$$\text{mL/hr loss} = (25 + \text{percent of body surface burnt}) \times \text{m}^2 \text{ surface area}$$

Albumin may need to be continued to replace loss of plasma protein via the wound surface. Packed red blood cells may need to be given in patients with hemolysis, and for correction of anemia produced by impairment of red blood cell production in the bone marrow. Packed cells are preferred and it is advisable to keep the hematocrit more than or equal to 30%.

Monitoring volume replacement by the same tissue perfusion parameters described in the immediate 24–36-hour resuscitation period may be misleading after the first 3 days. This is because wound inflammation may commence around this time, and this produces a hyperdynamic circulatory state with marked tachycardia. The latter, if present at this stage, may not necessarily be due to hypovolemia. In addition, the solute products of damaged tissue cells often induce a well-marked osmotic diuresis, so that the urine output may be excellent. It is necessary to check the specific gravity of the urine during this phase. A high specific gravity in association with a high urine output generally indicates the need for more fluid administration.

Care of the Airways and Pulmonary Support[6]

It is vital to ensure that the airway is patent. An upper airway obstruction can develop suddenly with catastrophic results. Problems within the lungs and in the large or small airways are most frequent in patients who have suffered a smoke inhalation injury. Inhalation of smoke in a fire causing burns can lead to severe hypoxia causing immediate symptoms due to this hypoxic injury. Smoke inhalation injury can also cause upper airways obstruction from heat and chemicals. Symptoms of airways obstruction may be delayed for 6–24 hours. Lower airways and parenchymal injury from chemicals in smoke can produce symptoms within hours, or these may take days to manifest. Airway problems can also occur in patients with full thickness burns to the face and neck.

Indications for prompt endotracheal intubation include stridor, respiratory distress, PaO_2 less than 60 mm Hg on 4 liters

Box 2: Indications for endotracheal intubation in severe burns

- Stridor
- Respiratory distress
- PaO_2 <60 mm Hg on 4 L oxygen via mask/nasal prongs; $PaCO_2$ >50 mm Hg
- Deep facial or neck burns resulting in massive facial edema
- Upper airways edema
- Presence of airways injury-oropharyngeal edema/erythema, hoarseness of voice, changing respiratory status
- Severe chemical burns causing bronchoconstriction, bronchorrhea, acute lung injury

oxygen through a mask or nasal prongs, $PaCO_2$ higher than 50 mm Hg, and the presence of deep burns to the face and neck. A severe deep facial burn can lead to massive facial edema over the next 12–18 hours, so that intubation, if necessary at this time, can become difficult or impossible. It is therefore wise to intubate these patients electively at an early stage.

Even when none of the above indications are present it is important to look for signs of airways injury. If oropharyngeal edema is present, or the voice is hoarse an indirect laryngoscopy should be performed. Nebulization with racemic epinephrine helps to reduce local laryngeal edema. If racemic epinephrine is unavailable, adrenaline 1 in 1,000 dilution could be nebulized effectively. Adrenaline however often produces tachycardia. Nebulization with budecort could also help reduce laryngeal swelling and edema. Systemic steroids may also be used for a day or two; prolonged use is contraindicated as it predisposes to infection. If upper airway edema persists and causes airway obstruction, the patient should be intubated. If erythema alone is present without much edema, the patient will still need close observation. Any deterioration in respiratory status on a close follow-up merits securing of the airway by intubation. If endotracheal intubation is impossible because of edema and swelling of the airways, a tracheostomy needs to be done. A tracheostomy in severe burns is generally associated with high morbidity and mortality, but in some patients it is the only available option.

Endotracheal intubation is also often necessary in patients with severe chemical burns that cause bronchoconstriction, bronchorrhea, and acute lung injury. The indications for endotracheal intubation in severe burns are listed in Box 2.

Ventilator support should be offered in the presence of acute respiratory failure or in the presence of incipient respiratory failure. Acute lung injury (ARDS) may occur at any time but is generally observed after the first 5–6 days. When present, it requires the use of PEEP. The patient may need to be paralyzed with pancuronium to enable efficient ventilatory support to be given. It is advisable to adjust ventilatory support so that peak inflation pressures do not exceed 30 cm H_2O, as these patients are particularly sensitive to barotrauma, and pneumothorax may easily occur.

During the post-resuscitative phase (36–48 hours to 5 days), fluid present in the interstitial compartment due to tissue edema often shifts back into the vascular compartment. This can cause hypervolemia and worsen the acute lung injury (ARDS).

Optimal pulmonary support should always be given during and after any surgical procedure on the burn wound. Surgical procedures as far as possible should be of short duration and preferably not exceed 2 hours.

Nosocomial infection with nosocomial pneumonia is an important complication of ventilator support. It can occur at any time but is more frequent after the first week. Appropriate antibiotics are imperative as soon as a diagnosis of nosocomial pneumonia is made.

Injury from burns, particularly smoke inhalation injury, is sometimes complicated by CO poisoning and rarely by cyanide poisoning. These produce immediate symptoms. CO poisoning is associated with mental disturbances and obtundation. A high index of suspicion is necessary for a correct diagnosis. CO poisoning should be suspected if the measured oxygen saturation of Hb is less than that predicted by the PaO_2, and if the patient has metabolic acidosis with a wide anion gap. The diagnosis can be confirmed by a carboxyhemoglobin level higher than 5%. Continuous administration of 100% oxygen decreases the half-life of carboxyhemoglobin from 4 hours on air to about 80 minutes.[12] Cyanide intoxication may often be impossible to detect. Acute metabolic acidosis in the presence of a normal PaO_2 and a normal oxygen saturation of Hb should suggest the diagnosis. Anticyanide therapy includes the use of sodium nitrate, sodium thiosulphate and hydroxocobalamin.

Electrolyte Disturbances[6]

These are generally observed in the post-resuscitative period (from 36–48 hours to 5 days). The following electrolyte disturbances are commonly seen—

Hypernatremia

Hypernatremia is due to inadequate replacement of insensible water loss and the use of N-saline in intravenous infusions. Salt restriction and infusion of 5% dextrose should correct hypernatremia.

Hyponatremia and Hypokalemia

They may result from frequent washing or bathing of the burns patient with water, instead of an isotonic solution. Intravenous infusions of N-saline with potassium supplements will correct this situation. Severe hyponatremia may need a titrated infusion of 3% saline. Hypertonic saline should be avoided or used with great circumspection in the presence of pulmonary congestion.

Hyperkalemia

Hyperkalemia may occur in the early stages due to tissue damage and red cell destruction. Dextrose-insulin infusions help to reduce serum potassium levels. After 3–5 days, renal losses of potassium may be excessive so that potassium supplements of 80–200 mEq/day may be necessary.

Box 3: Composition of the buttermilk diet (BMD)

- Curd – 1 liter
- Eggs – 4
- Bananas – 4
- Sugar – 10 tablespoons
- Total volume – 1,760 mL
- Calories provided – 1,760 kcals
- Proteins – 60 g
- Carbohydrates – 340 g

Hypocalcemia

Hypocalcemia is invariably due to hypoalbuminemia. Intravenous albumin infusions, and correction of hypoproteinemia are then required.

Acid-Base Disturbances[6]

Severe thermal injury causes rapid acidosis. A combination of metabolic and respiratory acidosis exists in severe burns associated with smoke injury to the lungs. The metabolic component is due to tissues damaged by acid metabolites, and due to relative hypoxia. The respiratory component is related to smoke injury to the lungs, or due to hypoventilation in some patients. These need prompt correction, as acidosis has an adverse effect on myocardial function and on the overall circulatory system.

Nutritional Support[6,13]

Early oral feeding is now the preferred method of nourishing a burns patient. It should be commenced when resuscitation is complete, i.e. within 48–72 hours. As the patient will find it difficult to chew and masticate the food, liquid food must be specially prepared and given orally or through a nasogastric tube. Small measured quantities given hourly are preferable to infrequently administered large nutrient boluses. The buttermilk diet (BMD) is a well-tried and safe diet providing 1 kcal/mL. It is hence easy to monitor the amount of supplementary nutrition received by the patient. The composition of the BMD is given in Box 3. Starting with 10 mL/hour through the nasogastric tube, the quantity administered is increased by 10 mL per hour every 6 hours to reach a maximum of 2 mL/kg per hour for adults and 3–5 mL/kg per hour for children. Each feed is preceded by nasogastric aspiration to rule out gastric stasis and to prevent gastric dilatation. Some units prefer to administer enteral feeds by a continuous drip through a nasogastric tube, over a period of 14–16 hours. Generally, after a period of 96 hours post injury, the patient can be started on full diet with discontinuation of intravenous fluids.

In the presence of impaired GI function, parenteral nutrition is necessary. This may be total or partial. A daily protein intake of 2–2.5 g/kg per day generally suffices with a total caloric intake of 2,500–3,000 calories/day, the energy requirements being provided by dextrose and lipids (see Chapter Nutritional Support in the Critically Ill Adult). Vitamin supplements are necessary; hyperglycemia may require the use of insulin.

Local Care of the Burn Wound

Contamination of the burn and invasive wound infection is the most dreaded complication. The wound must be covered as early as possible with a clean sheet over which cool water is constantly poured to lower the temperature and withdraw heat from the wound. This helps to reduce the thermal damage.

Blisters or bullae should not be excised. They are just punctured and the fluid drained. If the bullae have already ruptured, the loose non-viable skin should not be excised, but cleaned with saline and evenly spread out over the burn. This non-viable skin serves to protect the burnt tissues underneath, and prevents desiccation of the wound.

Tetanus is an important complication of burns in poor countries. Tetanus toxoid should be given on admission. Patients who have not been previously immunized should be given 250 units of tetanus human immunoglobulin and active immunization with tetanus toxoid should be commenced.

Treatment of the Burn Wound[6]

The exposure method of treatment has now been abandoned in burn centers all over the world, and the closed method of treatment has been universally accepted and adopted. After adequate resuscitation, the patient is given a bath and is dressed in the operation theater. The choice of the antiseptic used over the burn wound varies. A silver sulphadiazine cream 1–2% is most frequently used. Mafenide acetate 10% cream or 5% solution is preferred in some units in the West as this is believed to penetrate the eschar. It is unavailable in India and the silver sulphadiazine cream probably does just as well.[6] Povidone Iodine in solution form, along with Vaseline gauze, is used in some centers.

The nature of the agent used to dress and cover the wound varies. The *potato peel dressing* has been found to be eminently suited for this purpose. It is smeared with an antibacterial ointment (silver sulfadiazine cream) and gently applied over the burnt area; it is held in position with a gauze bandage. To prevent it from slipping, a single wet layer of plaster of paris is spread over the dressing and allowed to dry into a thin shell, almost as thin as an eggshell, hence called the "Egg Shell Dressing". These dressings are changed once a day. Many prefer to use a "collagen dressing" to cover the wound. A very frequently used biological skin substitute is termed *Integra*. This is a totally artificial material which is acellular and composed of two layers. The upper layer is of silastic and the lower layer is a cross-linked co-precipitate of collagen that is bovine in origin, and chondroitin-6-sulfate which comes from shark cartilage. Once the burnt tissue is excised, the Integra is stapled in place. When the lower layer has been populated by host cells, the silastic layer can be

removed to provide an excellent vascularized mesodermal base. A freshly harvested thin epidermal graft can be laid on top of this to complete wound cover.

Cultured Autologous Epidermis[14]

A recent skin resurfacing technique is the use of cultured autologous epidermis to assist the timely closure of burn wounds. This technique requires expertise and special facilities, and to the best of our knowledge, it is still in the experimental phase in certain centers in India.

The technique consists of taking a full-thickness skin biopsy consisting of a few square centimeters. After an in vitro culture period of 3–4 weeks, the autologous population of keratinocytes expands to approximately 1 m^2 of keratinocytes that are available for wound coverage. Cultured autologous epidermis (CAE) has to be combined with dermal replacement in the form of integra, alloderm or cell-free porcine dermis.

There are however several shortcomings with this technique. These include—

- A relatively low rate of engraftment or "take" of each CAE application.
- Graft fragility resulting in delayed loss.
- Prolonged immobilization of extremities in order to facilitate engraftment, leading to loss of function.
- A very high cost when purchased commercially—about $2,000 for each percentage of wound closure.

This fact makes the above technique an impractical proposition for the poor countries of the world.

Whatever method is used to cover the burn wound, the joints must be positioned in their optimal functional positions with some form of splintage. Gentle active and passive physiotherapy of the limbs is instituted after 48 hours and progressively increased over the next few days to achieve maximum range of motion to prevent stiffness and contractures.

Escharatomy

It is not always possible for burn wounds in developing countries to be managed by the ideal, closed method of treatment. Through lack of facilities, burns are sometimes treated by the exposure method, and the patient is referred subsequently to a unit with better facilities. By the time of referral, the burn tissues on the surface have already formed a hard inelastic eschar. The edema which occurs in the underlying tissues following burn injury exerts an excessive compression on the vascular network, and impairs the circulation. Dry gangrene results very often as does anaerobic infection when the eschar is circumferential. Such an eschar around the chest wall restricts the respiratory excursions and impairs ventilation. Releasing incisions in the midlateral positions of the involved extremity or trunk have been recommended. The incisions should be made only through the eschar and subjacent tissue, lest the larger blood vessels are cut, resulting in excessive blood loss.

Escharectomy and Split Skin Grafting

When the eschar separates out and is replaced by healthy granulation tissue (usually at 2–3 weeks post-burn), the wound is debrided and covered with a very thin split skin graft, preferably meshed 1:3. Blood loss at the time of surgery is rapidly corrected, or better still, is reduced by subcutaneous infiltration of normal saline with adrenaline 1:1,000,000. Post-grafting dressings are done every 2–3 days thereafter.

Early Excision and Grafting of the Burn Wound[14]

When good facilities exist, i.e. trained surgical and nursing staff, facilities for good anesthesia, adequate dressing material and equipment, adequate supply of blood and homograft skin, the ideal treatment today consists of excision of all full thickness and deep partial thickness skin burns along with homografting, starting within a few hours after the burn injury is sustained. However, such conditions are available in a few of our burn centers and make a significant difference to outcome in terms of survival. Moreover, in children with scald burns, conservative management with dressings is preferred over early excision unless the wound is clearly full thickness.

Fascial Excision and Skin Grafting

This is indicated in severely infected burns with invasive burn wound sepsis (>10^5 bacteria/gm of burnt tissue on burn wound biopsy). All the dead and infected tissues up to the level of fascia are excised en bloc and the resultant raw area is skin grafted with autografts.

Symptomatic Treatment of Pain and the Use of Antacids[6]

A partial thickness wound is very painful. Also, the surface of a burn wound dries up if kept exposed, and the process whereby an eschar forms can be extremely painful. The application of a semipermeable membrane relieves pain to a great extent. A small dose of a combination of ketamine 100 mg, tramadol 100 mg and midazolam 10 mg in a 50-cc syringe in a syringe pump titrated against the patient's response is frequently used as a continuous intravenous infusion, to relieve the pain. We have found this combination works in the following doses: resting pain 2–6 mL/hour and procedural pain 20–40 mL/hour depending on body weight and response. Following a burn injury, acute stress often leads to upper GI bleeds from acute mucosal erosions and from a Curling's ulcer. Blood loss may be significant and may need to be replaced. Sucralfate or antacids may help in preventing or reducing the incidence of GI bleeds. In burns greater than 40%, an intravenous H_2-antagonist is routinely given during the first 2 weeks post-burn.

MANAGEMENT DURING THE PERIOD OF INFLAMMATION AND INFECTION[15]

The hypermetabolic response to injury takes the form of the systemic inflammatory response syndrome (SIRS) which

starts around the 5th day of burns, and peaks at 8–10 days. This response is not necessarily associated with infection, though infection is a frequent and dreadful complication. It is extremely difficult, and in the initial stages, often impossible to distinguish inflammation-induced hypermetabolism from an infection-induced process. This phase is the most dangerous and difficult to manage in severe burns.

Symptoms and Signs of Invasive Wound Infections

Systemic features include tachycardia, tachypnea, hyperthermia or hypothermia. Disorientation, ileus, hypotension, oliguria, glucose intolerance and acidosis may be present. Leukocytosis is frequent, but sepsis may cause severe leukopenia and thrombocytopenia. These systemic features are indistinguishable from sepsis produced by central line sepsis, fulminant urinary infections or nosocomial pneumonia. Physical changes in the appearance of the burn wound are therefore more reliable signs of invasive burn wound infection than systemic features. Clinical signs of burn wound infection include—

- Focal dark or black discoloration of the wound.
- Conversion of a second degree burn to full-thickness burn.
- Unexpected rapid eschar formation.
- Hemorrhagic discoloration of eschar fat.
- Edematous, inflamed, violaceous wound edges.
- Extensive foul smelling slough over the wound, with a greenish discharge suggesting a *Pseudomonas aeruginosa* infection.
- Abscess formation and infected lesions outside the burn wound area.

Surface cultures of the wound do not necessarily distinguish colonization from invasive infection. Quantitative cultures also lack sufficient sensitivity, though colony counts of less than 10^5 per gram of biopsy tissue correlates with absence of invasive burn wound infection. Histological examination of a biopsy of the wound and underlying viable tissue is the best method of establishing invasive infection. The presence of micro-organisms in viable tissue points to tissue infection.

Wound Management

Severe burn wound infection is treated by local and systemic antimicrobial therapy. Twice daily applications of 1% silver sulfadiazine ointment covered by sterile gauze dressings are used. Dressings such as Acticoat are available which can be left on for several days and help reduce the pain associated with the dressing. Systemic antibiotics should be promptly started in full doses to treat not only local and systemic sepsis but also to prevent the onset and progression of multiple organ dysfunction and failure. Organisms most frequently encountered in infected burns include pseudomonas, klebsiella, E. coli, acinetobacter, Staphylococcus aureus and Group A streptococci. We have generally found a combination of ticarcillin/clavulanic acid + an aminoglycoside + metronidazole to be effective. A proven or strongly suspected staphylococcal infection would necessitate the use of amoxicillin/clavulanic acid or vancomycin, teicoplanin. An alternative antibiotic regime for severely infected burns (chiefly due to Gram-negative organisms) is the use of imipenam-cilastin 500 mg intravenously eight hourly or meropenam 1 g eight hourly given as an intravenous infusion. Either of these can be combined with vancomycin 500 mg six hourly or 1 g twice daily or teicoplanin 400 mg once a day in an intravenous infusion to cover possible staphylococcal infection. Local or systemic fungal infection merits the use of fluconazole and/or amphotericin B (see later section in this chapter on Antifungal Treatment).

Broad guidelines for antibiotic usage are outlined below[15]—

- Colonization of a large burn wound surface is impossible to prevent and invariably occurs. The mere culture of organisms is no indication for antibiotic use, in the absence of clinical evidence of infection.
- When clinical (and in particular histological) evidence of wound sepsis is associated with growth of organisms from an unhealthy infected wound, the choice of antibiotics should be guided by culture and sensitivity reports. Gram-negative infections are most frequently responsible for wound infection and need an appropriate antibiotic cover.
- Antibiotics once chosen should be continued for at least 5–7 days to allow them to act properly. Yet prolonged use of the same antibiotics can cause the emergence of resistant organisms. Appropriate antibiotic change should again be guided by culture and sensitivity reports.
- The pharmacokinetics of antibiotics in severe burns is considerably changed. If possible, drug dosage should be adjusted to ensure adequate bactericidal serum concentration levels. Unfortunately, the penetration of antibiotics into a burn eschar is unreliable in spite of adequate serum concentration of the drug.
- The prophylactic use of antibiotics in burns should be reserved for—
  - Preoperative and perioperative administration associated with excision, debridement and autografting.
  - Early phases of burns in children (a practice in some units).
  - *Cases of infection* In poor developing countries, transport of patients with severe burns to an intensive care unit or to a burns unit is often done in an unhygienic fashion so that infection is almost certain to occur. When this is so, many units in the city administer prophylactic antibiotics from the day of admission. Till definitive swab culture and sensitivity reports are available, a combination of ampicillin and an aminoglycoside is administered intravenously. The wisdom of this is disputable, though most experienced specialists in burns in this country believe that under existing circumstances, morbidity is reduced.

It should be noted that the mere use of local and systemic antimicrobial therapy does not always suffice. Aggressive surgical debridement and resection of infected tissue may

occasionally be imperative. Bacteremia, severe systemic sepsis, and even septic shock may follow such a major surgical procedure, and should be anticipated. The importance of correct local treatment to the burn wound by topical antibiotics and aggressive excision prior to this phase cannot be overemphasized.

Fluid Replacement and Cardiovascular Support

Adequate fluid replacement should take into consideration evaporative water loss and loss of blood and plasma from debridement of necrotic tissue. The catabolic state results in high fever necessitating further increase in evaporative losses at a rate of 8–10% per degree of rise in body temperature. The hematocrit should continue to be kept at 35% by packed cell infusions, and the albumin concentration should be maintained at around 3 g/dL. The hyperkinetic circulatory state is associated with a marked increase in the cardiac output to meet the increased oxygen demands. Myocardial dysfunction often supervenes, and inotropic support with dopamine and other inotropes as also vasopressors may be frequently necessary. Cardiopulmonary failure in this phase of severe burns is most frequently observed in elderly patients. This is because the circulatory and respiratory systems in the aged have a comparatively limited reserve which is unable to cope with the excessive metabolic demands of the stress response induced by severe burns.

Respiratory Support

Nosocomial pneumonia is a frequent complication, and the increased metabolic rate leads to increased carbon dioxide production necessitating increase in ventilatory requirements. Respiratory muscle fatigue often supervenes, so that patients, who were breathing spontaneously, may now require ventilator support. Acute lung injury (ARDS) may also complicate the picture at this stage, and this worsens the prognosis markedly as it is often the forerunner of multiple organ failure.

Metabolic Support

Maintenance of adequate nutrition is vital for survival during this phase, as the hypermetabolic state leads to a severe loss in lean muscle mass. The enteral route is always to be preferred, and this may be supplemented, if necessary, by parenteral nutrition. Total parenteral nutrition may be required at times.

Care of the Eyes and Ears

For protection of the eyes from infection, antibiotic eye-drops during the day and antibiotic ointment at night may be used. Mydriatics may also be used.

Chondritis is a dangerous complication which may result in the whole ear falling off due to infective destruction. It is treated by providing adequate fluffy padding for burnt ears with adequate antibiotic cream cover to prevent pressure necrosis of the fragile infected cartilage; this is combined with radical debridement of the dead infected cartilage.

Control of Infection[15]

A combination of an immunosuppressed host and bacterial colonization of the burn wound, the oropharynx and the tracheobronchial tree strongly predisposes to nosocomial infection. Nosocomial pneumonia, vascular catheter sepsis, urinary catheter sepsis and, above all, deep severe infection of the burn wound are all too common, and can trigger multiple organ failure.

A diagnosis of nosocomial pneumonia should be based on clinical and radiological grounds. Leukocytosis, fever, purulent sputum, or purulent tracheal aspirate showing many organisms on Gram stain, with an increase or change in pulmonary shadowing, suffice to make a clinical diagnosis. Empiric antibiotic treatment should not be delayed pending sputum culture sensitivity reports.

If possible, vascular catheter sepsis should be prevented by change of the central lines (every 7–10 days), by prompt removal of the arterial lines, and by avoiding the use of a Swan-Ganz catheter, unless this is absolutely necessary. Catheter tips should be sent for culture, and blood cultures should always be done in each and every patient with nosocomial infection, so as to enable a proper choice of antibiotic therapy.

Antifungal Treatment

Invasive fungal infection of the burn wound and/or systemic fungal sepsis are important complications, particularly in extensive severe burns. They carry a high morbidity and mortality. Candida species frequently colonize a burn wound but rarely cause an invasive wound infection. Aspergillus however can cause an invasive fungal wound infection which generally is limited to subcutaneous tissue and only rarely crosses fascial planes. Rarely fungal invasion of the wound by Mucor species may also occur. Colonization of a burn wound with Candida or Aspergillus can be countered by the local application of clotrimazole. However, if there is histologic evidence of fungal invasion of the wound, treatment consists of wound debridement and excision, and the use of intravenous amphotericin.

Systemic fungal sepsis with positive blood culture for fungi is either nosocomial through vascular catheters, or results as a superinfection due to prolonged use of broad-spectrum antibiotics, or results from vascular invasion. Fluconazole and/or amphotericin or caspofungin need to be given in an intravenous infusion. Some units use fluconazole prophylactically in situations where fungal infection is strongly anticipated.

Treatment of Complications and Support of Multiple Organ Systems

All organ systems need to be carefully supported. Renal failure may require dialysis. A progressively increasing serum creatinine and a progressively increasing blood urea nitrogen may necessitate dialysis regardless of the volume of urine excreted.[16] Bacterial infection is a frequent hazard and

complication, and death often results from infection rather than from renal failure.

Prevention

Burns treatment is far more advanced now than it was 50 years ago. The mortality and morbidity are much lower, but the pain suffered and the dreams shattered are as real as before. The basic aim or objective is to prevent burns. A great deal of research needs to be done in this direction for this objective to be adequately realized.

Rehabilitation

Physiotherapy is very important to maintain function. Pressure garments may be used to prevent hypertrophic scar formation. Moisturizing agents to soften scars and steroid creams to decrease itching are also commonly used. The use of silicon gel sheets to soften scars has been found to be useful. Quite often, for small linear scars, injection of triamcinolone acetonide given intralesionally in multiple doses spread over months helps.

CHAPTER 66

Critical Care in Poisonings

GENERAL CONSIDERATIONS

The evaluation and management of a patient, who intentionally or accidentally ingests or is exposed to a poison, is an important aspect of critical care medicine. There are a vast number of poisons; important poisons include drugs which in toxic doses produce dangerous and often life-threatening effects.

The diagnosis of acute poisoning though often obvious is at times difficult. The possibility of poisoning should always be considered in any obscure illness, or in any patient in whom the cause of unconsciousness is not clearly apparent.

Critical care of patients acutely ill with poisoning as a matter of urgent priority necessitates life support to keep them alive. Prevention of absorption of poisons, their quick elimination, and the use of specific antidotes are of further help in a number of situations.

This chapter outlines the principles of approach to poisonings in patients admitted to a critical care unit. It then briefly outlines the clinical features and management of a few important and common poisonings, particularly those observed in our part of the world.

PRINCIPLES OF APPROACH TO A POISONED PATIENT[1,2]

- First and foremost attention should be focused on the airway, breathing and circulation (ABC).
- Intravenous access is secured and blood tests sent, both routine laboratory tests and tests for possible poisons. An intravenous (IV) infusion of N-saline or Ringer lactate is started; hypotension is corrected initially with a volume load.
- If the patient has an altered mental state or is comatose, potentially reversible causes need to be promptly excluded—
  - Hypoglycemic coma is promptly reversed by a rapid IV infusion of concentrated glucose.
  - Acute deficiency of B1 is promptly reversed by IV 100 mg thiamine.
  - Opioid toxicity is reversed by IV Naloxone 0.2–4 mg.
- If the poisoned patient is admitted with seizures, it is important to control seizures by the use of appropriate IV anti-seizure drugs. The possibility that a more specific antidote may be necessary should however be kept in mind.
- *Diagnostic Evaluation* A careful history and detailed physical examination is necessary. The physical examination should determine if the poisoned patient falls into any one of the well recognized toxidromes. If such a diagnosis can be made an appropriate antidote should be given provided it is available.
- An attempt should be made to block the absorption of the poison and to enhance the elimination of the poison when appropriate.

The above principles are now briefly discussed and this discussion is followed by a discussion on specific important poisons and their management.

ATTENTION TO THE AIRWAY, BREATHING AND CIRCULATION

Airway, breathing and circulation need to be given prime immediate attention. If the patient is admitted to the ICU with a cardiac arrest or a near cardiac arrest, attention should first go to the resuscitation of the heart which is then promptly

followed by attention to keeping the airway open and ensuring breathing (see Chapter Cardiopulmonary Resuscitation and Cerebral Preservation in Adults).

Airway, Breathing and Respiratory Care

A blocked airway (chiefly with secretions), a loss of airway reflexes, respiratory depression and aspiration are frequent consequences of poisoning.

The airway should be kept open, the neck should be extended and the jaw pushed forward and secretions sucked from the back of the throat. Endotracheal intubation is promptly done if: (i) the patient is deeply obtunded or unconscious; (ii) swallowing is impaired; (iii) the cough reflex is poor or absent, the patient being unable to protect his airway; (iv) the patient requires ventilator support either because ventilation is poor or because of pulmonary edema.

Oxygen should be given in 100% concentration. It can never do harm as an initial life-support measure. The only relative contraindication is in patients with paraquat poisoning. In the latter situation, very high concentrations of oxygen can promote pulmonary fibrosis.

Ventilator support is necessary in patients with acute respiratory failure, i.e. in those with hypoxia and/or hypercapnia. Ventilator support should also be offered in those with incipient respiratory failure, i.e. in acute poisoning known to rapidly lead to acute respiratory failure. The use of prophylactic positive end-expiratory pressure (PEEP) is unwise; PEEP should however be given in patients with poison induced pulmonary edema resulting from increased capillary permeability.

Care of the Circulation

The circulation should be assessed *pari passu* with respiration. A large peripheral vein is promptly secured; a central venous line is also invariably necessary in acutely ill patients to determine central venous pressure, and to thereby allow adjustments for volume load. A self-retaining Foley's catheter is passed to enable the urine output to be monitored hourly. Hypotension should be immediately corrected as this causes poor tissue perfusion, metabolic acidosis and worsens prognosis. Hypotension in acute poisoning may be due to a variety of causes acting singly or in combination. These include a decrease in systemic vascular resistance causing arteriolar dilatation, venous pooling, myocardial depression and hypovolemia. The initial management (except in the presence of pulmonary edema) is a fluid challenge of 200 mL of a crystalloid solution. Repeated challenges are given, provided the central venous pressure (CVP) is not beyond 10 mm Hg, the arterial blood pressure rises and the urine output is close to 60 mL/hour. If a volume challenge fails to raise the blood pressure, and the CVP is at the upper limit of normal, the patient is given dopamine and/or vasopressor support so that the systolic blood pressure is kept over 100 mm Hg and preferably around 120 mm Hg. The principles of inotropic and/or vasopressor support in patients with severe myocardial depression are the same as in patients with cardiogenic shock.

Use of Emergency Drugs

Two important causes of deep coma or of mental obtundation with or without hypotension are severe hypoglycemia and narcotic poisoning. For diagnostic and therapeutic purposes, it would be justified in giving first 50 g of dextrose intravenously to reverse possible hypoglycemia. Blood is collected for blood glucose estimation before dextrose is administered. This can do no harm and produces a magical response in patients whose coma is due to very low blood sugar levels. 100 mg of thiamine are generally administered to prevent Wernicke's encephalopathy, particularly in alcoholics who are admitted with severe hypoglycemia.

If intravenous dextrose produces no response, many critical care units would give a diagnostic and therapeutic trial to naloxone, a specific antagonist to narcotics. The initial dose is 2 mg intravenously. Improvement in respiration occurs in 2 minutes. Repeated dosing may be necessary, as the half-life of naloxone is shorter than the half-life of the narcotic agent. Some synthetic opiates (meperidine or propoxyphene) may require higher initial doses (6–8 mg) for reversal.

Control of Seizures

A few poisons can produce frequent or continuous seizures. These can be life-threatening and need to be controlled. Benzodiazepines should be used initially; phenytoin, valproate or other anti-epileptics may be needed if diazepam or lorazepam is ineffective. In refractory cases, intravenous thiopental or the use of paralytic curare-like agents may be necessary to allow efficient ventilator support. It is however important to note that control of seizures may occasionally require therapy specific to the poison involved.

DIAGNOSTIC EVALUATION[1-3]

Principles

- One should always entertain the possibility that the patient has ingested more than one poison.
- In case of an overdose of a drug, again the possibility of polysubstance overdose must be kept in mind.
- If the nature of the ingested drug or poison is known, an antidote if available should be promptly given. The lethal ingestion of the following drugs which have specific therapies should be ruled out if immediate facilities to do so are available. These are—
  - Tricyclic antidepressants (detected by a urine screen and ECG).
  - Acetoaminophen (detected by serum level).
  - Salycylate (detected by serum level).
- It is important to take a detailed history and perform a detailed physical examination to help determine the nature of the poison. As mentioned earlier, the physical examination should be detailed but should be oriented toward determining whether the findings are compatible with one of the toxidromes that will be described later.

History

A history is impossible in an obtunded or comatose patient. Even otherwise it is often unreliable, particularly when a drug is taken with suicidal intent. It is important to question relatives, friends and coworkers to obtain as much information as possible. Vital clues may be given by the presence of specific drugs or poisons found at the site of a patient's home or workplace.

Physical Examination

A quick physical examination may give a clue as to the nature of the poison. Physical examination is initially toxidrome oriented, which means oriented toward detection of symptom complexes that are associated with different groups of poisons. The following features are quickly evaluated—

Vital Signs

Sympathomimetic drugs, anticholinergics often produce tachycardia, hypertension. Anticholinergics produce a dry hot skin; cocaine can also produce hyperthermia, but with diaphoresis. Sedative-hypnotics or narcotics can produce respiratory depression, bradycardia and hypotension.

Brief Neurological Examination

It should determine the level of consciousness, the presence and nature of hallucinations, pupillary and motor responses.

Level of consciousness In severe poisonings with narcotics, hypnotics and sedatives, the patient is obtunded or comatose. Confusion, agitation and coma can also occur with poisons with a cholinergic action (e.g. organophosphorus compounds), as also with drugs that have an anticholinergic action (tricyclic antidepressants).

Hallucinations These are frequently seen in atropine and *dhatura* poisoning, in poisoning with cocaine, phencyclidine and LSD. With cocaine, hallucinatory objects appear in the periphery of vision; with atropine, hallucinatory objects are small; *dhatura* poisoning is associated with finger picking movements, as if the patient is pulling threads from his fingertips; complex hallucinations characterize poisoning due to phencyclidine; lysergic acid diethylamide (LSD) poisoning is associated with visual and auditory hallucinations and illusions where the patient can "hear colors" or "see sounds".

Pupillary responses Miosis can be caused by organophosphate insecticides and by narcotics. Though opium and morphine cause pin-point pupils, in almost all such patients a very strong focused light produces a small contraction of the pupil, demonstrating the integrity of the third nerve and that portion of the midbrain concerned with the pupillary reflex. Both atropine and cocaine can result in mydriasis, though in cocaine poisoning, the pupil will react to light.

Nystagmus Alcohol, sedatives-hypnotics and anti-epileptics, like phenytoin, primidone, can all cause nystagmus. Lithium poisoning and poisoning with carbamazepine and solvents also produce nystagmus.

Motor response Seizures can be induced by a number of poisons. The only important poison which can produce recurrent seizures with the patient remaining alert, and with muscle tone being normal in between seizures, is strychnine. Drug-induced seizures often respond poorly to conventional antiepileptic therapy. Thus isoniazid-induced seizures (invariably associated with mental obtundation or psychosis) will respond to pyridoxine, and seizures induced by tricyclic antidepressants will respond to physostigmine.

Auscultation of the Lungs for Pulmonary Edema and Bronchospasm

A number of poisons can induce pulmonary edema; cholinergic drugs can induce severe bronchospasm and an increase in bronchial secretions. This is important both from the diagnostic and therapeutic points of view.

Auscultation of the Abdomen for Bowel Sounds

Bowel sounds are feeble in severe sedative or narcotic poisoning; hyperperistalsis and abdominal cramps (if the patient is conscious) are observed with cholinergic poisons.

Skin Temperature and Moisture

Sweating is frequently observed with poisons having a cholinergic and sympathomimetic action. The skin is dry and hot in persons with an anticholinergic effect.

Important features in physical examination in relation to "toxidromes" or symptom complexes produced by poisons which exert a sedative-hypnotic effect, or an opioid effect, or a cholinergic effect, or an anticholinergic effect or a sympathomimetic effect or cause extrapyramidal features are charted in Table 1.

Laboratory Investigations

Blood glucose estimation is important in any individual who is obtunded or comatose. Routine investigations should include a blood count, urine examination, serum electrolytes, urea, creatinine, determination of the degree of anion gap, serum osmolality, calculated osmolar gap, liver function tests, X-ray chest, ECG, arterial blood gas analysis. The patient needs to be continuously monitored if there are arrhythmias. The QT interval should be measured, as an increase in this interval produced by a number of drugs can precipitate serious rhythm disturbances. Other laboratory tests depend on the specific poison suspected in a given patient.

Specific drug levels for drug intoxication due to specific suspected drugs may need to be done if facilities are available. Drug levels of salicylates, barbiturates, ethanol, digoxin, iron, theophylline and lithium are done in our laboratories. Serum levels of any of these drugs in suspected poisoning help management. Estimation of blood levels of most common poisons is now possible at one of the medical centers in Mumbai.

Table 1: Clinical toxidromes observed with common poisons, drugs.

	Clinical features	*Drugs, poisons*
Sedatives-hypnotics	Central nervous system (CNS) depression, drowsiness, coma, slow shallow breathing, hypotension, bradycardia	Barbiturates Benzodiazepines Alcohols
Opioid	Hypopnea, slow respiratory rate, pin-point pupils CNS depression—drowsiness, coma, hypotension, bradycardia, hypothermia, pulmonary edema	Morphine Heroin Meperidine Codeine Oxycodone Fentanyl Methadone
Anticholinergic	Mydriasis, tachycardia, tachypnea, hyperthermia, agitation, delirium, dry hot skin, dry mouth, urinary retention	Tricyclic anti-depressants Antihistamines Atropine Belladonna Phenothiazines
Sympathomimetic	Tachycardia, hypertension, tachypnea, diaphoresis, mydriasis, agitation, hallucinations	Cocaine Amphetamines Ephedrine Theophylline Caffeine
Cholinergic	Salivation, lacrimation, diarrhea, vomiting, increased urinary frequency, abdominal cramps, miosis, bradycardia, bronchospasm, confusion, coma	Organophosphates Physostigmine Pyridostigmine Edrophonium
Extrapyramidal	Rigidity, tremor, trismus, torticollis, oculogyric crisis	Prochlorperazine Chlorpromazine Haloperidol Other antipsychotic drugs

Toxicological screening tests must be interpreted with circumspection. Qualitative urine or screening assays may point to exposure to various drugs but cannot discern whether the exposure is responsible for the clinical presentation. Many substances are not included on screens that qualitatively assay drugs of abuse. False negative results may be reported depending on the sensitivity of the drug test, on the time of ingestion of a drug, the co-ingestion of more than one drug even in the presence of intoxication. Therefore, toxicology screens should be used to support clinical suspicion but management strategies should be guided by the history, clinical findings and the identification (if possible) of a toxidrome.

Specific poison can be identified by attention to the anion gap, osmolar gap.

$$\text{Anion gap} = [Na^+] - ([Cl_2^-] + [HCO_3^-])$$

The normal anion gap ranges from 7–13 mEq/L varying with different laboratories. An increased anion gap may indicate ingestion of ethylene glycol, methanol or salicylates. Causes of an increased anion gap are listed in Table 2. The osmolal gap is the difference between measured and calculated osmolality. An increased osmolal gap points to the presence of an osmolitically active substance in the blood, which is not accounted for by routine calculation of osmolality. Poisons causing an elevated osmolal gap include methanol, ethylene glycol, paraldehyde and formaldehyde (Table 3).

Table 2: Causes of an increased anion gap

Poisonings	*Medical problems*
Salicylate (Aspirin)	Lactic acidosis
Methanol	Ketoacidosis
Ethylene glycol	Diabetic ketoacidosis
Iron	Alcohol poisoning
Isoniazid	Starvation
Paraldehyde	Ureteric anastomosis into the colon

Table 3: Increased osmolar gap

With a normal anion gap	*With a raised anion gap*
Isopropanol	Methanol
Mannitol	Ethylene glycol
Acetone	Paraldehyde

An oxygen saturation gap should also be looked for. Oxygen saturation as measured by the pulse oxymeter significantly lower than the oxyhemoglobin percentage (SaO_2) as calculated from the arterial PaO_2 indicates carbon

Table 4: Common poisons and their antidotes

Common poisons	*Antidote*	*Dosage*
Opiates (morphine, heroin, codeine)	Naloxone	0.4–2 mg IV bolus; can repeat to maximum of 10 mg (see text)
Organophosphorus compounds	Atropine + Pralidoxime	2 mg IV repeated every 5 minutes till total of 10 mg 0.5–2 g IV over 5–15 minutes; can be repeated every 6–12 hours
Cyanide	Sodium nitrate	300 mg IV over 2–5 minutes
Ethylene glycol	Fomepizole	15 mg/kg over 30 minutes; then 10 mg/kg 12 hourly x 4 doses; then 15 mg/kg 12 hourly as needed
Iron	Deferoxamine	5–15 mg/kg per hour Maximum daily dose 6–8 g/day
Methanol	Ethanol or fomepizole	Same as in ethylene glycol
Carbon monoxide	100% oxygen; hyperbaric oxygen	
Isoniazid	Pyridoxine	1 g for each of isoniazid ingested or 5 g maximum; infused IV at 0.5 g/min till seizures stop; remaining infused over 4–6 hours
Digoxin	Digoxin-specific antibody fragments	10–20 vials for acute poisoning 4–6 vials for chronic poisoning
Methemoglobinemia	Methylene blue	1–2 mg/kg IV over 5 minutes followed by 30 mL saline flush
Acetaminophen	Acetylcysteine	See text
Tricyclic antidepressants (TCAs)	Soduim Bicarbonate	1.2 mg/kg IV followed by 150 mEq in 1 L 5% dextrose at 2.5 mL/kg/min

monoxide, cyanide or hydrogen sulfide poisoning, or the presence of methemoglobinemia. A spectrometric analysis of the blood can measure the concentration of oxyhemoglobin, deoxyhemoglobin, methemoglobin, sulfhemoglobin and confirm the nature of poisoning.

Imaging Studies

A plain X-ray of the abdomen may show the presence within the gut of radiopaque drugs, iron tablets or enteric-coated tablets. These films also visualize drug packets in patients who ingest the latter to smuggle drugs through customs.

History, clinical examination and relevant investigations should help diagnosis. Differential diagnosis of acute poisoning includes acute infections, particularly those involving the neuraxis, and metabolic problems, in particular hypoglycemia, hypercalcemia, liver and renal cell dysfunction. Head injury (when no wound is visible) can also mimic poisoning, as can a cerebrovascular accident particularly when the latter involves the brainstem. The neurological features produced by cyanide poisoning which is not immediately fatal, resemble brainstem infarction or the effects of severe hypoxia.

MANAGEMENT[4]

Life support, with a quick clinical assessment, and laboratory help to determine the nature of the poison are now followed or accompanied *pari passu* by measures to prevent absorption, use of a specific antidote when this is available, and measures for removal of absorbed poison.

Use of Specific Antidotes

Comparatively very few poisons have specific antidotes. Therefore, it needs to be stressed that in the majority of poisons the treatment is largely supportive and symptomatic together with an attempt to prevent absorption or increase elimination of the poison as far as is feasible. Important antidotes to specific poisons are listed in Table 4.

Gastrointestinal Decontamination

Gastrointestinal decontamination in a poisoned patient can be carried out through gastric emptying procedures (induced vomiting, gastric lavage), adsorption of drugs using activated charcoal and increasing transit through the gastrointestinal tract by catharties or whole bowel irrigation. The current belief is that other than the use of activated charcoal to adsorb poisons, there is very little use of other interventions.

Gastric lavage[5] is used infrequently today and that too only in patients who are brought to treatment within 1–2 hours after ingestion of the poison. A large orogastric tube is inserted into the stomach with the patient in a propped up position (to reduce the risk of aspiration). Lavage is given with 100–200 mL alliquots of normal saline till all stomach contents (which should be preserved) are washed out. An obtunded, drowsy or comatose patient should be intubated before lavage so as to protect the airways. Complications include aspiration pneumonia, esophageal perforation and cardiovascular instability. Gastric lavage is contraindicated in poisoning with acid, alkali, hydrocarbons, in patients with bleeding diatheses and in patients who are rowdy and very restless.

It is currently believed that gastric lavage offers no clear benefit even when the patient presents within 1 hour of ingestion of the poison and should not be employed routinely in the treatment of poisoned patients. We restrict its use to a patient who has swallowed a large life-threatening amount of poison and when lavage can be given within 60–90 minutes of ingestion, or when it is likely that the toxin is present in the stomach.

Induced vomiting and the use of cathartics are procedures of a past era.

The use of activated charcoal[6] is becoming increasingly popular in the management of acute poisoning. Activated charcoal is an inert non-toxic adsorbent which binds high molecular weight compounds due to intermolecular attractions. Although activated charcoal binds many compounds, there are several potential poisons that do not bind well. These include bromides, caustics, alcohol, methanol, ethylene glycol, lithium and isopropyl alcohol. When activated charcoal is used in repeated doses, it can interrupt enterohepatic circulation and hence enhance the elimination of drugs whose pharmacokinetics includes enterohepatic circulation.

The efficacy of activated charcoal is greatest when given within 1 hour of the ingestion of the poison. Activated charcoal is administered in a dose of 1 g/kg in adolescents or adults, mixed in lemon barley or water or fruit juice and is either drunk or given through a nasogastric tube. When used in repeated doses[7] to interrupt enterohepatic circulation of a poison or drug, 25 g is given every 2–4 hours in adults. In children 0.25–1 g/kg is given every 2–4 hours. Constipation can result from the use of activated charcoal. A laxative like magnesium sulfate should be added to the first dose of activated charcoal to counter constipation. Drugs amenable to repeat dose charcoal therapy include carbamazepine, diazepam, digoxin, phenobarbitol, phenytoin, salicylates and tricyclic antidepressants.

Contraindications to the use of activated charcoal include an unprotected airway, poisoning by a hydrocarbon. The presence of a major GI pathology or recent GI surgery is a relative contraindication.

Use of Whole Bowel Irrigation

Whole bowel irrigation (WBI) involves the administration of a large volume of osmolically balanced polyethylence glycol electrolyte solution to induce diarrhea and rapid expulsion of the poison from the GI tract. The procedure is performed through a nasogastric tube. The recommended regime has been 1.5 liters enterally administered WBI fluid in an hour. This is repeated till the rectal effluent is clear. Though WBI is used perhaps in many units in the West, we have never used this method for evacuation of an ingested poison. It is a taxing procedure for the patient, particularly in elderly enfeebled individuals and is not recommended for routine use. It is contraindicated in the presence of an unprotected airway, ileus, bowel perforation or obstruction, GI bleed, colitis, persistent vomiting and hemodynamic instability.

Toxins and poisons can also enter the body through the skin, and through the ocular, pulmonary and parenteral routes. In ocular exposure the eyes should be irrigated with N-saline for 30–40 minutes. Contamination of the skin with poisons should be countered by removal of the poison with soap and water. This is especially important with reference to organophosphates, hydrocarbons and herbicides. Separate drainage areas should be provided to dispose off the contaminated water used for cleansing the skin.

Elimination of Drugs or Poisons

The three methods to eliminate the drug or poison are: (a) use of multiple dose of activated charcoal (MDAC); (b) Alkalinizing the urine to enhance renal elimination of certain poisons; (c) use of extracorporeal methods, hemodialysis and hemoperfusion.

The use of multiple dose of activated charcoal has already been commented upon. Poison or drugs are eliminated if the drug or poison diffuses from the blood into the gut where it is adsorbed by the activated charcoal. A similar adsorption occurs in drugs or poisons which have an enterohepatic circulation. Drugs which have a long elimination half life, low protein binding and a low volume of distribution are best suited for MDAC use.

Renal elimination of certain drugs or poisons can be achieved by alkalinizing the urine to a pH more than 7. This is brought about by an attempt at forced diuresis with IV fluids which includes IV infusion of sodium bicarbonate (1–2 mEq/kg IV) during 3–4 hours. In our opinion this is rarely necessary. If used, it should be reserved for specific poisons, fluoride, salicylates, barbiturates, chlorpropamide, methotreate and primidone. Fluid diuresis with alkalinization of urine should be avoided in older people as it can cause pulmonary edema. Hyponatremia, hypokalemia and a rise in intracranial pressure are other complications.

Hemodialysis and hemoperfusion[8] These methods are increasingly used to enhance elimination of poisons and drugs. Indications include patients refractory to other methods of treatment, those with extremely high levels of the poison in the blood necessitating quick removal, those in whom other routes of elimination are impaired (e.g. patients with renal and hepatic insufficiency), in severe toxicity from drugs that can be faster removed by extracorporeal method than by other forms of therapy. It is important that hemodialysis and hemoperfusion are used when poisons are capable of being removed by this form of therapy.

A list of important poisons whose elimination is enhanced by multiple dosing with activated charcoal hemodialysis and hemoperfusion is given in Table 5.

MANAGEMENT OF SPECIFIC POISONING

OVERDOSE OF HYPNOTICS-SEDATIVES[1-3]

This is a common poisoning particularly in the comparatively affluent strata of society in India. Hypnotic sedative drugs

Table 5: Selected toxins removal by hemodialysis and hemoperfusion

Hemodialysis	*Indications*
Methanol	Severe acidosis, renal failure, impaired vision; level >40 mg/dL
Ethylene glycol	Severe acidosis, seizures, obtundation; level >40 mg/dL
Salicylates (aspirin)	Severe acidosis, renal failure, hemodynamic instability, central nervous system features; level >100 mg/dL
Calcium channel blockers (nifedipine, nimodipine, nicardipine	Severe cardiotoxicity, conduction defects, refractory hypotension
Beta-blockers (sotalol, atenolol, acebutolol)	Refractory hypotension, heart block, marked bradyrhythm, renal failure
Lithium	Renal failure, cardiovascular system instability, seizures, coma
Hemoperfusion	*Indications*
Barbiturates	Severe refractory hypotension, renal failure
Carbamazepine	Ingestion of a life-threatening dose, deep coma, severe cardiorespiratory failure
Theophylline	Seizures, recurrent arrhythmias; refractory hypotension
Valproic acid	Increasing hepatic dysfunction, deep coma with severe hypotension, levels >1000 mg/dL

include barbiturates, all benzodiazepines and alcohol. Barbiturates and benzodiazepines are frequently involved in overdosage, and are generally taken with suicidal intent. The poisonous effect of a large dose of barbiturates is often potentiated by alcohol, by the simultaneous use of narcotics like opium, or by the ingestion of tranquilizers and antidepressants.

Clinical Features

Clinical features are characterized by progressive depression of the central nervous system (CNS) culminating in paralysis of the brainstem and medulla. In the early stages, or in cases with mild overdose of sedative-hypnotics, there is ataxia and dysarthria with an altered sensorium, the clinical picture resembling acute alcoholic intoxication. Progressive depression of the CNS leads to stupor, followed by deepening coma. By the time the patient is in coma, his deep reflexes are not elicitable. There is flaccidity of the limbs, corneal reflexes are lost, conjugate doll's eye movements are absent, the pupils are dilated, and the respiration is feeble, shallow and irregular. Hypotension may be a prominent feature. These features signify severe depression of the brainstem and medulla. It is important to note that quite often a slight reaction of the pupils to a very strong light can be observed even when the patient has all other features of medullary paralysis. Death occurs from respiratory failure, severe hypotension due to vasomotor failure. Non-cardiogenic pulmonary edema may be observed. Hypothermia aggravates shock and hastens the end. Oliguria with renal failure can also occur.

Lethal Dose

The lethal dose of barbiturates cannot be stated with certainty. Short-acting barbiturates on the whole are more dangerous than long-acting ones. Blood levels compatible with a fatal outcome have varied from 10 mg/100 mL in long-acting barbiturates, to 3 mg/100 mL in short-acting barbiturates. However, patients with much higher blood levels have recovered, so that the finding of a raised barbiturate level in the blood does not necessarily constitute a prima facie evidence of death from barbiturate poisoning.

Diagnosis

The intensivist must bear in mind the numerous other causes of coma. It is important to ascertain that coma is not due to structural damage or organic disease within the brain. It is equally important to exclude all metabolic problems that can cause an impaired conscious state. The usual routine tests required for proper care have already been detailed earlier. Arterial blood gas analysis and a chest X-ray are both mandatory. A blood sample should be sent for estimation of barbiturate, bromide, glutethimide and phenothiazine levels.

Ingestion of non-barbiturate sedatives, such as chloral hydrate, glutethimide, methaqualone should be given differential consideration. Co-ingestion of alcohol, benzodiazepines is not uncommon in barbiturate poisoning with suicidal intent.

Management

This is based on the principles outlined above.

Cardiorespiratory Support

It is imperative in severe poisonings. Coma calls for prompt intubation. It is important not to wait for the PaO_2 to fall to 60 mm Hg before initiating ventilator support. Ventilatory support is given to a comatose patient not only for airway control but in anticipation of impending, worsening respiratory failure. Many of these patients have a dramatic and fairly abrupt fall in the PaO_2 to dangerously low levels, as also an abrupt rise in the $PaCO_2$. This should be anticipated and not awaited. Early ventilator support is therefore strongly advocated.

Gastric Lavage

This should be done once ventilation and circulation are stable, provided the patient is brought within 2 hours of ingestion of the poison. Lavage in an unconscious patient should always be performed after a cuffed endotracheal tube

has been inserted. Many units avoid the use of gastric lavage and rest content with gastric decontamination through the use of activated charcoal.

Intake-output charts should be carefully kept, and fluid, electrolyte and acid-base balance should be carefully maintained.

Barbiturate poisoning is an indication for forced diuresis with alkalinization of the urine, in the hope that elimination of the drug is increased via the kidneys. Forced diuresis is more useful in poisoning by long-acting barbiturates which are largely excreted by the kidneys, than in short-acting barbiturates which are mainly metabolized by the liver. We have stopped using forced diuresis with alkalinization of the urine, as cardiorespiratory support with critical care suffices in the successful management of these patients.

Hemodialysis and Hemoperfusion

These procedures in our opinion are rarely necessary. Their chief indication is in patients who are comatose and who are oliguric and in renal failure. They may also be used in patients who are known to have ingested large quantities of sedative-hypnotics, and who have blood phenobarbitone levels close to 100 µg/mL (levels of other barbiturates around 50 µg/mL). We have however found equally satisfactory results in these patients with just cardiorespiratory support and good overall critical care, provided renal function remains adequate.

NARCOTIC POISONING[1-3]

Narcotic poisoning is encountered in patients attempting suicide with narcotics, and perhaps more frequently in addicts as a result of an accidental overdose. Children and elderly patients often show a marked sensitivity to morphine and other narcotics, so that serious toxic effects can occur with average usual doses. Myxedema, adrenocortical insufficiency, chronic liver disease, renal failure, head injuries, and increased intracranial tension from any cause are important medical problems where the use of opium, morphine or heroin can prove disastrous.

The clinical features are characterized by increasing paralysis of the central nervous system with severe involvement of the brainstem. Unconsciousness, with extra selective depression of the respiratory center (causing a very slow respiratory rate that can culminate into apnea), and pin-point pupils, form a triad observed in narcotic poisoning. The diminished tidal volume and slow respiratory rate result in a fall in alveolar ventilation. Hypoxic and hypercapnic respiratory failure result.

Bradycardia, hypotension, hypothermia also occur. Non-cardiogenic pulmonary edema can occur in 50% of the patients, particularly in heroin poisoning.

Organic or structural damage to the brainstem and organophosphorus poisoning can both cause coma and miosis. The intravenous atropine test is of great diagnostic value in organophosphorus poisoning. Organic or structural damage to the brainstem is associated with focal signs and disturbances in cranial nerve function or conjugate gaze. Patients with brainstem lesions are frequently hyper-excitable or have irregular breathing, rather than the slow shallow respiration observed in narcotic poisoning.

In addition to the toxic effect of a narcotic, an addict is exposed to a variety of neurological and infectious complications resulting from the use of crude adulterants (lactose, quinine, etc.), and various infectious agents (due to non-sterile administration). CNS complications from injections of heroin mixtures include toxic amblyopia and acute transverse myelopathy involving the cervical or thoracic cord resulting in paraplegia. Infective complications include sepsis, pyemic abscesses, and bacterial endocarditis most often involving the tricuspid valve, septic thrombophlebitis, Hepatitis B infection and HIV infection. Acute toxic myopathy with myoglobinuria causing renal failure can occur after injections with adulterated heroin.

Management

The principles of management remain unaltered. Cardiorespiratory support, and in particular ventilator support is life-saving.

Specific Antidote

Naloxone is fortunately a specific antidote. Between 0.4–0.8 mg is administered intravenously. When overdose is related to codeine, pentazocine or propoxyphen, a larger dose of 2 mg is given intravenously. Naloxone causes a dramatic improvement in respiration and circulation, the effect on respiration being observed within 2 minutes. It has however no effect on the pupils or on the level of consciousness. The drug has a short half-life and may need to be repeated frequently to reverse the effects of the narcotic on vital centers. If naloxone produces no effect on the shallow, slow respiration, the diagnosis of narcotic poisoning is questionable.

Complications of narcotic poisoning include pneumonia, atelectasis, pulmonary edema, and bacterial endocarditis chiefly involving the tricuspid valve. These need critical care.

OVERDOSE WITH TRICYCLIC ANTIDEPRESSANTS[9-11]

Tricyclic antidepressants such as tryptomer, amitriptyline, doxepin, block uptake of norepinephrine in adrenergic nerves. Toxic effects are due to α-adrenergic blockade, strong anticholinergic activity, inhibition of serotonin and norepinephrine uptake and myocardial depression. As they reduce intestinal motility due to their anticholinergic effect, absorption may be slow and prolonged, increasing the half-life of the drug to 3–4 days.

Clinical Features

Peripheral anticholinergic effects include tachycardia, mydriasis, urinary retention, ileus, dry, hot skin, altered mental state, seizures and occasionally respiratory depression.

Tricyclic antidepressants cause a blockade of the fast sodium channels in the myocardium producing a quinidine like effect. Cardiotoxicity is manifested by prolonged QT, prolonged PR, atrioventricular (AV) block, and tachycardia. Various arrhythmias including ventricular tachycardia, hypotension and impaired myocardial function are observed. Death commonly results from arrhythmias and/or hypotension.

Convulsions are commonly observed in TCA poisoning and in association with diminished sweating can cause life-threatening hyperpyrexia.

Diagnosis

A combination of anticholinergic effects and cardiovascular abnormalities should suggest the diagnosis. Tachycardia, prolonged PR interval and a prolonged QT interval on the ECG are commonly seen. The QRS interval is prolonged in patients with marked overdose; the mean QRS axis in the frontal plane is often upward and to the right, causing a prominent R in avR and a prominent S in lead I and avF.

Drugs levels are not necessary to make a clinical diagnosis of acute poisoning.

Management[10,11]

- Emergency management should concentrate on ensuring a secure airway, breathing and restoring hemodynamic stability. Seizures if present need quick control. Activated charcoal may be used if there are no contraindications.
- *Bicarbonate therapy* IV sodium bicarbonate is the antidote for cardiotoxicity. It can reverse hypotension, cardiac arrhythmias, AV conduction abnormalities and should be given when the QT interval is prolonged (>100 msec). The drug should also be given in the presence of acidosis (pH <7.20). The drug is given as an initial bolus of 1–2 mEq per kg followed by an infusion of 150 mEq in one liter of 5% dextrose at the rate of 2–3 mL/kg per hour. The target aimed at is an arterial pH of 7.45–7.50.

The benefits of sodium bicarbonate are in part related to the action of sodium on the conductivity of the sodium channels in the myocardium. Hypertonic saline has been used in refractory cases to restore conductivity in the sodium channels of the myocardium.

If arrhythmias continue in spite of IV sodium bicarbonate, anti-arrhythmic drugs may be necessary. Type Ia and Ic anti-arrhythmic like procainamide and flecainide should be avoided in the management of arrhythmias. Lidocaine has not been shown to be of use in VT caused by TCA. Magnesium sulfate is perhaps the drug of choice in wide complex tachycardia unresponsive to other drugs.

Hemodialysis or hemoperfusion are not beneficial in TCA poisoning as these drugs are strongly protein bound. Physostigmine should not be used to counter the anticholinergic effects of TCA because of the toxic effects this drug can cause.

COCAINE POISONING[12-14]

Cocaine addicts are on the increase. The drug can be sniffed, taken orally, injected intravenously, and can be smoked in a free base form, or mixed with baking soda and water and smoked as the "crack" form. Absorption from all sites is rapid.

Clinical Effects

Cocaine poisoning results in a sympathomimetic toxidrome. Mechanisms of action are enhanced catecholamine release with a marked increase in circulating catecholamines, inhibition of monoamine uptake and a blockade of sodium channel activity. Cocaine poisoning is typically characterized by life-threatening cardiovascular, CNS and pulmonary complications.

Cardiovascular effects are most prominent. These include hypertension and arrhythmias. Hypertension may be severe enough to cause intracranial bleeding or an aortic dissection. Both supraventricular and ventricular arrhythmias may occur. Myocarditis has followed cocaine use; this is associated with gross ST-T changes on the ECG, and a rise in the CK-MB fraction. Cocaine is a vasoconstrictor, and this may result in organ ischemia. Myocardial infarction, bowel infarction, renal infarction and ischemia involving a limb, have all been noted to occur.

The CNS manifestations of cocaine are important, they may be the presenting feature. These include seizures, cerebral infarction, subarachnoid and intracerebral hemorrhage. Intracerebral aneurysms and arteriovenous malformations are frequent on angiographic examination. Overdosage of cocaine, even in addicts, can lead to severe mental obtundation and coma. Cocaine abuse should always be considered in the differential diagnosis of a stroke in young patients. Strokes may occur 24 hours after the use of cocaine. Though commoner in chronic cocaine use, they may also occur after the drug is used for the first time.

Severe cocaine intoxication can cause non-cardiogenic pulmonary edema. Rhabdomyolysis and hyperthermia may occur with excessive muscle activity, particularly in those presenting with repeated seizures. Investigations should include an ECG, X-ray chest, creatine kinase (CK) estimation, urine for myoglobin. Relevant imaging studies of the head are necessary when CNS manifestations, in particular a neurologic focal deficit is observed. A toxicological screen for cocaine is asked for, to help diagnosis.

Diagnosis

Urine may test positive for cocaine for 2–3 days after ingestion; false negative results have also been observed.

Differential Diagnosis

Overdose of sympathomimetic drugs, (in particular amphetamine), anticholenergic drugs, theophylline can produce a similar picture. Cocaine intoxication could be confused with CNS infections. Cocaine overdose, as stated earlier, should

always enter into differential diagnosis of the etiology of a stroke, particularly in young patients.

Management[13,14]

Supportive measures include the use of activated charcoal in those who have ingested the drug. Cardiorespiratory support is essential in acute severe overdosage.

Benzodiazepines and antihypertensives (other than beta-blockers) form the corner-stones of therapy. Diazepam 5–10 mg is given at 5–10 minute intervals and serves to control agitation and other manifestations of toxicity. Symptomatic treatment should be offered with regard to cardiovascular, CNS and pulmonary complications.

Seizures should be controlled with IV diazepam or lorazepam. If uncontrolled and very frequent, the patient is paralyzed with a neuroparalytic drug, and kept on ventilator support.

Hypertension requires sedation and the use of antihypertensive drugs. Acute crisis may necessitate a titrated infusion of sodium nitroprusside. Calcium channel blockers and pentaloamine can also be used. Beta-blockers should not be given as unopposed α-adrenergic activity could worsen hypertension and cause coronary vasoconstriction.

Supraventricular arrhythmias are treated by calcium channel blockers. Pure beta-blockers should be avoided. Ventricular arrhythmias are best treated with IV lidocaine. Oxygen, use of benzodiazepine must always be given and any disturbance in electrolyte balance corrected. Myocardial ischemia can trigger arrhythmias; IV nitroglycerin helps to correct myocardial ischemia. Class Ia anti-arrhythmic drugs (procainamide) should be avoided.

Hyperthermia

Increase in body temperature may be marked in patients having repeated seizures. Treatment includes the use of sedatives and external methods of cooling.

Rhabdomyolysis

Rhabdomyolysis when present, is treated with intravenous fluids and alkalinization.

See Table 6 for drugs contraindicated in cocaine poisoning.

Table 6: Contraindicated drugs in cocaine poisoning

Beta-blockers	Contraindicated because of unopposed ∝-adrenergic action
Class Ia anti-arrhythmic—procainamide	May increase QT interval; worsen arrhythmia
Phenothiazines an antipsychotic drugs	Increased seizure risk Increased dystomic movement Increased QT interval
Succinylcholine	Can exacerbate rhabdomyolysis, induce hyperkalemia

ORGANOPHOSPHORUS OR INSECTICIDE POISONING[15-17]

Organophosphates are found in insecticides and herbicides. Drinking organophosphorus compounds (chiefly TIK 20 or Parathion) with suicidal intent has been for the last 40 years, the commonest form of poisoning in the lower socioeconomic strata of society in this country. Organophosphates act by causing irreversible inactivation of acetylcholinesterase. This results in the accumulation of acetylcholine at cholinergic receptors. Excess acetylcholine has muscarinic effects, nicotinic effects and toxic effects on the central nervous system.

Organophosphorus poisoning can occur from accidental ingestion of an insecticide, as also due to accidental dermal exposure. Inhalation via the lungs can also cause poisoning. Food, including stored grain contaminated by a spray of these insecticides has also been known to lead to severe toxicity.

Clinical Features

Organophosphorus poisoning results in a cholinergic "toxidrome". Peripheral muscarinic effects include bronchospasm, vomiting, diarrhea, miosis, blurred vision, salivation, diaphoresis, lacrimation and urinary incontinence. Tachypnea with severe respiratory distress is observed in many patients.

Nicotinic effects are chiefly observed in skeletal muscles; fasciculation, weakness and even paralysis can occur.

Patients may have bradycardia or tachycardia and may be hypertensive or hypotensive, depending on whether the muscarinic or nicotinic effects predominate.

Excess of acetylcholine also has a toxic effect on the CNS. Confusion, seizures and ultimately coma result. The terminal picture is one of flaccid paralysis, respiratory cum peripheral circulatory failure, pulmonary edema and deep coma. Respiratory failure is related to a combination of central depression, muscle weakness, bronchospasm and pulmonary edema. Severe organophosphorous poisoning is characterized by multiple organ dysfunction and failure, the organs chiefly involved being the lungs, the cardiovascular system, the central nervous system and the renal system. High SOFA scores (>10) are observed in some of these critically ill patients.

An "intermediate syndrome" may occur 1–4 days after an apparently well-treated cholinergic crisis. Its main clinical features are sudden respiratory paralysis, cranial motor nerve palsies, neck flexor muscle and proximal limb muscle weakness and paralysis. It has been documented for fenthion, diazinon, malathion, trichlorfon, dimethoate and sumithion. Treatment is by providing respiratory support; atropine and pralidoxime are ineffective. Recovery begins 5–15 days after onset of weakness.

In some patients brought in a comatose state, increased motor tone resembling decorticate or decerebrate rigidity may be observed.

Diagnosis

Coma with pinpoint pupils should bring to mind the possibility of organophosphorus poisoning. There is often a characteristic garlic odor to the breath. This diagnosis can be proved by estimating cholinesterase levels in the blood. Levels below 50% of normal indicate intoxication. Treatment in suspected poisoning should be immediate.

Management[17,18]

Activated charcoal should be administered, if the patient is brought within few hours of the ingestion of the poison.

Intravenous atropine is both of diagnostic and therapeutic value. A patient brought into a unit nearly dead with respiratory paralysis, coma, pulmonary edema following organophosphorus poisoning can still be resuscitated with prompt use of atropine and good cardiorespiratory support.

A 2 mg dose of atropine is given slowly intravenously every 5 minutes till the pupils start to dilate. As much as 50–100 mg may need to be used in some patients. Once the pupils dilate to a normal size, atropine is stopped; if over a period of hours the pupils again constrict, further atropine is necessary. The continued use of atropine after the pupils have returned to normal size, can lead to atropine intoxication. Atropine antagonizes the muscarinic effect of excess acetylcholine and reduces the effect of the poison on the CNS. It has no action on the nicotinic effects on skeletal muscles, nor does it restore acetylcholinesterase.

Atropine has also no effect on respiratory paralysis. Ventilator support is necessary. PEEP may be used in the presence of pulmonary edema, once the circulation and the blood pressure have stabilized.

Pralidoxime restores cholinesterase activity. The drug reverses the nicotinic effects of muscle weakness, and also reverses some of the CNS effects. It is used in conjunction with atropine. The dose of pralidoxime is 0.5–2 g (25–50 mg/kg), given intravenously over 5–15 minutes. Increased muscle strength and control of fasciculations are generally observed in 15–60 minutes. The drug can be repeated in 1–2 hours if muscle weakness and fasciculations persist or recur. Further doses of pralidoxime can be given every 6–12 hours, if necessary.

In severe poisoning atropine and pralidoxime may need to be given for several days. The drugs are discontinued when clinical improvement is persistent and satisfactory, and when clinical features of toxicity do not recur on withholding the drugs.

In many hospitals in the country, pralidoxime is not easily available. In its absence fresh blood transfusions should be tried.

Cardiorespiratory support is vital for survival. Early intubation, ventilator support (if necessary with PEEP) and inotropic support with dobutamine, dopamine, and vasopressor support with norepinephrine are all necessary in hypotensive patients with respiratory failure. Support to all other organ systems is important as organophosphorous poisoning leads to multiple organ dysfunction and failure.

Charcoal hemoperfusion significantly increases the clearance of organophosphorus compounds and is indicated in severe poisoning.

Seizures may need symptomatic control with diazepam (10–20 mg intravenously) and by phenytoin sodium.

ANTIHYPERTENSIVES

Beta-Blockers[19,20]

Beta-blockers are among the most frequently used drugs in hypertensive patients. Patients may take a larger dose than that prescribed, by sheer accident, and manifest signs of drug toxicity. Life-threatening toxicity may occur even if the dose taken is two or three times over the therapeutic range. Toxicity has also been observed with ocular preparations. Rarely beta-blockers are consumed in large doses with suicidal intent. Toxicity generally occurs within 6–8 hours. Ingestion of extended release preparations and sotalol may be associated with delayed toxicity, necessitating observation for 24–48 hours.

Clinical findings of beta-blocker toxicity are hypotension, bradycardia and AV conduction abnormalities. The latter may take the form of first, second or third degree AV block. SA block is also observed and the QRS interval is often prolonged. In severe poisoning, the blood pressure is unrecordable, the cardiac output very low due to the depressant action of the drug on the myocardium, and the patient goes into cardiogenic shock. Death is due to asystole.

The more lipophilic beta-blockers, like propranolol, metoprolol, timolol for unclear reasons, can cause CNS dysfunction in the form of delirium, seizures and coma, even in the absence of significant hypotension. Hypoglycemia and hyperkalemia may also be observed. Overwhelming life-threatening bronchospasm may occur in patients with asthma or chronic obstructive pulmonary disease (COPD).

Treatment

Patients who present within 2–4 hours after ingestion should be given activated charcoal, the dose of which can be repeated. Patients who appear stable should be closely monitored for 24–48 hours.

Bradycardia and hypotension are initially treated with intravenous atropine and a volume load with isotonic saline. If bradycardia and hypotension persist, the specific drug to use is glucagons 5 mg intravenously; the dose can be increased to 10 mg if the response is poor. If a response to glucagons is satisfactory, the drug is given in an intravenous infusion at the rate of 10 mg/hour. Bronchospasm is treated by nebulization with duolin, budecort and by IV hydrocortisone.

Calcium chloride 10% may be given intravenously slowly up to a maximum of 3 g. This improves cardiac contractility and helps to reverse hypotension.

Catecholamine infusions should also be started if hypotension is severe and persistent. Very often a combination of dopamine, dobutamine and epinephrine or norepinephrine is used; the response is often poor, so that very large doses may be necessary to produce a satisfactory effect. The danger of tachyarrhythmias due to large doses of inotropes should be kept in mind. External or transvenous pacing should be considered early in the presence of a marked bradyrhythm. Pacing may increase the heart rate without increasing blood pressure or cardiac output. At times the pacemaker fails to capture. Phosphodiesterase inhibitors such as milrinone may prove useful in patients with cardiogenic shock.

Beta-blockers have very large volumes of distribution and cannot be effectively cleared by extracorporeal methods. Atenolol, sotalol and acetabutol are exceptions that can be eliminated by extracorporeal methods in case of severe toxicity, particularly in patients with renal failure.

Calcium Channel Blockers[21]

Calcium channel blockers are also frequently used in the management of hypertension. The most commonly used calcium channel blockers are verapamil, diltiazem and nifedipine. These drugs are well absorbed from the gastrointestinal tract; they are metabolized in the liver.

Calcium channel blockers in an overdose have a marked negative inotropic effect on the heart and induce severe peripheral vasodilatation. Patients present with bradycardia, hypotension and various degrees of heart block that may result in death. Toxic effects outside the cardiovascular system include nausea, vomiting, non-cardiogenic pulmonary edema, mental changes, hyperglycemia and seizures.

Treatment

Calcium is administered intravenously. More often than not the result is unsatisfactory, as the calcium channels are blocked, so that additional calcium has little or no effect. Even so, calcium is administered as 10 mL of 10% $CaCl_2$ given over 2–3 minutes; additional doses are given every 2–3 minutes and if hemodynamic instability persists a continuous infusion of 10% $CaCl_2$ at 10 mL/hour is administered.

Glucagon and phosphodiesterase inhibitors should be used in the manner outlined for beta-blocker overdose. Glucose insulin infusion (keeping the blood sugar between 150–200 mg/dL) may help in patients who do not respond to the above measures. Atropine, 1 mg intravenously can be used to increase the heart rate in some patients. Hypotension should be further combated by a volume load and by catecholamine infusions. As in the treatment of beta-blocker overdose, a combination of dopamine, dobutamine, and epinephrine or norepinephrine may be necessary. Transvenous pacing should be done in patients with severe heart block.

SYMPATHOMIMETIC DRUG OVERDOSE[22]

Sympathomimetic drugs like amphetamine and methamphetamine are very popular drugs of abuse. However, sympathomimetic drugs are also present in over the counter preparations for colds, for appetite control, and include stimulants such as caffeine, ephedrine and pseudoephedrine.

These drugs (amphetamine and methamphetamine are classic examples) in an overdose, cause an excessive release of catecholamines, epinephrine and norepinephrine, resulting in a sympathomimetic toxidrome. The latter is characterized by tachycardia, hypertension, agitation, restlessness, anxiety and mydriasis. Hallucinations, acute and often paranoid psychosis and seizures may occur. The psychosis is indistinguishable from that observed in schizophrenia. It is temporary, but may take weeks or even months to disappear.

Other cardiovascular and CNS effects observed with severe overdose include myocardial ischemia, arrhythmias, strokes, intracranial hemorrhage. Hyperthermia, rhabdomyolysis, renal failure and diarrhea may also occur.

Methamphetamine is more frequently used than amphetamine as a drug of abuse. It is termed "ice" or "crank"; the drug can be ingested, smoked, inhaled or given intravenously. Another amphetamine-like drug increasingly used not only in the West but also in India and many countries of the world is 3–4 methylenedroxymethamphetamine. It is popularly called "Ecstasy" and acts both as a stimulant and hallucinogen. It produces the serotonin syndrome by inducing a release of serotonin in the brain and inhibiting its re-uptake. Besides its hallucinogenic and stimulant effect, the drug induces continuous physical activity. Complications include hyperthermia, rhabdomyolysis, circulatory collapse, strokes, intracranial hemorrhage and multiple organ dysfunction syndrome.

Diagnosis

When no history is available the sympathomimetic toxic syndrome should be distinguished form thyrotoxicosis, alcohol or benzodiazepine withdrawal, from poisoning caused by tricyclic antidepressants, and from symptoms induced by the interaction of monoamine inhibitors with other drugs.

Treatment

Treatment is directed to countering the cardiovascular system and CNS effects. Acute hypertension is an emergency that should be promptly controlled. A titrated solution of sodium nitroprusside given in an intravenous infusion is the quickest method to control a sharp rise in the blood pressure. Labetalol is a good choice in patients who have marked tachycardia and hypertension. Other beta-blockers should be avoided as increasingly severe hypertension could result from beta 2 adrenergic block and unopposed α-adrenergic stimulation.

Anti-arrhythmics like verapamil or adenosine are used to revert supraventricular arrhythmias.

Seizures should be treated with benzodiazepines, phenytoin and phenobarbitol. Benzodiazepines are probably the drugs of choice in the management of psychosis. Hyperthermia can be lethal. Abolishing seizures and restlessness with benzodiazepine and physical cooling of the skin by appropriate methods are important.

Myocardial ischemia requires close ECG monitoring and serial cardiac enzyme estimation. Tachycardia should be controlled; nitrates either orally or as an intravenous infusion of nitroglycerine should be administered for the treatment of myocardial ischemia.

ASPIRIN (SALICYLATE) POISONING[23]

Aspirin is one of the most commonly and widely used drugs today. Remarkably enough, poisoning with aspirin is rarely encountered in our country. The drug is available and sold over the counter as an aspirin preparation *per se*, or in combination with other drugs. Methyl salicylate (Oil of Wintergreen) poisoning occurs at times in children who ingest it because of its pleasant smell. This formulation contains as much as 7 g of aspirin per teaspoon, compared to the usual 300–600 mg aspirin per tablet in the usual aspirin preparations.

Aspirin after oral ingestion, reaches a peak level in the blood after 2 hours. It is metabolized in the liver, is also excreted by the kidneys and has a half-life of 4–6 hours. When an overdose is taken, the hepatic enzymes become saturated and the drug's half-life increases to 18–36 hours. The drug can now only be eliminated via the kidneys. When blood levels are high (>40–50 mg/dL), serious toxic effects can occur.

It is best to consider patients with aspirin or salicylate poisoning as falling into two groups, those who ingest the drug with suicidal intent, and those who take the drug on a long-term basis to counter pain. Overdose with aspirin in the latter group can have subtle manifestations which are easily missed and which contribute significantly to morbidity and mortality.

Clinical Features

Tinnitus, vertigo, vomiting and impairment of hearing are frequent. Mental confusion, restlessness, excitability may resemble alcoholic intoxication. Sweating, dehydration and hypotension are often observed. In severe cases hallucinations, seizures, coma and death occur.

Salicylates initially stimulate the respiratory center and induce hyperventilation with a respiratory alkalosis. They also directly cause a metabolic acidosis with an increase in the anion gap. Thus a combination of respiratory alkalosis with metabolic acidosis should strongly suggest the possibility of salicylate or aspirin poisoning. In children, or following large doses in adults, there can be a depression of the respiratory center so that a combination of respiratory plus metabolic acidosis results, with a life-threatening fall in the arterial blood pH.

Large doses produce hemorrhage due to hypoprothombinemia. Hematemesis and malena may result from acute erosive gastritis and duodenitis. Cerebral edema can occur and non-cardiogenic pulmonary edema results from increased capillary permeability. Salicylates uncouple the phosphoregulation process; this lead to increased glucose utilization, an increased metabolic rate and increased oxygen consumption. The clinical effects of the above are hypoglycemia and fever.

It is extremely important to note that features of hyperventilation, seizures, dehydration and even coma, can occur in patients with chronic poisoning, even when salicylate levels are not inordinately high (35–50 mg/dL).

Diagnosis

The diagnosis may be difficult in the absence of a relevant history. Chronic overdose in patients is very easily missed.

The occurrence of metabolic acidosis and respiratory alkalosis, in the absence of diabetes and renal failure should suggest the possibility of salicylate poisoning. The diagnosis can be proved by measuring salicylate levels in blood. This can be done at the bedside by doing the Phensitix test which detects salicylates in the plasma if the level is more than 20 mg/dL.

Common laboratory findings in salicylism include an elevated anion gap metabolic acidosis, increased prothrombin time, hypernatremia, hypo- or hyperglycemia, ketonemia, hypokalemia, and increased levels of liver transaminases.

The differential diagnosis is from poisoning by CNS stimulants which can also cause an altered mental state, confusion, and diaphoresis. Alcoholic ketoacidosis and other causes of metabolic acidosis need to be distinguished from salicylate poisoning. Encephalitis may present with hyperventilation, mental confusion and respiratory alkalosis. Sepsis can also be characterized by respiratory alkalosis or a combination of respiratory alkalosis plus metabolic acidosis.

Management

The repeated use of activated charcoal is helpful if the patient presents within 2–3 hours after ingestion of the drug.

Correction of dehydration and shock, and efficient cardiorespiratory support are of prime importance. Maintenance of electrolyte and acid-base balance is crucial for survival in severe poisoning. Severe metabolic acidosis should be promptly corrected with 75–150 mL of intravenous sodium bicarbonate (see Chapter Acid-Base Disturbances in the Critically Ill).

Use of forced diuresis with alkalinization of the urine In an alkaline medium, salicylates remain in the ionized form and do not diffuse into the tissues. Alkalinizing the urine facilitates excretion of salicylates. One should aim to maintain a urine pH of 7.5–8. Salicylism is one poisoning where forced diuresis with alkalinization should as far as possible be attempted. The simplest method of alkalinization is to use 1 L of half strength (0.45%) saline, to which is added two ampoules of 7.5% sodium bicarbonate and infuse this at the rate of 150–250 mL/hour. Potassium deficits are appropriately replaced. Intravenous mannitol 300 mL, as also furosemide 40 mg intravenously may be administered to increase diuresis. The intake should continue to keep pace with the output, and it is important to check serum electrolytes frequently so that electrolyte balance is well maintained. Hypernatremia, cerebral and pulmonary edema are complications that need to be carefully watched for.

Box 1: Indications for hemodialysis or hemoperfusion in salicylate (aspirin) poisoning

- Severe acid base disturbance
- Renal failure, hepatic dysfunction
- ARDS/ALI
- Severe refractory hemodynamic instability
- CNS features: Coma, seizures
- Serum salicylate levels >120 mg/dL for acute poisoning
- Serum salicylate levels >60 mg/dL for chronic toxicity

Hemodialysis and Hemoperfusion

These very effectively reduce salicylate levels in blood and are indicated under the following circumstances—

- Serum levels greater than 120 mg/dL in acute poisonings observed within 6 hours of ingestion, or greater than100 mg/dL if observed after 6 hours of ingestion of the poison.
- Chronic toxicity when blood level exceeds 60 mg/dL.
- In patients with renal failure and/or hepatic dysfunction.
- In the presence of pulmonary edema which prevents the use of forced diuresis and alkalinization.
- Progressive hemodynamic deterioration.
- In the presence of severe neurological toxicity, coma or seizures.
- In the presence of clinical deterioration in spite of conservative conventional management.

Indications for hemodialysis or hemoperfusion in salicylate (aspirin) poisoning are listed in Box 1.

Symptomatic Measures

Seizures may need the use of diazepam; blood transfusions may be necessary to replace blood lost in hematemesis. Vitamin K should be given to counter hypoprothrombinemia. Hypovolemia should be treated by fluid infusions. Non-cardiogenic pulmonary edema can result from the effect of salicylates on pulmonary capillaries. Intubation and ventilator support then become necessary.

PARACETAMOL (ACETAMINOPHEN) POISONING[24]

Paracetamol is an antipyretic and analgesic very frequently used in medical practice. Overdose with suicidal intent is one of the commonest poisonings in the West, but is uncommon in our country. Patients may suffer poisoning from the drug by inadvertently consuming excessive quantities in an attempt to treat their own pain and fever. It is important to bear in mind the fact that paracetamol is often present in combination with other drugs bearing different brand names.

The drug after ingestion is metabolized in the liver via the cytochrome P 450 oxidase system. Excessive quantities of paracetamol deplete glutathione stores. This leads to accumulation of toxic metabolites that are severely hepatotoxic and can result in massive hepatic necrosis. In adults doses of less than 125 mg/kg are rarely toxic except when patients have pre-existing liver disease. Acute ingestion of 150 mg/kg (10 g) or chronic ingestion of 4 g/day results in clinical toxicity. Ingestion over 200–250 mg/kg invariably leads to fulminant hepatic failure. Death occurs within 4–15 days after ingestion of the drug in these patients.

Clinical Features

Patients with an overdose of paracetamol are minimally symptomatic in the first 24 hours. Sweating, nausea, vomiting may be observed. Hepatotoxicity starts after 24–48 hours and usually reaches a maximum between 72–96 hours. It is characterized by deepening jaundice, mental confusion and asterixis. Drowsiness progresses to coma; hypoglycemia and excessive bleeding are observed. Death occurs from acute hepatic failure. The serum transaminases and bilirubin show a progressive rise *pari passu* with the clinical deterioration. The prothrombin time is markedly elevated and the serum ammonia levels are high.

Acute tubular necrosis with renal failure can also occur. Pancreatitis, myocardial dysfunction and hypersensitivity reactions have been reported.

Laboratory Investigations

The most important test is the serum acetaminophen level. It should be done 4 hours after ingestion of the drug. If this is over 150 µg/mL, the patient is at risk for massive hepatic necrosis and should be promptly treated with N-acetylcysteine.

In patients admitted later than 4 hours after ingestion, the paracetamol level should be plotted against time using the Rumack-Matthew nomogram. Plasma levels above the lower line "possible risk" should be given N-acetylcysteine (NAC). The administration of NAC should not be delayed in a witnessed poisoning. NAC should also be administered in patients who come after 24 hours of ingestion if there is a rise in liver enzymes or if there is a detectable acetaminophen level in the blood.

Liver function tests need to be done and followed-up at periodic intervals in patients who show hepatotoxicity.

Management

Activated charcoal should be given if the time lag between ingestion of the poison and admission to a unit is less than 6 hours. Activated charcoal also absorbs the antidote N-acetylcysteine, but the dose of the latter can be suitably increased. The use of activated charcoal is not likely to help in late admission to hospital or to a critical care unit.

Use of N-acetylcysteine The antidote is indicated: (a) in patients who have consumed excess quantities of the drug; (b) in those with toxic serum levels as indicated earlier; (c) in those showing evidence of impaired hepatic function.

The drug is most effective when given within the first 8 hours of ingestion. After this period, its efficacy decreases, but it should nevertheless be given. There is no benefit in giving acetylcysteine in the first 4 hours after ingestion. The

drug acts by increasing depleted glutathione stores, and by providing a glutathione substitute to allow for degradation and detoxification of metabolites of paracetamol within the liver.

N-acetylcysteine is usually given orally in a loading dose of 140 mg/kg followed by 70 mg/kg every 4 hours for 3 days. This antidote may unfortunately cause vomiting. Prochlorperazine or metoclopramide may be used to counter the latter. The drug can also be used intravenously in the same dose as stated above in patients where severe vomiting precludes oral use. It is best given in 500 mL of a diluent over a period of 2 hours.

Supportive care for liver cell failure is important. This has been discussed in another chapter. The indications for liver transplant in severe paracetamol poisoning have been discussed in the Section Critical Care in Acute Hepatic Failure to which the reader is referred.

CARBON MONOXIDE POISONING[25]

Carbon monoxide (CO) has a 200 times greater affinity for hemoglobin compared to oxygen. It therefore readily displaces oxygen from oxyhemoglobin (HbO_2), which is converted to carboxyhemoglobin (HbCO). Severe tissue hypoxia results and this can cause death. An exposure concentration of 0.4% of CO is fatal within an hour. CO is solely eliminated via the lungs, the time taken to reach half the original concentration being about 4 hours breathing air, and about 80 minutes breathing 100% oxygen.

Clinical Features

Tissue hypoxia results in a loss of consciousness followed by respiratory failure. Circulation may continue for some minutes after respiration has failed. There is a cherry pink color to the skin, nails and mucosa.

Diagnosis

This is generally obvious from the circumstances in which a patient is found. At times CO poisoning is insidious. A slow gas leak may not be evident, and the diagnosis in a patient found unconscious in such circumstances is easily missed. A diagnosis of a brainstem infarct is erroneously made. Hypoxia produces lactic acid acidosis and a common finding is low arterial blood pH, a normal PaO_2 with lactic acid acidosis. Low oxygen saturation in the presence of a normal or near normal PaO_2, should promptly arouse suspicion of CO poisoning or methemoglobinemia.

For the estimation of CO, 3 mL of heparinized blood is collected under liquid paraffin, and sent to the laboratory. Spectroscopic examination of the blood reveals the typical band of carboxyhemoglobin (HbCO), and confirms the clinical diagnosis. A rough but simple bedside test for carboxyhemoglobin is as follows, 1 mL of patient's blood is added to 10 mL distilled water plus 1 mL of 5% NaOH. Carboxyhemoglobin is present if the solution turns straw yellow (HbCO <20%), or remains pink (HbCO >20%). An HbO_2 solution turns brown.

Management

Emergency management consists of immediate cardiorespiratory support. The patient is quickly intubated and put on ventilator support with 100% oxygen. When facilities are available, hyperbaric oxygen at 2 atmospheres pressure rapidly produces dissociation of CO from hemoglobin, and this promptly corrects tissue hypoxia. Hyperbaric oxygen if available, can help resuscitate even moribund patients.

If resuscitation from CO poisoning is delayed, serious neurological sequele can result even after complete recovery of consciousness.

CYANIDE POISONING[26]

Cyanide is the quickest acting poison. It affects the cytochrome oxidase system within the cells thus preventing the latter from utilizing oxygen. Strangulation literally occurs at the cellular level. Death occurs within a few minutes following inhalation or ingestion. Oral ingestion of hydrocyanic acid acts more slowly, death occurring within an hour. An odor of bitter almonds and the sudden catastrophic episode, point to the diagnosis.

Clinical features include coma, rigidity, respiratory depression, bradycardia and hypotension. A patient brought alive to the ICU immediately after ingestion of cyanide showed deep coma, marked bradycardia, hypotension, absent brainstem reflexes, severe rigidity and extensor thrusts as in a decerebrate state. Plantars were unelicitable. A diagnosis of a brainstem infarct or hemorrhage was entertained. The correct diagnosis was made retrospectively after the patient miraculously recovered just on cardiorespiratory support after a period of 10 hours. He confessed to ingesting a powder, which on analysis contained cyanide.

Management

Immediate inhalation of amyl nitrite pearls (one every 2 minutes), should be followed by an intravenous injection of 10–15 mL of 3% solution of sodium nitrate given over 5 minutes. The above measures produce a methemoglobinemia, and the cyanide is bound as stable cyanmethemoglobin.

The next step is the administration of 50 mL of a 25% solution of sodium thiosulfate. This helps conversion of cyanide liberated from cyanmethemoglobin to thiocyanate.

Cyanide is rapidly destroyed in the body, so that if the patient can be tided over a period of a few hours, recovery may well occur.

ALCOHOLS[27]

All alcohols have a depressant effect on the CNS. Dysarthria, lack of co-ordination, altered often aggressive behavior, increasing drowsiness progressing to deep coma are observed. Respiratory depression and failure together with the characteristic alcohol odor in the breath allow a correct diagnosis.

Ethanol

The diagnosis of ethanol poisoning can be made from the above clinical features and confirmed by measuring the blood ethanol level. Treatment is largely supportive. In obtunded patients, the airway should be secured; mechanical ventilator support is essential in the presence of respiratory complications. It is important to remember that in an unconscious patient with the breath smelling of alcohol and with a raised ethanol level in blood, the unconsciousness is not necessarily related to alcohol. The unconsciousness may well be due to a subdural hematoma (related to a fall or injury) during a drunken state or to a coincident cerebrovascular accident.

The three non-ethanol toxic alcohols that on ingestion can cause life-threatening emergencies and death if not diagnosed promptly, are methanol, ethylene glycol and isopropanol.

Methanol

Poisoning occurs through ingestion of methylated spirit due to suicidal intent or as a substitute for ethyl alcohol. Adulteration of ethyl alcohol with methanol is very common in what is termed in India as country liquor.

Clinical Features

Toxic effects may occur after a latent period of 12–48 hours. Major toxicity of methanol is related to the oxidation of methanol to methanal, formic acid and finally detoxified to carbon dioxide. Toxic manifestations consist of increasingly severe metabolic acidosis, blurred vision progressing to blindness due to optic atrophy, seizures, respiratory failure, coma and death. There is an increase in both the anion gap and the osmolar gap. Epigastric pain, vomiting and other features of alcoholic intoxication as observed with ethanol poisoning often occur to start with. These are followed or accompanied by the more serious toxic effects mentioned above.

Laboratory Investigations

Metabolic acidosis with an increase in the anion gap is always present. An osmolar gap is also a characteristic feature. Definitive diagnosis can be made by measuring methanol levels in blood. However, late presentations of poisoned patient may have undetectable methanol levels but raised formate levels.

Management

Counter acidosis Intravenous sodium bicarbonate is administered to counter severe acidosis. Large amounts may need to be given because toxic acid metabolites are produced in large quantities. Hypernatremia may result from large doses of sodium bicarbonate.

Block or reduce toxic metabolites This is achieved by the administration of ethanol orally or intravenously. The dose of ethanol in an adult is 2 mL/kg of 50% ethanol orally or 10% ethanol intravenously. Ethanol infusions if given intravenously should be at the rate of 0.05–0.1 mg/kg per hour to provide ethanol levels of 100–150 mg/dL. Alcohol dehydrogenase which metabolizes methanol has a higher affinity for ethyl alcohol, and preferentially metabolizes the latter. The methanol therefore remains unmetabolized with less resulting toxic effects.

When available, fomepizole is generally preferred to ethanol as a competitive inhibitor of alcohol dehydrogenase in patients who have methanol levels greater than 20 mg/dL, well marked metabolic acidosis and a large anion and osmolar gap. The drug is given in a dose of 15 mg/kg IV over 30 minutes, followed by 15 mg/kg every 12 hours as needed till methanol levels fall less than 20 mg/dL. Folic acid should be given 50 mg IV every 6 hours to convert the formate to CO_2 and water.

Methanol when taken in a large dose kills quickly and treatment should begin promptly on suspicion of the diagnosis without awaiting results of methanol levels in blood.

Hemodialysis In seriously ill patients, after the above measures are instituted, hemodialysis is used to remove both methanol and its toxic metabolites from the blood.

Ethylene Glycol

Ethylene glycol is present in anti-freeze and is consumed with suicidal intent. Toxicity is related to the formation of toxic metabolites, glycolaldehyde and oxalates because of the action of alcohol dehydrogenase on ethylene glycol. Early toxicity consists of CNS depression. This is followed after a latent period of 5–72 hours by severe metabolic acidosis, renal failure, convulsions, mental obtundation progressing to coma. The urine may fluoresce under wood light and show oxalate crystals. Metabolic acidosis, anion gap, osmolar gap occur quickly. Fomepizole should be used in the dose mentioned above. Hemodialysis is indicated with blood levels of ethyelene glycol greater than 30 mg/dL, severe metabolic acidosis, or renal failure. Seizures are common and treated with benzodiazepines and by IV calcium gluconate if hypocalcemia is present.

Isopropanol

Isopropanol is a component of rubbing alcohol and a few other household compounds, and may be ingested with suicidal intent. It causes epigastric pain, vomiting, GI bleeding, depression of the CNS, ketosis and respiratory failure. The breath has a fruity odor of ketones. Diagnosis is made from the above symptoms and by the presence of unexplained ketosis or an elevated serum osmolar gap.

Treatment is largely supportive as in ethanol poisoning. Hypoglycemia may contribute to a confused obtunded state and should be treated with IV glucose. GI toxic manifestations require use of proton pump inhibitors; GI bleeding necessitates volume replacement and RBC infusions if necessary.

Hemodialysis can successfully remove isopropanol in patients with severe poisoning.

FERROUS SULFATE (IRON) POISONING[28]

Soluble iron when ingested in a marked overdose produces intense vomiting, circulatory collapse, and at times even perforation of the stomach. Jaundice, metabolic acidosis, coma and respiratory failure are observed.

The specific antidote is deferoxamine mesylate (Desferal). This antidote combines with iron to form a harmless compound which is excreted in the urine. After a gastric lavage with 10% sodium bicarbonate, 5–7 g of desferal in 100–200 mL of water is given orally. 2 g of desferal in 6 mL distilled water is given intramuscularly, and the drug is then given in a slow intravenous drip at the rate of 7–10 mg/kg per hour. The maximum dose should not exceed 80 mg/kg in 24 hours. Hemodialysis is effective in severe poisoning.

CHAPTER 67

Envenomation

GENERAL CONSIDERATIONS

Snake bite is an important yet neglected public health issue and hazard in tropical countries. An accurate measure of the global burden of snake bite envenomation is unknown. There are also no reliable figures with regard to morbidity and mortality following snake bites from countries where snake bite is a frequent and an important problem. South Asia is by far the most affected region and India has the largest number of deaths due to snake bite in the world.[1] The World Health Organization has reported that 50,000 people die of snake bite in India. In Pakistan, 40,000 bites are reported annually with 8,900 fatalities; Nepal and Sri Lanka have recorded 20,000 and 33,000 bites from poisonous snakes respectively with significant morbidity and mortality.[1] Bangladesh has estimated an annual incidence of 4.3 per 100,000 with a case fatality of 20%.[1] The highest figures in Asia so far come from a community-based survey conducted in Southeast Nepal which revealed an incidence of 1,162/100,000 and a mortality of 162/100,000.[1] The figures quoted above for different South Asian countries are a gross underestimate as a number of cases in South Asian countries unquestionably go unreported.

In the last two decades of the twentieth century the annual death rate from snake bites in Brazil was about 4 per 100,000, in Burma 15 per 100,000 and in the United State about 2,000 per year. In Europe deaths from snake bite are rare.

Snake bite is estimated to account for a tenth as much of the mortality as malaria. This would roughly amount to over 100,000 deaths per annum. Unfortunately, there is no global strategy against snake bite as there is against malaria. There is a tremendous shortage of snake antivenom all over the world, particularly in India and Africa. Research, development and funding for antivenom appear to have sadly lost momentum.

Snake bite is an important occupational hazard in rural areas chiefly affecting farmers, other agricultural workers, herders and fishermen. Open houses and the habit of sleeping on the floor expose individuals to the bites of nocturnal snakes. Bites generally occur on the lower limbs, are common among young men and women and are frequent in the rainy season. Extreme weather conditions such as storms, floods are associated with both an increase in frequency and mortality of snake bites. During the 2007 monsoon flood disaster in Bangladesh, mortality from snake bite was second only to drowning and significantly more than death from diarrhea or respiratory disease.[1] This perfectly illustrates the public health issues and hazards in relation to the important problems in the tropics.

There are over 3,500 species or kinds of snakes in the world, of which about 375 are poisonous.[2-4] The important poisonous families are—

- Elapidae (cobras, kraits, mambas, coral snakes), found all over the world except in Europe.
- Viperidae (true vipers), and the Crotalidae (pit vipers and rattlesnakes).
- Colubridae, seen as a few species with rear fangs in Africa.
- Hydrophiidae (sea snakes) found in the sea close to the coastline, and in large collections of freshwater.

The common varieties of poisonous snakes in India are cobras, the common krait, Russell's viper, the *Echis carinatus* and sea snakes. The cobras include the common Indian cobra and the king cobra. The krait is a small but extremely poisonous snake and includes the common krait and the banded krait. The vipers include the pit vipers, so-called because of a "pit" below the eyes, and the true vipers. Two features common to all poisonous snakes are—

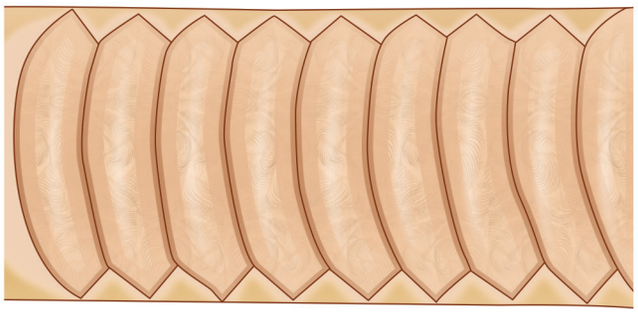

Fig. 1: Ventral scales in a poisonous snake extending right across the belly

Fig. 2: Canalized fang of a Russell's viper to the left grooved fang of a cobra to the right

Source: Vakil RJ, Udwadia FE. Diagnosis and Management of Medical Emergencies. Bombay:OUP; 1982.

1. All poisonous snakes have broad ventral plates on the belly that extend right across (Fig 1). In nonpoisonous snake there are number of small teeth instead of the two fangs of a poisonous snake. If therefore a pin is passed along the margin of the upper jaw and it strikes many small teeth, the snake is harmless; if however two prominent teeth are struck the snake is poisonous.
2. All poisonous snakes have two fangs attached in front to the upper jaw, through which snake venom is injected into the prey. Fangs are specially developed teeth, either grooved or tubular (Fig. 2). Poison glands (secreting venom or poison) are present on either side of the upper jaw. A duct carries the poison from the gland to the base of the fang on either side. When the snake bites, the poison gland is squeezed through the ducts into the fangs, and enters the prey (Fig. 3).

IDENTIFYING FEATURES OF INDIVIDUAL SNAKES

The salient features that help in the identification of the common poisonous snakes of India are given below—

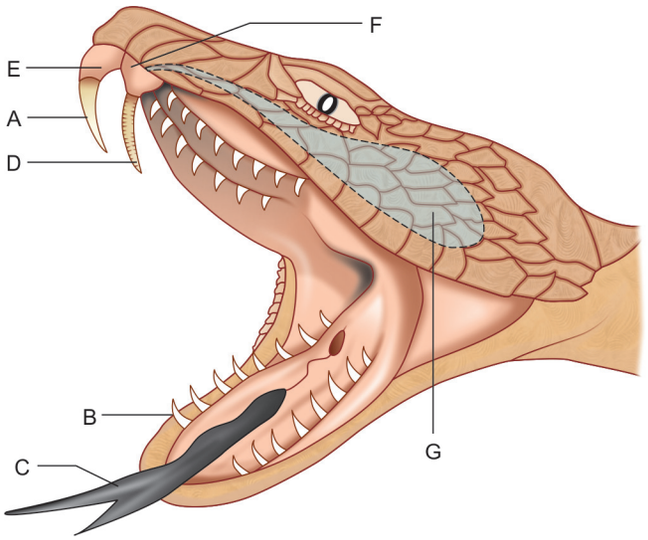

Fig. 3: Head of a Russell's viper showing the poison glands and the cannulated fangs. A—fangs; B—curved teeth; C—tongue; D—orifice of the fang; E—sheath over the fang; F—poison duct at base of the fang; G—poison gland

Source: PJ Deoras—Snakes of India.

Identification of a Cobra (Fig. 4)

It has a well-marked hood, which opens out when the snake is irritated but which may not be evident after the snake is killed. The hood often bears a mark like a ☬ a spot surround by an ellipse.

- The third shield of the upper lips is big and extends from the eye to the shield containing the nostril (this is also observed in coral snakes).
- The shields under the tail are double.
- The Indian cobra quite frequently has two or three series of very dark belly plates under the neck.

Identification of a Viperide (Fig. 5)

- The head is triangular and large and covered by small scales exactly as on the body; the pupils are vertical.
- The pit viper has a sharp pit or depression between eye and nose.
- The pitless viper frequently has marks on the dorsum of the body and head. The head of the Russell's viper has the mark of the letter V with apex in the front, and the body has three rows of large black spots one going down the middle and one down either side. The rows resemble chains (hence also the name Chain Viper).

Identification of a Krait (Fig. 6)

- It is usually 3-feet-long and has broad plates on the belly.
- The head is covered with shields.
- The central row of scales down the back is distinctly enlarged and the prominent scales are more or less hexagonal.
- The plates under the tails are undivided.

COMPOSITION AND EFFECTS OF SNAKE VENOM[5,6]

Snake venoms contain numerous toxic proteins and proteolytic enzymes. The Indian cobra contains a neurotoxin, a hemolysin, a cardiotoxin, cholinesterases, phosphatases, phospholipase B, glycerophosphate, nucleotidase and an enzyme inhibiting cytochrome oxidase. The neurotoxins in cobra venom are polypeptide toxins. α-bungarotoxin and cobrotoxin are postsynaptic ∝ neurotoxins that bind to acetylcholine receptors at the motor end-plate. β-bungarotoxin is a presynaptic β neurotoxin that releases acetylcholine at the nerve endings and then damages the end-plate, so that further release of acetylcholine is arrested.

The viper venom besides containing digestive enzymes, hyaluronidase, also contains a thrombin like factor X and a prothrombin activating factor.

Snake venom produces the following effects—

- *Neurotoxic* This results in a curare-like paralysis of voluntary muscles, a paralysis of the muscles supplied by the cranial nerves, and terminally, paralysis of the brainstem and medulla.
- *Necrotizing* The toxin causes severe inflammation and local necrosis.
- *Hemolytic and hemorrhagic*—The toxin causes intravascular hemolysis and results in severe hemorrhage due to interference and depletion of normal clotting factors.
- *Shock,* which is produced by exudation of fluid into the bitten extremity, by vasodilatation with a generalized increase in capillary permeability, and by severe hemolysis and hemorrhage. In viperine bites, shock may occur before the local features are clinically marked, and before the occurrence of hemorrhage or hemolysis.

The venom of elapids (cobra, kraits, coral snake) chiefly produces a neurotoxic effect, though some degree of hemolysis and local tissue necrosis may also occur.

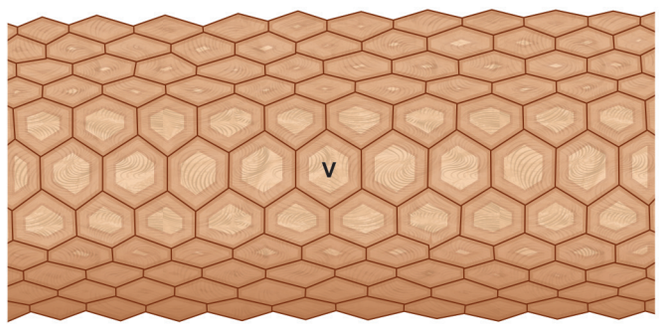

Fig. 6: Back of a Krait showing enlarged vertebrals (V)

The venom of viperidae (vipers) produces a severe local necrotizing lesion, hemolysis, disturbance in the coagulation mechanism with profuse hemorrhage and shock.

CLINICAL FEATURES[7-9]

Before discussing the clinical features the following points deserve notice—

- A bite from a poisonous snake does not necessarily cause envenomation. The patient might have been protected by clothing, or the snake may have emptied its poison on an earlier prey, so that very little or no venom may enter the patient.
- A bite by any snake, even if nonpoisonous, can cause severe fright. A patient may faint from fright. Death has been known to occur from severe fright and acute panic. A history of the patient turning violent and agitated soon after a bite is the result of a hysterical reaction induced by fright; it is not due to envenomation.
- A bite from a poisonous snake leaves two prominent fang marks. Absence of clear fang marks in the wound points to a nonpoisonous snake. The bite in the latter case takes the form of an inverted U (∩) without fang marks.

- Envenomation is invariably far more serious in children than in adults.
- The presence of pathogenic bacteria in the mouth of the snake or on the skin of the victim, can lead to secondary infection of the wound. Tetanus and clostridial infections can complicate bites of poisonous and nonpoisonous snakes.
- If the victim is perfectly well 6–8 hours after a bite, the snake is generally nonpoisonous. Exceptions are observed with some species of viperidae when acute hemolysis or hemorrhagic tendency may manifest 24 hours or even later after a bite. However, even in these patients, some degree of local inflammation around the bite is invariably present.

Cobra Bite

A burning pain is felt over the bite in 5 minutes, often followed by a numbness around the wound which may spread a variable distance up the limb. A red inflamed ring is generally present around the fang marks, but the degree of inflammation is never as marked or necrotizing as with viperine bites.

The systemic effects are observed within 10 minutes to 2 hours of the bite. Early symptoms, before objective neurological features appear, include vomiting, vertigo, circumoral paresthesia, excessive salivation, blurring of vision, and heaviness of the eyelids. This is followed by an increasing weakness and ataxia of the limbs so that the patient is unsteady and finds it difficult to walk. A progressive curare-like paralysis involves muscles supplied by the cranial nerves and skeletal muscles, so that muscle power is reduced and ultimately lost. *Ptosis followed by a varying degree of ophthalmoplegia is generally the first paralytic sign to be observed.* The pupils are increasingly dilated and fixed; bilateral facial palsy occurs. Paralysis of the palate and pharynx makes swallowing difficult, so that secretions collect in the back of the throat. The muscles of the tongue are often involved early; the tongue can be protruded with difficulty, and it feels heavy and stiff so that speech is indistinct. Salivation is often increased, and when associated with an inability to close the mouth and the lips, leads to continuous dribbling of saliva. Weakness of the muscles of the neck allows the head to fall forward on the chest if the patient is made to sit up (broken-neck sign). The skeletal muscles are soon involved leading to a well-nigh total paralysis. Ultimately, paralysis involves the muscles of respiration (the intercostals and diaphragm) so that breathing is shallow and irregular. The patient hypoventilates and has both hypoxia and hypercapnia. Involvement of other vital centers in the brainstem particularly the vasomotor center leads to hypotension and shock.

The patient is generally conscious to the end, perfectly aware and helpless against the relentless increase in the paralysis that ultimately kills him. Death generally occurs within 4–12 hours of the bite; it may however occur within an hour, or may be delayed for 72 hours. Some degree of hemolysis and a mild bleeding tendency may be observed in those who live more than 24 hours. If the patient does not die, paralysis quickly recedes and complete recovery without any sequelae occurs.

Krait Bite

The symptoms are similar to cobra bite, with the addition of severe abdominal pain and cramps.

Sea Snake Bite

Headache, sweating, vomiting, thirst, heaviness of the tongue are first observed. Within 30 minutes to 4 hours, there is a painful stiffness of the muscles; trismus is frequent. This phase is followed by a generalized flaccid paralysis. Myoglobinuria following rhabdomyolysis occurs within 3–8 hours after the bite and may lead to renal failure. Hyperkalemia often results due to the release of potassium from damaged muscles; it can lead to cardiac arrest.

Viperine Bites

Local Effects

These are marked and are observed very often within a few minutes of the bite. Severe pain, increasing redness, edema and bulla formation are observed spreading outward from the fang marks. A serosanguinous discharge oozes from the wound. The necrotizing inflammation involves the soft tissues, may even involve muscle, and may be severe enough to cause gangrene. It creeps up the limb if the bite is on an extremity. Skin lesions may be observed.

Systemic Effects

- *Acute circulatory failure* Shock with pallor, tachycardia, sweating, hypotension, restlessness and oliguria can occur within a few hours. Several factors contribute to shock. These include hemolysis, extravasation of fluid into the bitten limb, a generalized increase in capillary permeability and hemorrhage. In many patients shock occurs before all the above features are clinically apparent. It is probably due to specific factors within the venom that directly induce acute circulatory failure.
- *Severe intravascular hemolysis* Hemolysis causes a profound fall in hemoglobin, icterus, hemoglobinemia, hemoglobinuria and acute tubular necrosis, resulting in renal failure.
- *Disturbances in clotting mechanism with hemorrhage* Bleeding typically takes the form of bleeding from the gums and tooth sockets (often the first sign), epistaxis, hematuria, hematemesis, and rectal bleeding. Bleeding can also occur into various organs, such as the brain, lung, into the pleural space or into muscle and tissue. Disseminated intravascular coagulopathy can occur. Bleeding in some instances may only take place from one site, e.g. a severe rectal bleed, or bleeding from the urinary tract. Though bleeding generally occurs within a few hours, it occasionally may occur 24 hours or even later

after a bite. Bleeding from one or more sites may be the sole manifestation of a viperine bite.

- *Fever* of 100–104°F, with well-marked leukocytosis (20,000–40,000/mm^3), is invariably present. Vomiting is early and frequent; rarely seizures may also occur.
- *Acute renal failure* is an important and frequent complication of viperine bites. It can result from acute circulatory failure and shock, from acute intravascular hemolysis, from disseminated intravascular coagulopathy or from a combination of factors. It is most often due to acute tubular necrosis.

Death when it occurs in viperine bites, generally occurs in 12–24 hours.

MANAGEMENT[8-11]

Unfortunately, envenomation from snake bite chiefly occurs in rural India and not in the large towns where critical care units or emergency departments are available. What is more, many patients after being bitten by a poisonous snake prefer to go to traditional healers rather than be treated by allopaths or be treated in hospitals.

Critical care or at least basic well-directed medical attention can however make a difference between life and death in patients suffering from severe envenomation following a snake bite. Critical or emergency care whenever possible is mandatory under the following circumstances—

- Systemic effects of envenomation are present following a snake bite. The patient should be admitted to the intensive care unit (ICU) even if systemic features are mild. Sudden clinical deterioration can occur, particularly in a krait or cobra bite.
- Local inflammation around the bite is marked soon after a snake bite, even in the absence of systemic features. Bites causing acute inflammation within a matter of minutes or hours are invariably due to poisonous snakes. Two telltale fang marks are generally visible. They are generally viperine bites, and sudden severe bleeds may occur within the first 24 hours.

First Aid

It is generally agreed by all experts in the field that snake bite victims should be transported as quickly as possible to a healthcare center or hospital, where they can be clinically evaluated and antivenom promptly administered if the bite is found to be poisonous. In fact the time of transfer has been shown to be a crucial determinant of mortality and morbidity following a bite from a poisonous snake. Delayed antivenom administration is unquestionably associated with increased mortality and increased complications. The victim should be reassured, the bitten limb immobilized with a makeshift splint (of the lower limb) and sling (for the upper limb). The patient should not be allowed to walk as muscular contractions of the lower limbs can promote spread of the poison.

Traditional measures as incising the area of the bite, attempts to suck poison, application of herbal medicine are not only useless but also dangerous as they can lead to secondary infection of the wound.

The application of a tourniquet proximal to the bite though useful as an emergency measure is not likely to help if admission to a health center or hospital is delayed beyond 30 minutes. The continuous application of a tourniquet is contraindicated as it can lead to gangrene, increased fibrinolysis, bleeding distal to the tourniquet, compartment ischemia and increase in the local symptoms of envenomation. *The current recommendation is to avoid the use of a tourniquet.* Instead the bitten limb is immobilized by bandaging it tightly with a crepe bandage starting from the toes or fingers and extending the bandage up to the knee or elbow. A splint is incorporated into this dressing for better immobilization. This method was developed by Struan Sutherland and his colleagues in Australia. It should be used only for cobra and krait bites, whose poison is chiefly neurotoxic. It should not be used for viperine bites as tight bandaging could worsen edema and tissue necrosis of the limb.

In conclusion, first aid basically consists of immobilizing the bitten limb as described above, preventing the patient from walking or using the bitten limb and arranging for quick transport of the patient to a health center or hospital, where the patient is quickly evaluated and antivenom promptly administered if the bite is felt to be poisonous.

During urgent transport to a hospital, emergency department or local dispensary, care is taken to avoid aspiration if the patient is vomiting. Oxygen is administered if there is cyanosis and adrenaline 0.5 mL subcutaneously administered for autonomic disturbances or hypotension. Cardiopulmonary resuscitation may be necessary during transport, in desperate situations.

The immediate priorities in severe envenomation after admission to the emergency department of a hospital or to a critical care unit are—

- Cardiorespiratory support, and also support to other organ systems.
- *Neutralization of the poison with antivenin* Both these priorities should be addressed more or less simultaneously.

A large peripheral venous line is promptly secured and blood sent for a blood count, hematocrit, platelet count, bleeding time, clotting time, prothrombin time, aPTT, electrolytes, urea and creatinine. In viperine bites presenting with bleeding, a coagulation profile is necessary. The reticulocyte count and tests for hemoglobinemia and hemoglobinuria should be done in patients with hemolysis. A urine examination is done and an intake output carefully charted. A central venous line is secured for administration of fluid, drugs and for monitoring the central venous pressure. Arterial blood pH, and blood gases are estimated, and the patient's ECG monitored.

Neutralization of the Poison

The only effective treatment against venom that has entered the circulation is its neutralization by the use of antivenin.

Ideally, to be most effective, antivenin should be given as soon as possible. It is however never too late to administer antivenin provided systemic signs of envenomation are present. It has thus been reported to be effective when given to patients who remain defibrinated weeks after a viperidae bite. In India, the Haffkine Institute in Mumbai prepares a polyvalent antisnake venom serum. This is prepared by hyperimmunizing horses against the venoms of four common poisonous snakes: cobra, Russell's viper, common krait, and the Echus (saw-scaled viper). Each mL of the concentrated serum neutralizes the following quantities of dried venom when injected along with the venom in white mice; cobra 0.6 mg, Russell's viper 0.6 mg, common krait 0.45 mg, Echus 0.45 mg. The serum is lyophilized, and to be reconstituted has to be dissolved in distilled water.

Use of Antivenin[10-14]

A sensitivity test is first performed. If the patient is not sensitive, 5 mL of the reconstituted polyvalent serum is injected locally around the wound. Local infiltration of antivenin should never be done into a finger or toe, as it can induce sloughing and gangrene.

The next step is the systemic use of antivenin. This is preferably preceded by the subcutaneous injection of 0.5 mL of 1 in 1,000 adrenaline, as also by an injection of an antihistamine. Antivenin should as far as possible be administered intravenously, particularly in patients who are seriously ill or in shock. Hundred mL of the polyvalent serum is added to 300–500 mL N saline, and given as an infusion over 1–2 hours. This dose may be repeated twice or even more frequently in serious life threatening situations.

In patients who are sensitive to the polyvalent serum, a rapid desensitization should be attempted. 0.05 mL subcutaneously is first given; this is followed by progressively increasing doses till 2 mL is given intramuscularly. A further gradual increase in intramuscular dosage to 10 mL and then to 40 mL is made. This may need to be done under cover of adrenaline, antihistamine and corticosteriods. If no reaction occurs to a large intramuscular dose then 75–100 mL of the polyvalent serum is diluted in 500 mL N saline, and given as a slow infusion over 2 hours. A careful watch should be kept for untoward reactions.

In small children in whom it may be impossible to quickly find a vein, polyvalent serum should be given intramuscularly. The dose in children is the same as in adults, since envenomation in children is always more serious than in adults. About 60–100 mL (divided doses) is given intramuscularly with hyalase, to help absorption. If however a vein can be secured, the same dose is given as an infusion in normal saline over 2 hours. Intravenous administration whenever possible is to be preferred to the intramuscular use of the antivenin.

The use of antivenin is followed by a prompt reversal in the systemic features of envenomation. Spontaneous bleeding in viperidae bites stops within an hour and the coagulation profile reverts to normal within 6–12 hours. Systemic envenomation can however recur after hours or even days of initial good response. This is due to the continued absorption of the venom from the wound after it has been initially cleared from the blood stream by the antivenin. The dose of antivenin should then be repeated, and the patient observed closely for 3–5 days.

The success of antivenom depends on the ability of the immunoglobulin to bind and remove poisonous toxins from the body. The efficacy of immunoglobulin in restoring cardiovascular stability and hemostasis is well-established; however, the ability of antivenom to prevent local tissue necrosis in viperine bites and severe neurotoxicity is controversial. Thus it has been observed that the administration of antivenom to krait bite victims, who already have respiratory paralysis, does not reverse paralysis. Perhaps treatment outcomes vary with the geographical areas, as the composition of venom and the antigenic properties of toxins can be variable across the range of a given snake species. Indian antivenoms are produced using venoms from snakes captured in the small geographical areas within the state of Tamil Nadu. It is possible that these antivenoms may not be as effective in other regions of the country. Most of the antivenoms that have been used routinely in South Asia have not been subjected to preclinical testing, nor to evaluation in clinical trials.

Cardiorespiratory Support

This is of vital importance in seriously ill patients. Immediate endotracheal intubation with ventilator support is necessary in cobra or krait bites that cause a curare-like paralysis. It is important to secure and protect the airway and anticipate respiratory failure in these patients. In bites of Elapidae causing a curare-like paralysis, prostigmine 2.5–5 mg intramuscularly has been tried (as in myasthenia gravis). Prostigmine generally produces little or no improvement. It should never be relied upon to prevent respiratory paralysis in these patients. Ventilatory support is also necessary in patients in severe shock, so often observed with viperine bites. Intensive respiratory care goes pari passu with ventilatory support.

A sufficient volume load should be given to ensure a left ventricular filling pressure of 15 mm Hg. This may require the use of a Swan-Ganz catheter. Inotropic support is also often necessary in these patients.

Support to Other Systems

- Acute hemolysis is treated by small packed cell transfusions of carefully matched blood.
- Severe hemorrhage due to deficiency of clotting factors is treated by infusions of fresh frozen plasma: 8–10 units or more may be necessary. When fibrinolysis occurs following snake bite, the use of epsilon aminocaproic acid 0.1 g/kg in a slow intravenous infusion is of help. Cryoprecipitate should be infused (8–10 units or even more), if fibrinogen levels are low.
- Renal function must be supported by care over fluid and electrolyte balance, and avoiding the use of nephrotoxic drugs. Acute tubular necrosis with a mounting serum

creatinine requires hemodialysis till such time as kidney function returns to normal.

- Metabolic acidosis if present is countered by attempts to increase oxygen transport, and improve tissue perfusion. Intravenous sodium bicarbonate may be given so that the arterial pH is not less than 7.3.

Care of the Wound and Surrounding Inflamed Area[15]

Strict asepsis after admission to the unit is necessary. The wound should be washed with Condy's lotion or potassium permanganate, and suitably dressed with an antibiotic ointment. Tetanus toxoid should always be administered to prevent tetanus. Crystalline penicillin in a dose of 1 milion units is given intravenously 6 hourly. If Gram-negative organisms are present on examination of the discharge from a wound, a third generation cephalosporin, like ceftazidime 1 g intravenously 8 hourly, may be given.

Pain in and around the wound is relieved by analgesics. Morphine is contraindicated in cobra and krait bites.

Cryotherapy has been advocated locally in the treatment of viperine bites. It consists in packing the bitten extremity with freshwater ice in plastic bags, whilst keeping the rest of the body warm. The objective is to chill the tissues (and not freeze them) in order to retard the local proteolytic and enzymatic activity of the venom. It is important not to pack the bitten extremity in freshwater ice during administration, the antivenin, and for 12 hours after administration, as reaction of the antivenin with the venom may otherwise be interfered with. Current experience however throws doubt on the efficacy of cryotherapy. It could do more harm by increasing tissue necrosis.

Use of Corticosteroids

Good results have been reported with the use of corticosteroids. In viperine bites both local and systemic effects of envenomation seem to be reduced. A correct and unbiased appraisal of the efficacy of corticosteroids in snake bites is however difficult. In severely ill patients, particularly those in shock it is advisable to give hydrocortisone hemisuccinate 300 mg intravenously, followed by 300 mg in a slow infusion over 24 hours. 100 mg intravenously 8 hourly may then be given for the next 2–3 days.

TREATMENT OF LATE COMPLICATIONS

Late complications like renal shutdown, local gangrene, or severe tissue necrosis need expert specialized management. Hemodialysis is often necessary for the management of acute renal failure following viperine bites. *In the southern part of our country, snake bites would constitute one of the most important causes of acute renal failure necessitating the use of hemodialysis.* The management protocol used for snake bites has been summarized in Box 1.

Box 1: Summary of management protocol in snake bites

- Neutralization of poison promptly with antivenin
- Cardiorespiratory support—
  - Immediate endotracheal intubation with ventilator support in cobra/krait bites causing curare-like paralysis, and in patients in severe shock following viperine bites
  - Maintain left ventricular filling pressure around 15 mm Hg with use of sufficient volume load
  - Inotropic and/or vasopressor support may be required
- Support to other organ systems—
  - Treat hemolysis with transfusions of packed cells/whole blood
  - Deficiency of clotting factors treated by infusions of fresh frozen plasma and cryoprecipitate. Epsilon aminocaproic acid may be useful for fibrinolysis
  - Support renal function by maintaining fluid and electrolyte balance, and avoiding use of nephrotoxic drugs
  - Counter metabolic acidosis
- Care of the wound and surrounding inflamed area
- Use of tetanus toxoid, antibiotics, analgesics
- Use of corticosteroids
- Treatment of late complications, e.g. renal shutdown, local gangrene or severe tissue necrosis

OTHER POISONOUS BITES

Scorpion Sting[16-18]

Some species are deadly poisonous. The poisonous species encountered in Western Maharashtra is the—Indian red scorpion Mesobuthus tamulus. In North Africa the yellow scorpion (*genus liturus*) is chiefly responsible for lethal envenomation.

The venom from a scorpion sting deposit in the subcutaneous tissue may take as long as 6–8 hours for complete absorption. Elimination of the venom by the body is slower, with estimated half-life of 4.2–24 hours.

The local effects of envenomation following a scorpion bite are burning pain, inflammation and ecchymosis. Scorpion venom stimulates the release of catecholamines and acetylcholine. Early symptoms include vomiting, sweating, abdominal colic, diarrhea, salivation, piloerection and occasionally priapism. A tachy-brady rhythm may occur. Ultimately a shock like state with hypotension and tachycardia evolves. In a large study conducted over several years in a hospital in Mahad (situated on the outskirts of Mumbai), hypertension was observed in 27% of patients and pulmonary edema, at times fulminant, in 18%.[16,17] The cause of hypertension in some patients is related to stimulation of the α-adrenergic receptors by the venom. The venom also has a toxic effect on both the left and right heart. Severe left ventricular dysfunction leads to a raised pulmonary capillary wedge pressure with

resulting pulmonary edema.[18] The cardiotoxic effect of the venom can also cause marked bradycardia and arrhythmias. The venom over a period of time can result in multiple organ dysfunction. Death generally results from acute circulatory failure or from fulminant pulmonary edema.

Treatment

Mortality depends on the time lag between the scorpion sting and the start of medical treatment. It also depends to an extent on the quality of care offered. Death occurs in 5–35% of patients.

If the patient is brought to the unit within 30 minutes of the bite, cryotherapy in the form of application of ice in plastic bags around the bitten area, may help to retard the local proteolytic effects of the poison.

Scorpion antivenin if available should be promptly administered intravenously. Experimental and clinical studies suggest that it could reverse the circulatory, metabolic and ECG changes caused by the venom. Unfortunately scorpion antivenin is even more scarce than snake antivenin.

Supportive treatment is imperative, particularly with regard to the cardiorespiratory system. Hypovolemic shock is treated by a volume load. Severe pulmonary edema particularly when associated with hypertension responds to an intravenous infusion of nitroprusside. Severe left ventricular dysfunction needs dopamine and dobutamine support.

The study in Mahad referred to earlier suggests that prazosin (an alpha blocker) in a dose of 250 µg in children and 500 µg in adults given 3 hourly is of considerable use. It controls both hypertension and pulmonary edema. Patients receiving prazosin early in this study did not develop pulmonary edema.[16,17]

Centipede Bite

The clinical features are similar to a scorpion bite and may prove fatal, particularly in children. Local inflammation around the bite is followed by restlessness, salivation, diaphoresis with a shock-like state that may culminate in death.

Treatment is symptomatic; cardiorespiratory support with management of the shock-like state is important.

Bee and Wasp Stings

Multiple stings are observed particularly in hikers who unwittingly disturb a beehive. The usual reaction to a sting is a sharp pain followed by a local wheal and severe edema, particularly if the sting is on the face. A sting into a peripheral nerve leads to a temporary loss of function of the nerve. With multiple stings or in hypersensitive individuals, a picture of anaphylactic shock is observed—severe urticaria, bronchial spasm, and hypotension, followed at times by cardiac arrest.

If brought as an emergency to the ICU, adrenaline in a dose of 0.75–1 mL is injected subcutaneously. If hypotension and a state of anaphylaxis prevail, adrenaline may need to be given intravenously (see Chapter Anaphylactic Shock), and emergency resuscitation with cardiorespiratory support should be promptly initiated. The airway should be quickly secured by endotracheal intubation in patients with increasing urticaria involving the skin and mucosa. Intravenous hydrocortisone and antihistamines are of help particularly in patients with severe urticaria.

CHAPTER 68

Drowning

INTODUCTION

Drowning is asphyxiation resulting from submersion in a liquid (invariably water).

In India, drowning accidents are most often related to sheer rashness when swimmers or holiday makers who can barely swim venture into an area of the sea in spite of an express warning pointing to the hazards of doing so. The paucity of trained life guards along the coastline compounds the problem.

The use of alcohol can be an important risk factor, as alcohol reduces the ability to deal with emergency situations, impairs coordination as also the cognitive ability to quickly realize the gravity of a dangerous situation.

Lack of appropriate supervision by adults is an important cause of drowning accidents in children or in those learning to swim in swimming pools.

Perhaps the most ghastly of drowning tragedies occur in boating accidents. The commonest cause of boating accidents in India is overcrowding of ferries and boats during crossing of rivers. Collision on the high seas between ships or between ships and a rugged coastline or against rocks or an iceberg (as with the Titanic) can lead to deaths of several people from drowning.

Finally, medical catastrophes can contribute to drowning accidents. These include seizures while swimming, cerebrovascular accidents or a cardiac arrest following myocardial infarction.

The official nomenclature for submersion injuries was laid down during the World Congress on Drowning[1] in 2002. The term fatal drowning is used to describe death by submersion in water and near-fatal drowning to describe at least temporary survival after respiratory impairment from submersion in water. However, the terms drowning and near-drowning often continue to be used as synonyms for fatal and near-fatal drowning respectively.

PATHOPHYSIOLOGY

Two major mechanisms are responsible for morbidity and mortality in drowning—severe hypoxia and hypothermia. The effects of both are additive. At times hypoxia is the sole cause of death as in warm tropical waters and at times hypothermia plays an equally important role. For example, deaths after the sinking of the Titanic were more because of hypothermia due to exposure to extremely cold water rather than to the inability to float.

The role of hypoxia and hypothermia are considered separately in the ensuring discussion.

Role of Hypoxia

The following sequence is believed to occur in most cases.[2] After immersion, there is a period of voluntary breath holding as the victim's mouth and nose are below water. This is followed by a phase of intense laryngeal spasm which prevents breathing; the laryngeal spasm is triggered by the presence of water in the pharynx and/or larynx. In about 10% of patients, the unrelenting laryngeal spasm leads to asphyxia and death from hypoxia with very little water entering the lungs. In most victims, however, the laryngeal spasm abates followed by involuntary breaths, resulting in aspiration of quantities of water into the lung. Water may also be swallowed which again is regurgitated and aspirated into the lungs. The severe hypoxia renders the patients unconscious; death results from hypoxic cardiac arrest.

Freshwater as in lakes, ponds, swimming pools and saline water as in the sea, act differently on the lungs. Freshwater acts

by inactivating surfactant and by damaging type II pneumocytes, thereby preventing the formation of surfactant.[3] This results in damage to the alveolar capillary membrane and leads to acute respiratory distress syndrome.[3] Atelectasis due to increased surface tension and bronchoconstriction also occur. On the other hand, aspiration of hypertonic seawater into the alveoli draws fluid from the plasma into the alveoli resulting in pulmonary edema in the presence of a reduced intravascular volume. Surfactant damage and damage to type II pneumocytes by hypertonic saline may contribute to pulmonary edema.

Notwithstanding the different pathogenetic mechanisms that injure the lung following freshwater and saltwater aspiration, failure in gas exchange, hypoxia, hypercapnia and death from cardiac arrest constitute the end-result.

In near-fatal drowning, bacterial pneumonia, chemical pneumonitis, barotraumas and oxygen toxicity during resuscitation can cause complications and respiratory deterioration in the post-resuscitation period.[4] In near-fatal accidents effects on other organ systems are chiefly the result of prolonged hypoxia.

Effects on the central nervous system strongly influence prognosis. Hypoxic encephalopathy is the single most important complication and is identical to hypoxic brain damage from other causes. It includes cerebral edema, focal areas of necrosis and ischemic changes most marked in the cerebral cortex, hippocampus and cerebellum. Hypoxic encephalopathy may ultimately cause death or lead to persistent coma, seizures, aphasia, cortical blindness and varying disturbances in cognition. Predicting outcome following hypoxic encephalopathy may be impossibly difficult, though several studies have attempted to do so.[5,6]

In near-fatal drowning, cardiac complications often occur. These include atrial fibrillation, and prolonged QRS and QT intervals. Various arrhythmias including ventricular fibrillation and asystole can occur, ultimately causing death. Focal myocardial necrosis observed at autopsy is believed to be related to excessive catecholamine release, similar to that observed in patient with pheochromocytoma.

Renal effects in near-fatal drowning include acute tubular necrosis and hemoglobinuria. Metabolic acidosis is often present due to increased lactic acid in the blood.

Serum Electrolyte Changes

It used to be emphasized some decades ago that submersion in freshwater led to hemodilution, hemolysis, hyperkalemia and hyponatremia, and that these changes could contribute to ventricular fibrillation and death. Submersion in hypertonic saltwater (seawater) was believed to draw water from the blood and interstitial compartment into the alveoli causing hypernatremia and pulmonary edema. Currently, it is believed that in near-fatal drowning the body corrects these alterations so that the clinical impact of the electrolyte changes is minimal.[7]

Hematological Effects

Near normal hemoglobin values have been generally observed in near-fatal drowning. However, disseminated intravascular coagulopathy has been described as a complicating factor in freshwater drowning.[8]

Infectious Complications

Near-fatal drowning victims may have their clinical course complicated by infectious complications, the most frequent and important being pneumonia. Pneumonia is due to aspiration of contaminated water, gastric contents and mouth contents. Gram-positive, Gram-negative organisms as also fungi have been shown to be causative agents. Most pneumonias occur following warm water submersion as most organisms generally do not survive in very cold waters.

Hypothermia

As mentioned earlier, hypothermia plays an important role in drowning accidents in cold climes, particularly in winter months. The effects of hypothermia are complex. On the one hand, survival can occur after long submersion if the victim has been submerged in icy water, and the core body temperature reduced quickly and the brain metabolic activity slowed down rapidly so as to prevent hypoxic brain damage. On the other hand, humans tolerate hypothermia poorly as is seen in deaths after the sinking of the Titanic. Submersion in very cold water can cause death in three ways—first, by inducing a vagally mediated asystole (immersion syndrome); second, by producing arrhythmias, particularly ventricular fibrillation. These arrhythmias are refractory to resuscitative attempts unless the core temperature of the body is sufficiently raised. Thirdly, a fall in core temperature can cause a loss of consciousness, which leads to aspiration of water in the lungs.

CLINICAL FEATURES

In the history, it is important to determine the duration of submersion, whether submersion was in freshwater or seawater, roughly the temperature of the water, whether submersion occurred during swimming, following diving or because of a boat accident. A knowledge of comorbid conditions affecting the victim is of help.

Physical Examination

Physical examination must be brief, chiefly concentrating on vital signs, and on possible injury, in particular to the cervical spine. Detailed examination may be performed well after resuscitative efforts have been established.

Tachypnea and tachycardia are the chief physical signs in near-fatal drowning accidents. The patient may however at times be apneic or have gasping irregular breathing. There may be auscultatory signs of pulmonary edema with frothing at the mouth. The temperature is often subnormal and physical findings associated with hypothermia or cerebral hypoxia may be evident.

Modell and Conn have classified near-fatal drowning victims into three categories.[9]

Category A Patients are alert one hour after presentation in the emergency department. These patients do well neurologically.

However, these patients should be kept under observation as pulmonary edema (which may be quite severe), can develop a few hours later.

Category B Patients are obtunded but arousable. Most of these patients survive and severe neurological sequelae generally do not occur.

Category C Patients are comatose with abnormal respiration and abnormal response to pain. Category C is further divided into C1 decorticate posturing; C2 decerebrate posturing; C3 flaccid state.

Patients in the C category have a very high mortality and survivors show severe neurological sequelae.[10]

Laboratory Examination

Laboratory studies include routine blood and urine tests, blood chemistry, arterial blood gases, serum lactate, serum creatinine, prothrombin time, partial thromboplastin time and electrocardiography.

An X-ray of chest and X-ray of the cervical spine (if there is a suspicion of injury) should be done. Radiological examination of the chest shows evidence of pulmonary edema in most patients.

TREATMENT

Initial Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation in apneic and pulseless victims takes precedence over all other procedures and should be promptly initiated as soon as the patient is brought out of the water. It should be continued uninterrupted during transport to a hospital's emergency department or intensive care unit (ICU) (see Chapter Cardiopulmonary Resuscitation and Cerebral Preservation in Adults). Once in hospital, either in the emergency department or the ICU, advanced cardiopulmonary support is initiated.

How long should resuscitation continue? Resuscitation should be continued in victims of cold water submersion at least until the victim has been rewarmed. Core temperature (measured through a low reading rectal thermometer) should be measured promptly and monitored throughout the period of resuscitation. All drowning victims with cardiopulmonary arrest and hypothermia should be rewarmed rapidly to a temperature between 32°C and 34°C and then maintained at that level.

The following procedures are used for rewarming, depending on facilities and expertise available in the hospital to which a patient is admitted—

- Removal of wet clothing at the site of accident or in the ambulance with inhalation of warm oxygen.
- In the hospital, warmer blankets are used and heated oxygen inhaled. Infusing warm fluids intravenously and performing gastrointestinal irrigation with warm fluids also helps. If available, hemodialysis and peritoneal lavage can help quicker rewarming.
- In patients who have severe hypotension, especially in patients with circulatory collapse, cardiopulmonary bypass can rapidly achieve rewarming with rapid elevation of the core temperature. This method also corrects metabolic acidosis which is often present. Cardiopulmonary bypass obviously should be used only when both expertise and experience are available.

How long does one resuscitate victims of normal or warm water submersion? This is difficult to answer. The decision to terminate cardiopulmonary resuscitation may depend on factors peculiar to a given patient. Inability to resuscitate a patient over 30 minutes generally is an indication to stop resuscitative attempts.

Once a patient has reached hospital and is either in the emergency department or in the ICU, advanced cardiopulmonary support should be forthcoming. An apneic patient or patient with severe pulmonary edema is promptly intubated and put on ventilator support. It is important to use lung protective measures during mechanical ventilation—low tidal volumes of 5–7 mL/kg, not allowing plateau pressures to be greater than 30 cm H_2O.

In patients with milder pulmonary edema who are not very hypoxic noninvasive ventilatory support can be given a try (see Chapter Acute Respiratory Failure in Adults and Chapter Mechanical Ventilation in the Critically Ill).

Other important therapeutic measures include the following—

- Correction of fluid and electrolyte disturbances.
- Correction of metabolic acidosis. The lack of appreciation of this factor has led to unfortunate fatalities. 7.5% sodium bicarbonate is administered intravenously if the arterial pH is less than 7.25. Some drowning victims have a respiratory acidosis; this is corrected by ventilatory support.
- Use of drugs—
  - Frusemide is of use in patients with pulmonary edema.
  - Victims who in addition to pulmonary edema have severe bronchoconstriction are helped by nebulizing duolin and by the use of intravenous hydrocortisone.
  - Febrile victims are empirically given a broad spectrum antibiotic and treated symptomatically to reduce any rise in temperature.
  - Symptomatic treatment with vasopressors and/or inotropes is necessary to maintain blood pressure during early emergency treatment.
  - Cardiac arrhythmias if present need appropriate management.

The World Congress on Drowning in 2002[1] recommended the following interventions following cardiopulmonary arrest from drowning—

- Restoration of spontaneous circulation is of the highest priority.
- Core temperature should be monitored.
- In patients with cardiopulmonary arrest a core temperature of 32–34°C should be maintained for a period of 12–24 hours. The use of therapeutic hypothermia

has been substantiated in outpatient cardiac arrest in two randomized controlled studies published in 2002. Hyperthermia should be prevented at all costs during the acute recovery period.

- Seizures should be diagnosed and appropriately treated.
- Hypoxemia and hypotension should both be avoided.

Finally, it is important to remember that the sudden occurrence, while swimming, of an acute myocardial infarction, a cardiac arrhythmia, an epileptic seizure or a stroke can precipitate a drowning accident. It is equally important to realize that in older subjects, a myocardial infarct or a dangerous arrhythmia can occur subsequent to severe hypoxia and exhaustion following a drowning accident.

CHAPTER 69

Heat Stroke

INTRODUCTION

Heat stroke is an acute calamity produced by high environmental temperature. A relatively high humidity is a predisposing factor as is also a prolonged exposure under a hot sun. The condition is characterized by a failure of the thermoregulatory mechanism of the body whereby the heat gained by the body is far more than that lost, so that the body temperature rises, the core temperature exceeding 40°C.

Heat stroke is more common in the very hot summer months of hot tropical equatorial countries or the hot desert lands in the Middle East, where environmental temperature may be well past 45°C. Heat waves in Europe have also led to heat stroke, particularly in elderly individuals living alone in poorly ventilated apartments.

The thermoregulatory center at very high ambient temperatures is overwhelmed even if it is functioning normally, so that the heat gained through the hot environment is far in excess of the heat lost.

Heat strokes can also occur following endogenous heat production during strenuous exercise or exertion. Heat production during exercise or exertion ranges from 300 kcal/hour to 900 kcal/hour. Even in conditions allowing maximum evaporation of sweat not more than 500–600 kcal/hour of heat may be lost. The progressive heat gain in these circumstances leads to a progressive rise in the core temperature of the body culminating in a heat stroke.

Endogenous heat production can also be increased by fever, thyrotoxicosis, or the hyperactivity associated with amphetamine and hallucinogen use. Under the above circumstances even healthy individuals with normal thermoregulatory centers may develop heat stroke during exercise in warm ambient surroundings. Exertional heat stroke is typically seen in younger individuals, athletes, marathon runners exercising at higher than normal ambient temperatures. On the other hand, classical heat stroke due to very high ambient temperatures is more often observed in older individuals.

Precipitating factors are a poorly functioning thermoregulatory center with impaired ability to provide adequate heat loss, poor sweating, dehydration and impaired cardiovascular function. A poor cardiovascular performance leads to a decreased blood flow to skin and muscles, thereby decreasing the movement of heat from the core to the environment.

Many drugs are known to predispose to heat stroke. These include phenothiazines, butyrophenones and antiparkinson medications. Hypothalamic lesions also impair thermoregulation.

PATHOPHYSIOLOGY

Excessive rise in the body temperature leads to cellular toxicity and ultimately to cell death. The critical thermal maximum is a temperature above 42°C.[1] Cellular damage and cell death are ultimately due to cessation of mitochondrial and enzymatic activity and to instability of the cell membrane. The effect on cell structure and metabolism is widespread and occurs in all organ systems of the body.[2]

The stress produced by heat to the body provokes a systemic inflammatory response characterized by activation and increased circulation of tumor necrosis factor α, IL-2, IL-6, IL-8, IL-10, IL-12 and interferon gamma.[3]

Bacterial translocation from an ischemic gut leads to Gram-negative endotoxemia and further aggravates the inflammatory response. Endothelial injury is an important

feature of heat stroke. It activates the coagulation cascade which is responsible for microthrombi in the small vessels of all organ systems thereby perpetuating multiple organ dysfunction and failure. Dehydration when there has been excessive sweating and also metabolic acidosis worsen the situation. Metabolic acidosis is mild in classic heat stroke except terminally, whereas metabolic acidosis may be the presenting feature in heat stroke induced by exercise or exertion in high environmental temperature.

Effects on the Central Nervous System

Though all organ systems are affected by excessive heat stress, the clinical manifestations of striking importance are related to the central nervous system (CNS). Thermal toxicity leads to cell death within the brain and spinal chord, cerebral edema and focal hemorrhage. These changes result in stupor progressing to coma and seizures. The Purkinje fibers of the cerebellum are particularly vulnerable to the effect of heat. Progressive cerebellar atrophy has been documented in high resolution computed tomography (HRCT) of the head and by magnetic resonance imaging (MRI).

Cardiovascular Effects

Cardiac output is increased due to lowered peripheral vascular resistance and increased vasodilation. Dehydration occurs frequently from excessive sweating, sweat rates being at times as high as 1.5–2 L/hour.[4] Not all patients sweat profusely; in fact, some sweat poorly and in these patients the core temperature of the body rises both faster and higher. Hypotension occurs frequently. As the condition progresses and worsens there is myocardial depression, a fall in cardiac output and the frequent occurrence of tachyarrhythmias. Focal hemorrhage and necrosis within the epicardium and within myocardial muscle fibers is present at autopsy.

Renal Effects

Renal damage occurs in all patients with heat stroke; it is potentiated by rhabdomyolysis, hypotension and dehydration. Acute tubular necrosis is a well-known complication.[5] Very high creatinine phosphokinase values increase the risk of renal failure.

Effect on the Musculature

Muscle necrosis occurs as a direct result of high temperature. Muscle damage is more marked in heat stroke related to exercise or exertion. Rhabdomyolysis is extremely common with exertional heat stroke but may also occur in classic heat stroke.

Hematological Effects

There is a leukocytosis which often leads to the wrong suspicion of infection. A bleeding diathesis is invariably present, particularly in fatal cases. It is due to thrombocytopenia, direct inactivation of platelets due to heat, poor platelet aggregation and most important of all by the development of disseminated intravascular coagulation (DIC) which occurs most frequently on the 2nd or 3rd day of the heat stroke. DIC is due to activation of the coagulation cascade caused by the stress of heat. When fully evolved it worsens multiple organ dysfunction and is invariably fatal.

Pulmonary Effect

Acute respiratory distress syndrome (ARDS) is a well-known complication of heat stroke. Pulmonary edema may also result from myocardial depression and failure.

Fluid and Electrolyte Disturbances

Fluid and electrolyte disturbances could be marked particularly in patients who have sweated profusely. Hyperkalemia can be marked when heat stroke follows exercise or exertion particularly if there is rhabdomyolysis.

CLINICAL FEATURES[6]

The classic features of heat stroke are—

- A core temperature above 40°C often over 42°C. Temperature as high as 43–44°C (110°F) have been recorded.
- A disordered mental state which could vary from delirium, apathy, obtundation and coma.
- Elevated creatinine kinase present in most patients.
- A compatible historical setting.

Among other important but not necessarily constant features are seizures and anhidrosis in the presence of high core temperature. Absence of anhidrosis does not however negate the diagnosis. Ataxia, dysmetria, dysarthria with other cerebellar signs may be seen acutely and in survivors of heat stroke.

A careful examination often reveals dysfunction of all or most organ systems. Hypotension and cardiovascular collapse are frequent, forming the most common cause of death. Renal failure, metabolic acidosis, rhabdomyolysis, DIC and ARDS are all important complications. The cerebrospinal fluid (CSF) may show a rise in protein and some degree of pleocytosis often leading to a suspicion of meningitis. CSF culture is however normal.

PROGNOSIS

Heat stroke with core temperature at or over 42°C carries a high mortality. Cardiovascular collapse and DIC are very grave prognostic factors. A full blown DIC with bleeding in a patient with heat stroke is almost always fatal. Neurological sequelae are often present in survivors.

DIFFERENTIAL DIAGNOSIS[7]

In regions where malaria is endemic, the differential diagnosis of fulminant *Plasmodium falciparum* infection from heat stroke may be difficult or impossible without examining

a peripheral blood smear. In case of doubt particularly in zones highly endemic for malarial infection, treatment for *P. falciparum* infection should be empirically given. Acute pyogenic meningitis should be excluded by lumbar puncture. Other fulminant infections may be missed as heat stroke and vice versa. A blood culture should always be sent. It is important to stress that leukocytosis is fairly frequent in heat stroke so that its occurrence does not negate the diagnosis.

Rarely an Addisonian and also an acute thyroid crisis are associated with hyperpyrexia. Acute encephalitis or hypothalamic lesions can produce hyperpyrexia by upregulating the temperature set point. The temperature in hypothalamic lesions remains fixed and unvarying and the presence of associated lesions, in particular diabetes insipidus should help diagnosis. Imaging of the head should be done if there is suspicion of a CNS lesion.

Investigations with regard to all organ functions should be asked for and carefully monitored. A coagulation profile and a radiographic examination of the chest are of particular importance.

MANAGEMENT

The prime need is to reduce body temperature by heroic measures. If possible the patient is nursed in an air-conditioned room with the temperature of the room kept as low as the air-conditioner will allow. He or she should be covered in sheets soaked in very cold water, and a revolving fan is allowed to play on the body to further aid cooling. Rubbing ice on the body is not very effective but adding some alcohol to the cold bath water or in the water used to sponge the patient helps to increase heat loss from the body. An ice water enema is also useful to lower the temperature in hyperpyrexia. The head should be kept cool with ice on the head and with frequent ice cold compresses to the forehead. Oxygen should be given at 4–6 L/minute by a nasal catheter or a mask.

The reduction of body temperature by the above methods should be controlled by periodic checks of the rectal temperature. The ice bath or the cold sponge should be stopped when the rectal temperature reaches 102°F. A too sudden and drastic fall in temperature is uncommon, but should be avoided as it can cause sudden death.

A proper fluid and electrolyte balance should be maintained. Normal saline may be given particularly if there is history of excessive sweating prior to the stroke. All organ systems need to be meticulously supported. Hypotension should be countered by a volume load and by inotropes/vasopressors. The airway in unconscious patients should be secured and maintained. Clotting factors and platelets should be given to patients with DIC. Patients often need ventilator support. Renal replacement therapy should be offered to patients who have prolonged acute tubular necrosis. It should be noted the dantrolene is ineffective in heat stroke.[8] Unfortunately, there are no randomized clinical trials that have compared the effectiveness of different cooling methods in any hyperthermic syndrome.

CHAPTER 70

Hypothermia

When the core temperature falls below 95°F (35°C), a patient is said to be hypothermic. Induced hypothermia is used by anesthetists to reduce cellular metabolism notably in heart surgery as also in other conditions as after resuscitation from cardiac arrest.

CAUSES OF HYPOTHERMIA[1]

Accidental hypothermia is due to exposure to cold (poverty in Asian countries and alcoholic stupor are two important background factors). Mountaineers and skiers who ski at high altitudes in inclement weather, hikers caught in rain and snow are situations where hypothermia poses real danger. Wet clothes aggravate the degree of hypothermia as does the presence of rain, wind and snow in freezing temperatures.[2,3] Deaths from complete immersion in cold water due to cold shock or inexorable hypothermia far exceed deaths from drowning without cold.

Urban hypothermia is particularly observed in old people, in destitutes who can afford neither proper clothing, nor shelter nor food. There are many in North India who die of cold in the winter months just as there are many who die of hyperthermia in the hot summer months in the Gangetic plains or in the tropical southern part of the country.

Fatigue worsens hypothermia as it decreases muscle glycogen stores, reduces heat production and reduces both the capacity to exercise and shivering.

Drugs[3,4] like phenothiazine, barbiturates and alcohol, frequently produce hypothermia in temperate or cold climates by depressing sensory afferents, the hypothalamus and efferent responses.

MEDICAL CONDITIONS

Hypothyroidism is the most important medical condition causing hypothermia. Myxedema coma is associated with subnormal temperatures in the vast majority of patients and has a high mortality unless treated with exogenous thyroid. Hypoglycemia and hyperosmolar nonketotic diabetic coma are also known to cause hypothermia.

CENTRAL NERVOUS SYSTEM DISORDERS

Strokes, tumors, Wernicke's encephalopathy or any pathology that can directly affect hypothalamic function have been known to be associated with hypothermia.

Skin disorders characterized by vasodilatation and increased transepithelial water loss may lead to hypothermia, as in extensive psoriasis, ichthyosis and erythroderma. Third degree burns are noted to have a huge evaporative heat loss, losing up to 6 liters of fluid and more than 3,400 kcal/day.

Trauma victims, particularly those with moderately elevated trauma severity scores, not uncommonly show hypothermia during the first few days of hospitalization.[5] The causes of hypothermia are listed in Box 1.

PATHOPHYSIOLOGY[6]

Profound metabolic changes occur in every organ system when the core temperature falls below 35°C. Temperature dependent metabolic changes occur in two phases. The shivering state usually occurs between 35°C and 30°C. Shivering is characterized by intense energy production from the breakdown of glycogen and other body fuels very similar

Box 1: Causes of unintentional hypothermia

- Old age
- Exposure to cold
- Drugs
- Myxedema, in particular myxedma coma, hypoglycemia
- CNS disorders involving the hypothalamus
- Skin disorders characterized by vasodilatation and excessive transepithelial water loss
- Trauma

to that observed in strenuous physical exercise. In the non-shivering phase the metabolism slows down markedly. All organ systems are affected, ultimately leading to multiple organ failure.

CLINICAL FEATURES[8]

Clinical features are related to the degree of hypothermia. At 34–36°C, hypothermic individuals are very conscious of being very uncomfortably cold. With a further fall in temperature, mental and physical problems increase; some victims are withdrawn and some become aggressive. At 33–34°C, victims often stagger, become confused and drowsy. Increasing bradycardia and hypotension are observed. Paradoxical undressing is sometimes observed because paradoxically there is a feeling of heat due to hypothalamic dysfunction causing an alteration in set-point temperature.

At 26–33°C, increased mental obtundation progressing to coma is observed. At 17–20°C, cardiac output is inadequate to sustain life. Death generally occurs from asystole or ventricular fibrillation. Nevertheless, it should be noted that successful resuscitation at core temperature well below 15°C has been reported.

COMPLICATIONS[6,7]

- After removal from a cold environment, there is often a further fall in core temperature for 10–20 minutes—the "after drop"; this might take the core temperature into the lethal zone.
- Arrhythmias particularly ventricular fibrillation are common. The ECG typically shows a J wave (junctional deflection at the junction of the QRS complex and the ST segment) and a prolonged QT interval.
- Metabolic acidosis.
- Pancreatitis.
- Rhabdomyolysis.
- Pneumonia.
- Sepsis.
- There is evidence of multiple organ dysfunction due to the effect of a low core temperature on the metabolism and function of all organ systems.

MANAGEMENT[6-8]

Management of the hypothermic victim is similar to that of any semiconscious or comatose patient. Immediate attention is focused on the *circulation, airway control breathing* and *rewarming*. Oxygen is promptly administered. Abnormalities in arterial pH; electrolytes corrected. The core temperature should be continuously monitored, preferably with a low reading rectal thermometer.

During rewarming, circulatory and respiratory support is essential. Blood volume should be expanded by infusion of normal saline or by a colloid infusion. Inotropic and vasopressor support is often necessary. A transvenous pacemaker is often required in the presence of severe bradycardia. Defibrillation of a hypothermic fibrillating heart is unlikely to succeed at a core temperature of less than 30°C.

If the respiration is very slow, irregular or shallow, the patient will need intubation and ventilator support.

Important complications other than cardiopulmonary failure include pancreatitis, rhabdomyolysis and pneumonia. The CPK should always be done; it may be over a thousand in the presence of rhabdomyolysis. Acute tubular necrosis is an important complication of the latter. Infection is common—in particular pneumonia—appropriate antibiotics are necessary. All organ functions need adequate support.

Rewarming of a hypothermic casualty needs to be done no sooner the patient has been rescued. A variety of rewarming methods are available. In milder cases, warm blankets and hot drinks suffice. Though commonly used, "metallized space blankets" are of no proven benefit. Warm intravenous fluids are helpful. In extreme cases peritoneal lavage with warm fluids, or if experience and expertise are available, cardiac bypass can also be used. Hot sponges or hot baths are effective but it should be remembered that they could cause a paradoxical fall in core temperature as blood flow is rapidly restored to cold extremities. As a general rule, if hypothermia in a victim has been prolonged in onset or duration, rewarming must be undertaken with extreme caution. In critical cases where rapid warming is needed, full resuscitation facilities must be at hand.

Pronouncement of death in patients with severe hypothermia should be made with great caution because of the marked bradycardia, marked respiratory depression and the very low stroke volumes present in these patients. It is best to warm the patient and then ensure that there is truly a cardiac arrest and that there is no respiration before pronouncing the patient's demise.

Critical Care of the Cancer Patient

- Critical Care of the Cancer Patient

CHAPTER 71

Critical Care of the Cancer Patient

GENERAL CONSIDERATIONS

The cure rate in cancer has increased over the last three decades. Patients with common cancers, like breast cancer, colorectal cancer and lung cancer, still defy a cure once these cancers have metastatized. There are however a number of cancers which can be cured even after metastasis. These include acute lymphatic or myeloid leukemia, chronic myeloid leukemia (after extensive radiation and allogenous bone marrow transplant), gestational choriocarcinoma, testicular tumors, Hodgkin's disease, aggressive non-Hodgkin's lymphomas, Wilm's tumor, Ewing's sarcoma and, in rare instances, small cell lung carcinoma. Survival of patients with other forms of metastatic cancers can also be extended for varying periods of time.

The definite increase in cancer cure rates is related to the development and use of new and more targeted therapeutic drugs. However, these drugs that have the potential to cure often lead to drug-related organ toxicities and increased susceptibility to infection. Many of these constitute acute life threatening complications that are potentially reversible and therefore unquestionably merit critical care. To give one example, the timely recognition and critical care of respiratory failure in cancer patients due to infectious, malignant or toxic complications is often extremely rewarding. Equally rewarding is the critical care management of systemic complications or syndromes directly related to cancer—for example, the tumor lysis syndrome and the hemophagocytic syndrome.

Though an acute, life-threatening reversible pathology in cancer patients does need critical care, the priority for such care is obviously low if the basic disease process is so advanced as to very sharply limit the expected life span. The priority increases and, in fact, admission to the intensive care unit (ICU) is imperative if the patient has a cancer which is either potentially curable, or which if effectively treated can result in an extended period of survival. However, therapeutic considerations in the ICU all over the world particularly in developing countries are being increasingly influenced by cost and outcome concerns. The intensivist, the treating physician or surgeon caring for a cancer patient faces the challenge in the ICU, to decide not only what should or can be done but also to decide if and when to do it, or whether to do anything at all.

POSTOPERATIVE CRITICAL CARE

In surgical ICUs, ICU admissions are related chiefly to immediate postoperative care after major surgery, or to surgical and other complications arising soon after massive surgery. Principles of surgical care are exactly the same as after major surgery unassociated with cancer.[1] The main postoperative support necessitating ICU stay is dependence on mechanical ventilation, especially over an extended period of time. Generally, the risks of untoward outcomes in the ICU correlate with the extent and magnitude of the surgical procedure. For example, ovarian cancer surgery involving resection of the gut, ventilatory dependency and hemodynamic instability requiring the use of a Swan-Ganz catheter, carries a higher morbidity and longer stay in the ICU. Considering the recent advances in surgery, postoperative risks are determined to a lesser extent by the technical aspects of the surgical procedure, than by existing comorbidity and general underlying factors that prevent an uncomplicated recovery.

Most surgical operations in cancer patients carry a procedure specific morbidity and mortality rate. Potentially lethal complications generally do not occur in the immediate or early postoperative phase, but later. Re-surgery (for whatever reason) carries a high morbidity and mortality. Postoperative

infection either in the surgical area or systemic infection is probably the greatest hazard, particularly in cancer patients who have received chemotherapy prior to surgery.

Critical care in cancer patients may be necessitated for several other reasons—

i. *Overwhelming or serious infection related to immunosuppression* (see Section The Immunocompromised Patient) Advanced malignancy is always associated with a reduction in immune response. Protein synthesis is abnormal, and continued rapid growth and spread of the tumor produces cachexia. Malnutrition worsens immunosuppression at this stage. A far more important cause of immunosuppression is related to severe neutropenia observed as a feature of acute myeloproliferative disease, or related to the use of chemotherapy and/or radiation. The more dose-intensive the chemotherapy or radiation therapy regime, the greater the likelihood of damage to host cells, and of severe thrombocytopenia and granulocytopenia. Immunosuppression often leads to acute infection which may be due to the usual micro-organisms infecting immunocompetent patients, or to opportunistic organisms. This has been dealt with in the Section The Immunocompromised Patient. Severe thrombocytopenia following radiation or chemotherapy may induce bleeding either within the skin and the mucosa, or in internal organs and other anatomical structures of the body.

ii. *Complications due to a mitotic lesion which can produce life-threatening emergencies* These complications can result directly from the tumor effects at the primary site or from spread of the tumor. Non-metastatic complications of malignant diseases can also result in serious problems meriting critical care.

iii. *Complications directly related to the side effects of antimitotic drugs or radiation (other than immunosuppression already mentioned above).*

Complications listed under (ii) and (iii) can best be considered in relation to different organ systems with specific reference to critical care requirements.

METABOLIC COMPLICATIONS AND SYSTEMIC CANCER-RELATED COMPLICATIONS OR SYNDROMES[2-5]

The systemic cancer-related complications or syndromes are the tumor lysis syndrome and the hemophagocytic syndrome. The main metabolic complications include hypocalcemia and hypercalcemia, hypophosphatemia, fluid and electrolyte disturbances, notably the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Tumor Lysis Syndrome[6-8]

This is particularly observed in rapidly proliferating tumors that are very sensitive to chemotherapy. The syndrome is classically associated with Burkitt's lymphoma, but in our part of the world it is most frequently observed during treatment of other malignancies.[9] These include acute lymphoblastic leukemia, chronic myeloid leukemia in an acute blast crisis, non-Hodgkin's lymphoma, and occasionally in small cell cancer of the lung, and metastatic breast cancer.

The syndrome is caused by rapid lysis of malignant cells resulting in hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia and an increase in blood urea nitrogen. Though hyperuricemia and increase in uric acid excretion typically occur following chemotherapy in malignancy, these abnormalities can also occasionally occur in untreated patients with rapidly growing tumors.

Life-threatening complications include acute renal failure from precipitation of uric acid in renal tubules with uric acid nephropathy, and cardiac arrhythmias from hyperkalemia and hypocalcemia. Oliguria and azotemia are warning features; hypocalcemia can result in tetany, cramps and seizures.

Management[8]

Prevention consists of hydrating patients before and during chemotherapy, and using allopurinol 500 mg/m^2 per day for 3 days; this is reduced to 200 mg/m^2 per day after 3 days of chemotherapy. Chemotherapy is best instituted 24–48 hours after proper hydration and use of allopurinol. During chemotherapy, relevant blood biochemistry should be done every 12–24 hours.

Treatment

If metabolic aberrations are observed in the form of increasing hyperuricemia, oliguria and electrolyte abnormalities, as stated above, chemotherapy is either postponed or stopped. Allopurinol is given as above; the dose is decreased in the presence of renal insufficiency or if serum uric acid levels are controlled. Patients should be carefully hydrated, but in the presence of increasing oliguria, fluid overload should be watched for. Furosemide is given in a dose that maintains urine flow at over 100 mL/hour. An increase in urine output should be matched by an increase in oral and intravenous fluid intake. The urine should be alkalinized to a urine pH greater than or equal to 7 by the use of intravenous sodium bicarbonate. This is given in a dose of 75–100 mEq/L to start with, and subsequently the dose is adjusted to maintain an alkaline urine. Once the urine output increases and the serum uric acid falls, alkalinization of urine is no longer necessary. In patients who develop an acute renal shutdown, intravenous fluids are avoided for the purpose of hydration, else pulmonary edema occurs.

Hyperkalemia

Hyperkalemia needs urgent attention with 50% dextrose-insulin given intravenously, the use of intravenous bicarbonate and of an exchange resin sodium polystyrene sulfonate (see Section Fluid and Electrolyte Disturbances in the Critically Ill).

Hypocalcemia

Hypocalcemia is corrected by the use of 10% calcium gluconate intravenously, which can be repeated as and when necessary.

Hyperphosphatemia

Hyperphosphatemia is typically severe (serum levels ranging from 6 mg/dL to 35 mg/dL), and is due to both tumor lysis and increasing renal failure. It is treated with 20% dextrose-insulin till the phosphate levels are less than 6 mg/dL. Aluminum hydroxide 30–60 mL 6 hourly is given orally to bind phosphates in the gut. Good hydration, both orally and intravenously, helps excretion of phosphates via urine.

Some patients do not respond to the above therapy. They develop increasing oliguria and renal failure with hyperuricemia, persistent hyperkalemia and hyperphosphatemia. The criteria for starting dialysis are as follows—

- Serum uric acid levels higher than 10 mg/dL.
- Serum K^+ higher than 6 mEq/L.
- Serum phosphates higher than 10 mg/dL.
- Fluid overload.
- Symptomatic uncorrected hypocalcemia.

Hemophagocytic Syndrome[10]

The hemophagocytic syndrome has many underlying etiologies. An underlying lymphoma or cancer is an important cause of this syndrome which, if unrecognized and untreated, leads to almost certain death. It can also occur in infants and children as a primary event due to a genetic disorder. Secondary causes besides cancer and lymphoma also include viral infections and autoimmune disease.

It is characterized by high fever, splenomegaly, hepatic dysfunction, anemia, leucopenia, thrombocytopenia and hemophagocytosis, characterized by an enhanced macrophage and phagocytic activity which engulfs hemopoetic cells. It is caused by decreased lymphocyte killer T-cell activity; this results in a marked proliferation of lymphocytes and macrophages which infiltrate all organ systems and which produce various cytokines leading to multiple organ dysfunction and failure. Its laboratory markers are a sharp increase in serum ferritin (>10,000 µg/L), a sharp fall in fibrinogen levels and a marked increase in triglycerides. This syndrome requires expert critical care.

Treatment

Treatment consists of—

- Dexamethasone 100 mg/m^2 per day for the first 2 weeks; 5 mg/m^2 per day for the 3rd and 4th week; 2.5 kg/m^2 for the 5th and 6th week; 1.25 mg/m^2 for the 7th week tapering to zero over the 8th week.
- Etoposide 150 mg/m^2 intravenously twice weekly for the first 2 weeks; then once weekly for a total of 8 weeks.
- Methotrexate Intrathecal methotrexate and hydrocortisone are administered for four doses (weekly during weeks 3–6) only in the presence of neurological symptoms or a persistently abnormal cerebrospinal fluid (CSF).
- Supportive therapy Antimycotic therapy is given during the initial dexamethasone therapy. Trimethoprim 5 mg/kg is given thrice weekly as prophylaxis against pneumocystis.

Other Metabolic Problems in Malignancy

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

The SIADH can cause mental obtundation, coma, seizures and even death. It occurs most frequently with a small cell lung cancer, but can occur with other malignant lesions as well. Besides being a non-metastatic complication of the tumor itself, SIADH can also result from chemotherapy, notably following the use of cyclophosphamide or vincristine. The treatment has been detailed in the Section Fluid and Electrolyte Disturbances in the Critically Ill. It is important to raise serum sodium gradually in these patients, so as to minimize the risk of central pontine myelinolysis.

Hypophosphatemia

Serum phosphate levels less than 3 mg/dL are occasionally observed with rapidly growing tumors and in severely malnourished cancer patients. The clinical features of hypophosphatemia are characterized by increased weakness which could also involve the respiratory muscles, poor myocardial function, as also leukocyte and platelet dysfunction. Phosphate levels less than 1 mg/dL can cause hemolysis and rhabdomyolysis. Treatment in an emergency consists of the administration of 30–40 mmoL/L of a neutral sodium or potassium phosphate solution at the rate of 50–100 mL/hour.

Hypercalcemia[11,12]

Hypercalcemia is the most common metabolic complication of malignancies, and one that most often requires critical care. It occurs in 10% of cancer patients[3] and, in some instances, constitutes a life-threatening emergency. It is most frequently associated with multiple myeloma, lung cancer, breast cancer, cancers involving the head and neck, T-cell lymphomas, renal carcinoma as well as other solid tumors. A rapid onset hypercalcemia can cause confusion, obtundation, psychosis and even coma. Vigorous hydration with intravenous normal saline combined with the use of furosemide is the standard therapy, and has been outlined in the Section Fluid and Electrolyte Disturbances in the Critically Ill. Corticosteroids, diphosphonates, mithramycin and calcitonin can all reduce serum calcium levels by reducing bone resorption of calcium. A combination of calcitonin and corticosteroids has the quickest effect in reducing serum calcium. Mithramycin has a good, but poorly sustained effect. Diphosphonates act slowly, but the effect is more sustained.

Table 1: Dosages of commonly used agents in the treatment of hypercalcemia

Drug	*Route of administration*	*Dosage*
Prednisolone	Oral	1–2 mg/kg per day
Salmon calcitonin*	Subcutaneous	100–400 u/6–12 hours
Mithramycin	Intravenous	25 µg/kg, once or twice per week
Diphosphonates (alendronate disodium)	Intravenous	7.5 mg/kg per day for 7 days

*Also used as a nasal spray.

Methods to counter hypercalcemia have been discussed in an earlier chapter, but for reasons of convenience, the dosage schedules of corticosteroids, calcitonin, diphosphonates and mithramycin are given in Table 1.

Hypocalcemia

Hypocalcemia in cancer can result from the following causes—

- Osteoblastic metastatic deposits in the bone from a prostate cancer or from a breast cancer on hormone therapy. Prostate cancer is the most common cause of hypocalcemia. More than 30% of patients with prostate cancer and extensive osteoblastic deposits develop hypocalcemia.
- The tumor lysis syndrome can result in hyperphosphatemia, with an increase in calcium phosphate product leading to deposition of calcium in various soft tissues. Hypocalcemia followed by the development of secondary hyperparathyrodism results.
- Low vitamin D_3 levels can also lead to hypocalcemia.
- Magnesium deficiency leads to hypocalcemia. This occurs in cancer patients on prolonged hyperalimentation when magnesium is not adequately replaced. It can also occur in patients on diuretics, in chronic diarrhea, in patients on cisplatin therapy and in those receiving intravenous phosphate. Both calcium and magnesium need to be given to correct hypocalcemia in these patients.

Clinical features have been described in the Section Fluid and Electrolyte Disturbances in the Critically Ill. They include tetany, muscle cramps, laryngeal spasm, headache, irritability and seizures. Chvostek's and Trousseau's signs are often positive and the electrocardiogram (ECG) shows a prolonged QT interval.

Treatment Treatment consists of intravenous administration of 10% calcium gluconate repeated after 20–30 minutes or as and when necessary. Magnesium in a dose of 1 g over 12–24 hours is given intravenously if there is an associated hypomagnesemia (<1.5 mg/dL).

Hyperglycemia

Hyperglycemia can occur in malignant disease without insulin deficiency. It has been reported in glucagonomas, somatostatinomas, and rarely in pheochromocytomas and adrenocorticotropic hormone (ACTH) secreting tumors. Nonketotic hyperosmolar hyperglycemic coma can occasionally result as a complication of cyclophosphamide, vincristine or prednisolone therapy, in patients who are mildly diabetic and in patients who are on intravenous alimentation. Hyperglycemia generally responds to treatment of the tumor either by resection, radiation therapy or chemotherapy.

Hypoglycemia

Hypoglycemia due to tumors is most frequently due to an insulinoma. However, an insulin-like substance causing severe persistent hypoglycemia can be secreted by some tumors. These include large retroperitoneal fibrosarcomas, mesotheliomas, and renal, adrenal and primary hepatocellular carcinoma. Extensive metastasis within the liver can also lead to hypoglycemia. Associated liver cell disease, hypopituitarism from any cause (including tumors) and myxoedema may also be responsible for hypoglycemia.

The immediate treatment is an intravenous infusion of 10–20% glucose to keep the blood glucose level higher than 60 mg/dL. Removal of the tumor whenever possible grants relief from hypoglycemia.

Hypokalemia Due to Ectopic ACTH Secretion

Besides adrenocortical tumors secreting cortisol and thereby producing Cushing's syndrome, a number of other tumors can secrete ectopic ACTH resulting in hypokalemia and Cushingoid features. These chiefly include small cell lung cancer, carcinoid tumors of the bronchi, cancers of the ovary, thyroid, and prostate, hematological malignancies and sarcomas.

The differential diagnosis of hypokalemia and potassium replacement in hypokalemia are both considered in the Section Fluid and Electrolyte Disturbances in the Critically Ill. Ideally, the effective treatment of hypokalemia and the induced Cushing's syndrome due to ectopic ACTH secretion is removal of the underlying tumor. If the tumor is unresectable chemotherapy should be tried.

HEMATOLOGICAL COMPLICATIONS[3]

The chief hematological complication requiring intensive care is bleeding. Bleeding may be directly related to a cancerous lesion in the gastrointestinal (GI) tract, or it may result from thrombocytopenia, or may be due to disseminated intravascular coagulopathy (DIC). Thrombocytopenia may result from neoplastic disease chiefly through infiltration of the bone marrow or could be drug induced. DIC can occur with a variety of cancers, but especially with promyelocytic leukemia, prostatic carcinoma, and cancer of the breast, lung

and the GI tract. Patients with DIC require transfusions with whole blood, packed cells, fresh frozen plasma and platelet infusions. Fibrinogenemia is countered by intravenous infusions of cryoprecipitate; 2–3 bags/10 kg body weight is infused initially, followed by 1 bag/15 kg body weight daily [see Chapter Transfusion (Blood Product) Therapy].

PULMONARY COMPLICATIONS[3]

Pulmonary complications in malignancies meriting critical care include—

- Acute respiratory failure.
- Central airways obstruction from tumor involvement of the upper airways or from pressure on the airway by mediastinal glands.
- Massive atelectasis of a lung due to endobronchial obstruction or to extrinsic pressure.
- Acute infections.
- Massive hemoptysis.

Acute Respiratory Failure

This most frequently results from lymphangitis carcinomatosis or alveolar cell carcinoma or widespread metastatic spread of cancer within the lungs. *These patients should be treated in the wards and not in critical care units.* In our opinion, they should not be ventilated; treatment is directed toward symptomatic relief. Acute respiratory failure could also result from complicating pneumonia, due to community acquired or nosocomial or opportunistic infection, or due to pulmonary embolism. These patients need expert critical care for survival.

Acute myeloblastic leukemia or chronic myeloid leukemia in a blast crisis can cause leukostasis with obstructed blood flow to small pulmonary blood vessels. This can lead to hypoxemic respiratory failure.

Respiratory failure may also result from treatment given to cancer patients.[13] A number of chemotherapeutic agents, in particular bleomycin and mitomycin, can cause pneumonitis with progressive pulmonary fibrosis and increasing hypoxemia.[13] Similarly radiation therapy can produce acute pneumonitis over a period of 6 or more weeks. Progressive fibrosis with respiratory failure can result due to a chronic radiation effect, particularly if large areas of the lung are irradiated or the patient has simultaneously received chemotherapy. It is believed that radiation injury to the lungs, with damage to the alveolar capillary wall produced by chemotherapy, is due to the formation of free oxygen radicals. The pathogenesis of lung injury in these patients is similar to oxygen toxicity produced by inhalation of very high oxygen concentrations (FiO_2), over a long period of time. Administering a high concentration of oxygen to these patients could conceivably increase the degree of lung injury, and may well produce irreversible lung damage. The lowest possible FiO_2 that can maintain an oxygen saturation of hemoglobin around 90% should therefore be used.

Central Airways Obstruction

Central airways obstruction from tumor involvement of the upper airways or by extrinsic pressure from mediastinal glands can produce asphyxia, and needs urgent surgical attention.

Massive Atelectasis

Massive atelectasis from endobronchial obstruction can cause acute respiratory failure. Temporary relief of the obstruction by therapeutic procedures performed via the bronchoscope may help.

Acute Infections

Acute leukemias, chronic myelogenous leukemia in blast crisis, Hodgkin's disease, malignant lymphomas and other malignant lesions are often treated with high dose chemotherapy. Radiation together with bone marrow transplants are also used in the treatment of leukemias. Patients with advanced breast cancer are also at times treated with very aggressive regimes. This causes prolonged severe neutropenia and thrombocytopenia. Bacterial, viral (particularly cytomegaloviral) and fungal infections can be fulminant and cause death in spite of vigorous antibiotic therapy and support. Cytomegaloviral pneumonia and diffuse interstitial pneumonia are dangerous complications following bone marrow transplants and carry a high mortality (see Section The Immunocompromised Patient).

Massive Hemoptysis

Hemoptysis can be severe in some patients with non-small cell lung cancers, and is particularly severe in squamous cell lung cancer. Intrapulmonary hemorrhage with hemoptysis can also occur in patients with severe thrombocytopenia; fluffy lung shadows with progressively increasing hypoxemic respiratory failure result.

CARDIOVASCULAR COMPLICATIONS

Cardiac Tamponade

Cardiac tamponade is an important complication that may necessitate critical care in patients with malignant disease. Tamponade is most frequently due to malignant pericardial effusion, but can be due to constrictive pericarditis arising from encasement of the heart by tumor tissue or to irradiation fibrosis.

Pericardiocentesis is urgently required to reverse hemodynamic abnormalities in malignant pericardial effusions. Surgical procedures by an experienced oncosurgeon may be necessary for long-term benefit.

Congestive Cardiomyopathy[3]

An extremely important cardiovascular complication in patients with mitotic disease is congestive cardiomyopathy,

induced by chemotherapeutic agents such as adriamycin or high dose cyclophosphamide. Progressive cardiac enlargement, increasing breathlessness, and pulmonary and systemic venous congestion can occur over a short period of 2–4 weeks, though in some patients the clinical features of heart failure may be delayed by a few months. A clinical follow-up, as also a follow-up by 2D echocardiography with specific reference to the ejection fraction, is of value in early diagnosis. Management consists of strict bed rest, the use of digitalis, diuretics and the use of angiotensin converting enzyme inhibitors to reduce the afterload. The incriminating drug should be avoided. Varying degrees of improvement in cardiac function may be observed with proper management.

SUPERIOR MEDIASTINAL SYNDROME[14]

The superior mediastinal syndrome most commonly results from a lymphoma or a metastatic carcinoma (chiefly from a carcinoma within the lung). However, the possibility of a benign cause for a superior mediastinal syndrome should always be kept in mind. For this reason it is wrong in principle to give chemotherapy or radiation to such a patient without a tissue diagnosis. In our part of the world, massive mediastinal adenopathy with a superior mediastinal pressure syndrome can result from tuberculous adenitis, particularly in the younger age group.

Patients with cancer, who have central venous catheters in situ, may develop superior vena caval thrombosis. This results in engorged neck veins and resembles a superior mediastinal pressure syndrome. An infusion of urokinase, through a catheter placed directly above the clot in the superior vena cava, often dissolves the clot and gives excellent relief. This is preferably followed by an intravenous infusion of heparin at a rate of 1,000 units/hour for 3–4 days. Long-term oral anticoagulation may be necessary in some patients.

Severe tracheal obstruction or obstruction to a large bronchus from a metastatic adenopathy due to cancer or lymphoma may need urgent relief. Stenting with a self-expanding metal endoprosthesis provides successful relief in 90% of patients. Chemotherapy is used in patients with small cell lung cancer, lymphoma and germ cell tumors. Radiation therapy is the only alternative for other cancers. It may temporarily increase upper airway obstruction, or further obstruct the superior vena cava, necessitating the insertion of a stent within the trachea and the superior vena cava.

GASTROINTESTINAL COMPLICATIONS[3]

Perforation of the gut may be a direct complication of a malignant lesion involving the GI tract. Perforation can also result from enterocolitis in neutropenic patients. Fever, diarrhea, abdominal pain and tenderness are present. The classical signs of acute abdomen after perforation may not be present in a severely neutropenic patient. Surgery is imperative, but the morbidity and mortality are high.

Severe GI bleeds, or localized intra-abdominal abscesses may also be serious enough to merit critical care in some patients.

Obstruction to the gut may be due to the disease process itself. Surgery, radiation therapy or intraperitoneal therapeutic interventions may however cause adhesions or damage to the gut, with resulting obstruction. It is often difficult to distinguish whether problems involving the gut are related to the malignancy per se or to therapy used against the disease. Expert surgical advice is imperative.

NEUROLOGICAL COMPLICATIONS[2,3]

Acute complications requiring critical care include increase in intracranial tension because of a primary tumor within the brain or due to metastasis within the brain.

Early diagnosis and prompt treatment of acute spinal cord compression due to metastatic disease or a primary neoplasm are of utmost importance. This requires a good clinical examination plus imaging studies. Cord compression diagnosed after myelopathy has already set in has the most unfortunate consequences on what remains of the patient's life—often a bedridden existence, with an indwelling catheter and with an increased risk of bedsores, pneumonia and urinary infection.

Once a clinical diagnosis of cord compression is made, the patient should be given pulsed doses of 1 g methylprednisolone for 3 days, as this helps reduce cord edema. Definitive neurosurgical treatment to decompress the cord should be prompt so as to avoid a permanent myelopathy.

Severe metabolic encephalopathy in a patient with malignant disease can be due to hyponatremia or hypercalcemia. Antimitotic drugs, like cytarabine, etoposide, methotrexate, ifosfamide, can also cause metabolic encephalopathy. Interleukin-2 (IL-2) and interferon-α can also cause somnolence and confusion. Paranoid psychosis, seizures and coma have been reported with IL-2. Management is chiefly symptomatic and supportive, and the offending drug should be promptly stopped.

ANTICANCER THERAPY REQUIRING INTENSIVE CARE

It is hardly ever necessary to give chemotherapy in an ICU setting. Recently however biological therapy chiefly with IL-2 is being increasingly administered under critical care conditions.[3] IL-2 therapy is particularly useful in patients with renal cell carcinoma and melanoma, the results being superior to other modalities of treatment. Other biological factors being used are the tumor necrosis factor (TNF) and interleukin-1 (IL-1). IL-2 is presumed to have a lymphokine-activated killer (LAK) cell activity.[3] An IL-2 regime however produces a predictable range of toxic effects which requires management in a critical care setting.[15-17]

IL-2 infusions can produce—

- Severe hypotension due to an increased vascular capacitance with a lowered systemic vascular resistance.
- Non-cardiogenic pulmonary edema.[3]

The hypotension is similar to that observed in septic shock, and is associated with a warm skin and a good pulse volume. Poor perfusion of organ systems results if the blood pressure is not raised. It is inadvisable to raise the blood pressure by a volume load, as this increases the tendency to produce non-cardiogenic pulmonary edema. It is best to raise the blood pressure by an infusion of phenylephrine 50 mg in 250 mL of 5% dextrose, the infusion being given at a rate of 20–40 μg/minute. If hypotension persists despite increasing doses of phenylephrine, the patient is given inotropic support either with dopamine or dobutamine. These patients invariably have a fair degree of left ventricular dysfunction. The deleterious cardiovascular effects of IL-2 are reversed within hours if the drug is discontinued. The drug can be restarted with a 25% reduction in dose, after the patient is hemodynamically stable.

The danger of non-cardiogenic pulmonary edema is minimized by restricting fluids and avoiding volume load. Hypoxia if present, is corrected by an appropriate increase in the FiO_2. If hypoxia persists with a hemoglobin oxygen saturation less than 90%, IL-2 is best omitted. It should be noted that the respiratory toxicity of IL-2 is not as easily reversed as the cardiovascular effects.

When LAK cells are infused together with IL-2, further complications include an additive effect on declining respiratory function, due to sludging of cells in the capillary bed. Bronchospasm and acute pulmonary edema have also been observed. Continuous positive pressure breathing or intubation with ventilatory support, may be necessary at times.

It is possible that in the decades to come, biological agents will be used with increasing frequency. The intensive care physician will therefore need to be aware of the potential grave complications, so that he can handle them successfully.

CONCLUSION

The survival rate of cancer patients requiring ICU admission has increased. It is imperative that potential salvageable life threatening emergencies in cancer patients are treated in critical care units. There are many reasons for improved survival of cancer patients in the ICU. They include quicker diagnosis and better treatment of acute respiratory failure, prevention of tumor lysis syndrome, earlier diagnosis and treatment of the hemophagocytic syndrome, better management of acute kidney injury, recognizing drug-related organ toxicities, advances in oncology, hematology and better over-all ICU care.[18]

Control of Pain and Anxiety and the Use of Muscle Relaxants in the Critically Ill Patient

- Control of Pain and Anxiety and the Use of Muscle Relaxants in the Critically Ill Patient

CHAPTER 72

Control of Pain and Anxiety and the Use of Muscle Relaxants in the Critically Ill Patient

INTRODUCTION

Pain is an important symptom of disease, and indiscriminate suppression of pain may delay diagnosis and prevent correct management. Once a diagnosis is made and effective treatment planned, pain must necessarily be relieved. Postoperative and post-traumatic pain also need effective relief as it serves no useful purpose and may prove detrimental to the patient in many ways.[1]

In the intensive care unit (ICU), pain management poses many challenges. Many critically ill people are incapable of communicating clearly, either due to their disease or injury or because of intubation and the need for sedation. Assessment and treatment of potentially painful conditions therefore become difficult. Also, there are many sources of pain that may be unrelated to their disease, but caused by procedures and therapies used to fight their disease. These sources of pain include for example surgeries, invasive procedures, and placement of monitoring devices, intubation and the use of dialysis to maintain renal function. An overall pain assessment in a conscious patient who can communicate requires a careful history into the nature, site and cause of discomfort or pain that is perceived. It is important to remember that a very strong overwhelming pain invariably suppresses lesser pains arising from one or many other sources. These may become evident when the cause of the very severe pain has been effectively dealt with.

DEFINITION

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage.

ANATOMY OF PAIN[2]

"For all the happiness mankind can gain is not in pleasure but relief of pain."

—John Dryden

Nociceptive stimuli are perceived by nerve endings throughout the body, and are conveyed by unmyelinated and small myelinated sensory axons to the posterior root ganglion in the spinal cord. A neuronal relay transmits the pain to the posterior horn cells. Many of the afferents terminating in the region of the spinal cord contain neuropeptides, including substance P. cholecystokinin and somatostatin. These peptides probably play an important role in sensory transmission. The spinal dorsal horn is divided into a series of layers. Neurones processing noxious or nociceptive stimuli are found in a number of these layers. Unmyelinated afferents terminate in substantia gelatinosa (Layer II), while the myelinated afferents end in Layers I and V. The axons of neurones arising from the dorsal horn cross to the opposite side to ascend upward as the ventrolateral spinothalamic tract. The spinothalamic tract can be conceptually divided into two systems based on its connections: (1) a direct tract ending in the ventrolateral nucleus of the thalamus, and (2) a phylogenetically older, spinoreticulothalamic tract that terminates at several levels within the reticular formation of the brainstem. This indirect tract is part of a polysynaptic system terminating in the medial thalamic nuclei.

Descending Analgesic Fibers[2]

In addition to this major ascending spinothalamic system, the nervous system contains descending nerve fibers that

suppress nociceptive inputs. These descending fibers (at least in animals) originate in the periaqueductal gray matter, synapse in the nucleus raphe magnus in the medulla, and then project downward into the spinal cord to the dorsal horns. The descending pathways can to an extent gate or restrict the initial nociceptive stimuli received in the dorsal horns. The descending analgesic pathways described above contain endogenous opiate peptides and opiate receptors. Opiate receptors are also present in the thalamus and the limbic system. These structures may therefore play an important role in the analgesic response to systemically administered narcotics.

Biogenic amines, like serotonin and norepinephrine, are other neurotransmitters also present in the fine terminals of the descending analgesic pathways. A major descending analgesic pathway originates in the nucleus locus coeruleus of the pons. This pathway contains norepinephrine and inhibits nociceptive responses within the posterior horns through an alpha-adrenergic mechanism.

PATHOPHYSIOLOGY OF PAIN[2]

Perception of pain within the neuraxis excites segmental and central responses. Segmental response is characterized chiefly by increase in muscle tension, which intensifies pain. The central response consists of an increase in sympathetic tone resulting in tachycardia, and a rise in both blood pressure and cardiac output. The metabolic rate and both oxygen demand and oxygen consumption may increase. Pain also excites a neuroendocrine response. There is an increased secretion of catecholamines, cortisol, adrenocorticotropic hormone (ACTH), aldosterone, antidiuretic hormone, glucagon and an increase in the production of a large number of cytokines. Insulin secretion can decrease. Severe unrelieved pain increases the catabolic state, and may cause a negative nitrogen balance; this could result in decreased immune function and delay wound healing. Nociceptive stimuli if unrelieved can result in insomnia, nausea, vomiting, ileus, prolonged immobility and a feeling of increasing anxiety, distress and frustration in the patient. Unabated chest pain as after cardiothoracic surgery can also contribute to poor respiration, through restriction of movements of the chest wall and diaphragm. This increases the chances of postoperative atelectasis. Pain may contribute to immune dysfunction, hypercoagulable states, increase in blood glucose levels and patient-ventilator asynchrony. It robs the patient of rest and sleep and indirectly retards the healing process in a critically ill individual.[3] Management of pain and anxiety is therefore a vital aspect of critical care.

The following section first describes the use of both narcotic and non-narcotic drugs for analgesia in a critical care setting. It then discusses the use of anxiolytic and sedative agents in critically ill individuals, and ends with a brief description of muscle relaxants in the ICU.

USE OF OPIOIDS OR NARCOTIC ANALGESICS FOR PAIN RELIEF[4]

Opioid or narcotic analgesics are the drugs most frequently used to relieve pain in critical care units. They may be used alone or in combination with non-steroidal anti-inflammatory agents. Remarkably enough, analgesics are often overused or underused. Their administration should be guided by the background disease, the immediate cause and the severity of pain. The dose should always be individualized and titrated as needed. Pain relief must always be balanced against potential side effects of narcotics (chiefly respiratory depression, hypotension), and the effect these side effects could produce on the overall clinical outcome in a gravely ill individual.

Opioids (narcotic analgesics) can be given orally, intramuscularly or intravenously. Over the last 20 years, new delivery systems have been developed, so that opioids can also be administered by the epidural, intrathecal, transdermal and transmucosal routes. Opioids produce both analgesia and sedation through their action on the opioid receptors of the central nervous system.

The intramuscular route of administering narcotic drugs is universally accepted for pain relief. We prefer to administer the drug as and when needed; the drug could also be given at fixed intervals (at 4–6 hours), provided the patient is carefully monitored. The major advantage of the intramuscular use of opioids is a lesser incidence of respiratory depression and hypotension, when compared to intravenous (IV) use. The disadvantage is a comparatively erratic absorption, erratic blood levels and slower action.[4]

Relief of severe pain in a critical care setting is quicker and easier with a titrated IV administration of a narcotic analgesic.

INTRAVENOUS NARCOTIC ANALGESICS[5]

The IV administration of narcotics brings prompt relief of pain and anxiety in an ICU setting. The dosage and the exact method of IV administration (either by bolus injections or by a continuous IV infusion) need to be individualized for each patient. Morphine (5 mg) or buprenorphine (0.1–0.3 mg) given in a very slow IV bolus dose affords quick relief from pain. If IV morphine is given at intermittent intervals, the dose is 0.03 mg/kg every 10–20 minutes, care being taken to ensure that respiration is not unduly depressed, and hypotension does not occur. Naloxone can reverse the respiratory depressant effect of morphine. A smaller dose of 2 mg morphine or 0.1 mg of buprenorphine should be initially given in elderly or frail patients so as to note the effect on respiration and circulation. Morphine fortunately is a little more easily available in India (though it requires a permit) compared to the difficulty obtaining it a few years ago. When unavailable, ICUs make do with buprenorphine in its place.

Morphine or buprenorphine can also be given in a continuous IV infusion. An infusion rate of 0.5–1.5 mg/hour

of morphine, or 0.01 mg/kg per hour of buprenorphine, allows a steady level of the narcotic within the blood, and offers good relief. Alternatively, 0.5–1 mg/kg together with 50 mg promethazine is added to 100 mL of 5% dextrose saline, and given intravenously in an infusion over 30–40 minutes. Here again, respiratory depressant and hypotensive side effects of the narcotic should be watched for. The patient ideally should remain sedated and free of pain, but yet easily arousable.

Hydromorphone (Dilaudid) is frequently used in the West for its potent analgesic effect. It is unavailable in our country, except through a special permit. When used intermittently, the recommended dose is 10–30 µg/kg intravenously at 2 hourly intervals. The infusion dose ranges 7–15 µg/kg per hour.

OTHER SYNTHETIC NARCOTIC-ANALGESICS

Pentazocine

Pentazocine belongs to the benzomorphan group of synthetic compounds. It is indicated in the treatment of pain of intermediate severity. Around 30 mg of pentazocine is equivalent to 10 mg of morphine. The drug can be given intramuscularly, by intermittent IV injection, or in an IV infusion in the dose stated earlier. Its main advantage is that it does not cause dependence unless used in high doses for prolonged periods. Unlike pure narcotic agonists, its effects cannot be reversed by nalorphine. IV naloxone is an effective antidote.

Pethidine (Meperidine)

Pethidine is similar to morphine, but has a shorter duration of action, and is less potent in relieving pain. It is usually administered in a dose of 1 mg/kg intravenously. Its use is contraindicated in patients who are on monoamine oxidase (MAO) inhibitors. Pethidine is metabolized by the liver; a principal product of metabolism is norpethidine, which can cause tremors, apprehension, delirium and seizures, and may interact with antidepressants.

Fentanyl

Fentanyl is a recent synthetic opioid which is 50–100 times more potent for pain relief compared to morphine. The IV dose for an adult weighing 60–70 kg is 1–2 µg/kg. The drug has a short duration of action and has no significant effect on the circulatory system. It is increasingly used both in general anesthesia and as a potent analgesic. Though fentanyl is the quickest and shortest acting analgesic, repeated doses may cause accumulation and prolonged effects. When administered as an IV infusion, the dose is 0.2–0.5 µg/kg per hour.

In patients with lesser degree of pain, fentanyl can be applied transdermally as a patch. The subdermis acts as a reservoir from which a slow and steady absorption of the drug occurs. Patches can deliver 25 µg/hour, 50 µg/hour, 75 µg/hour and 100 µg/hour. Peak analgesic levels occur after a time lag of 10–12 hours. A careful watch on possible respiratory depression and hypotension should be kept. Transdermal fentanyl should not be used for severe pain where need for urgent analgesic relief is important.

Remifentanil

Remifentanil is even quicker and shorter acting than fentanyl, as it has a half-life of 3–10 minutes. It is given in an infusion in a dose of 0.6–15 µg/kg per hour. The short action and quick arousal after discontinuing the drug is useful when frequent clinical and, in particular, neurological assessment is called for.

Butorphanol Tartrate

Butorphanol tartrate is a recent opioid analgesic now available in India. It has a short half-life and is seven times more potent than morphine. When given intravenously, its peak action is within 0.5–1 hour and its duration is 3–4 hours. The IV dose is 1 mg repeated every 3–4 hours. Depressant effects on respiration and circulation need to be carefully watched for.

Ketamine

Ketamine is a potent analgesic and anesthetic. It is chiefly used in the ICU for bedside procedures and has been discussed in a later section of this chapter.

PATIENT CONTROLLED ANALGESIA[4,6,7]

Patient controlled analgesia (PCA) permits self-administration of a preset quantity of a narcotic intravenously, as and when needed. PCA enables a patient to control his own analgesic requirements. A lockout device is incorporated into the system to prevent overdosage of the narcotic. This method provides effective analgesia, effective control over pain and anxiety, improves pulmonary function in postoperative patients, reduces sleep disturbances, and is shown to reduce the overall drug requirement, when compared to other methods of narcotic administration. The dosage in PCA needs to be individualized. An example of a prescribed dosage schedule with morphine is as follows: 2–5 mg as a loading dose over 15–30 minutes, followed by a patient triggered bolus of 1–2 mg via the PCA pump, programmed with a lockout interval of 15 minutes. This schedule may be changed according to the patient's response.

A similar schedule for morphine is as follows: 0.3–0.5 mg as a loading dose, followed by 0.1–0.2 mg of a patient triggered bolus via the PCA pump, with a lockout interval of 15 minutes.

The PCA method of pain control can be combined with a slow infusion of a narcotic which allows a steady blood level of the drug to exert a continuous analgesic effect. It is essential to check the respiration, basic circulatory parameters, and the level of mental obtundation when using this combined approach to the relief of pain.

Caution is required in the use of continuous infusion of opioids in critically ill patients, as these patients have altered and fluctuating volume status, altered protein binding capacity and may have renal and/or hepatic dysfunction.

RECOMMENDATIONS FOR ANALGESIA IN ICU PATIENTS

It is important that the intensivist familiarizes himself with just a few opioid (narcotic) analgesics. The clinical practice guidelines on the use of analgesics in the critically ill adult have the following recommendations to make on analgesia[5]—

- A therapeutic plan and goal of analgesia should be established for each patient.
- If IV doses of an opioid analgesic are required, fentanyl, remifentanil and morphine are recommended agents. In our country where morphine is difficult to obtain, buprenorphine could substitute for morphine.
- Scheduled opioid doses or a continuous infusion is preferred over an "as needed" regime for consistent analgesia. In our opinion this may hold for a certain group or category of patients, and "as needed" approach is safer and almost as effective.
- Fentanyl or remifentanil is preferred for a rapid onset of analgesia in acutely distressed patients.
- Fentanyl or hydromorphone (not available in India) is preferred for patients with hemodynamic instability or renal failure.
- Morphine (buprenorphine is a substitute) is preferred in intermittent therapy because of its longer duration of effect.

ADVERSE EFFECTS OF OPIOIDS

The following are the adverse effects seen with the use of opioids—

- Depression of respiration. This needs to be carefully watched, particularly in the old and feeble.
- Hypotension, due to a sympatholytic effect and a vagally mediated bradycardia.
- Marked depression of the conscious level, which interferes with clinical assessment.
- Rarely hallucinations and agitation are observed.
- Gastric hypomotility, ileus, urinary retention, constipation occur particularly with prolonged or frequent administration; these require symptomatic treatment.
- Increase in intracranial pressure has been reported in patients with head injury.

It should be noted that tolerance to the drug over time is observed with all opiates. Synthetic opioids like fentanyl exhibit tolerance more quickly than the non-synthetic ones, because of their higher receptor affinity. Rapid withdrawal or de-escalation of an opioid can cause withdrawal effects with resulting delirium which may be wrongly attributed to other causes.

EPIDURAL AND INTRATHECAL OPIOIDS[8,9]

Epidural anesthesia is extremely useful for relief of pain following orthopedic, thoracic or vascular procedures. It also helps to improve postoperative outcomes in high-risk patients as manifested by a reduced incidence of postoperative thromboembolism, myocardial infarction and by improvement in pulmonary and bowel functions.[9] A Cochrane review comparing epidural to systemic opioid technique for pain relief showed that epidural analgesia was superior. It was also associated with reduced cardiovascular, gastrointestinal and renal complications, and with reduced time on ventilator support. Epidural analgesia using opioids is extremely useful not only for pain relief but also for reduced morbidity and mortality in patients with multiple (>4) rib fractures following trauma to the chest.

Epidural and intrathecal administration of opioids relieves pain by acting on spinal pain receptors. Epidural administration of a narcotic is much more frequently used. It produces good relief with a relatively small quantity of the drug, without blocking motor and sympathetic nerves. It requires the placement of a catheter in the epidural space. Morphine and buprenorphine are the most frequently used analgesic narcotics. Since buprenorphine is more easily available, 150 μg of the drug diluted in 10–20 mL of N-saline is administered slowly. This provides pain relief that may last for 12–16 hours, after which the dose can be repeated. Pethidine can also be used epidurally in a similar fashion, for pain relief.

Morphine and buprenorphine have been shown to spread in a cephalic direction to reach the fourth ventricle, after epidural administration. Two phases of respiratory depression may be observed. The first phase occurs within 30–45 minutes, and reflects absorption of the drug into the blood via the epidural veins. The second phase of depression occurs after 6–8 hours, and occasionally as long as after 24 hours; it is due to rostral spread of the drug into the fourth ventricle, causing a direct depressant effect on the respiratory center. Most patients become sedated before developing respiratory depression. An increasing sedative effect should be watched for, as it precedes respiratory depression. It is best to avoid the systemic administration of narcotics if the epidural route is being used, as the danger of serious respiratory depression significantly increases.

Fentanyl, like morphine, is a lipophilic agent which travels rostrally when given intrathecally or through a catheter placed in the lumbar epidural space. It however travels in a cephalad direction less slowly than morphine, and is not as effective as the latter for relief of thoracic pain, but has fewer side effects.[10,11]

Epidural administration of narcotic analgesics can be given in the bolus form, as a continuous infusion (using an infusion pump), or can be administered as an infusion that can be controlled by the patient, as per his/her requirements (PCA).

SPINAL ANESTHESIA

Spinal anesthesia through intrathecal techniques is used for operative and immediate postoperative pain control. This mode is not used for pain control in ICU patients because of increased risk of complications. Intrathecal administration of

opioids leads to a much higher cerebrospinal concentration of the drug when compared to epidural administration. The risk of severe respiratory depression and hypotension is therefore considerably enhanced.

REGIONAL ANESTHESIA[4]

Regional blocks to relieve pain are also of considerable use in certain circumstances. A typical example is the use of a regional intercostal block to relieve pain and ease breathing in a patient with rib fractures. Brachial plexus blocks can relieve severe pain in the upper limb, and local infiltration of a wound area in suitable cases can relieve pain arising from a serious wound. Regional anesthesia blocks both afferent and efferent pathways of the reflex arc, and minimizes metabolic and neuroendocrine responses to painful stimuli. However, when local anesthetics are used intrathecally, care must be taken to minimize side effects. These include hypotension and limb weakness or even paralysis secondary to sympathetic and somatic nerve block.

Lidocaine 1–2% is the most commonly used local anesthetic in the ICU, because of its rapid action lasting for a significant period of time, and its low incidence of side effects. It is used locally prior to the insertion of central lines and the pulmonary artery catheter. It is also used topically (in 4% strength) in the nose, mouth, throat, tracheobronchial tree, esophagus and urethra. An uncommon but important side effect following the local use of lidocaine is a hypersensitivity reaction that can rarely cause anaphylaxis. Lidocaine is also used to provide pain control in spinal, epidural, caudal, nerve and field blocks.

Bupivacaine 0.25% is used in obstetric anesthesia. It is slow-acting, but produces marked analgesia for a prolonged duration of time. It is often used for epidural anesthesia and for intercostal nerve blocks (Table 1).

Table 1: Types, indications and considerations for regional blocks in the intensive care unit

Types of blocks	*Indications*	*Special considerations*
Thoracic epidural	Thoracic surgery, chronic pancreatitis, upper abdominal surgery, rib fractures	Epidural hematoma or abscess Accidental intrathecal puncture Hypotension from sympathetic blockade
Lumbar epidural	Trauma, lower extremity surgery	Same as above
Femoral or sciatic block	Lower extremity pain (thigh, knee, leg)	Positioning difficulties with sciatic block
Intercostal block	Rib fracture, chest tube insertion	Pneumothorax, empyema
Phrenic nerve block	Upper extremity pain, trauma, surgery

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS[4]

These drugs act by exerting an inhibitory effect on prostaglandin synthesis. Non-steroidal anti-inflammatory drugs include diclofenac sodium (50 mg 8 hourly intramuscularly or orally), and piroxicam (40 mg daily intramuscularly or orally). These drugs can relieve mild to moderate pain, but do not have the same efficacy observed with the narcotic group of drugs in the relief of severe pain. They often cause gastritis, acute upper gastrointestinal (GI) erosions, occasionally ulceration in the small or large gut which can bleed profusely, platelet dysfunction, and interstitial nephritis leading to renal dysfunction. Elderly patients with hypovolemia or hypoperfusion, and those with pre-existing renal insufficiency are more prone to non-steroidal anti-inflammatory drug (NSAID)-induced renal failure.

A number of oral NSAIDs are available, which include ibuprofen and naproxen. More selective COX-2 inhibitors are also available for oral administration. They are believed to produce less gastric irritation on long-term use. Acetaminophen is also useful to relieve mild pain. NSAIDs can on occasions be combined with the use of opioids for pain relief, so that the dose requirement of opioids is reduced.

A valuable addition to the non-steroidal anti-inflammatory drugs is ketorolac tromethamine, which can be given intramuscularly or intravenously for pain relief.[4] This drug has no direct effect on opiate receptors. It is a potent analgesic—30–90 mg given intramuscularly has an efficacy comparable to 10 mg of morphine. The dose should be halved in elderly patients, and the drug should preferably not be used for more than 5 days for fear of inducing renal insufficiency. Ketorolac is non-addicting and does not depress respiration. Its side effects are similar to those of other non-steroidal anti-inflammatory drugs. It should be avoided in patients with renal dysfunction, or in patients with a bleeding tendency.

We prefer as far as possible to avoid the use of non-steroidal anti-inflammatory drugs in critically ill patients. Oral or IV paracetamol is used for relief of mild pain and opioids for relief of more severe pain as indicated earlier.

Table 2 lists commonly used opioid and non-opioid analgesic drugs in a critical care setting.

ANALGESICS AND ANESTHESIA FOR BEDSIDE PROCEDURES[4,12]

Cardioversion

Diazepam (5–10 mg) or midazolam (2–3 mg) given intravenously is a safe and effective premedication prior to cardioversion, provided of course that there is sufficient time to use the premedication. Diazepam offers sedation, hypnosis and a period of amnesia.

Table 2: Common analgesic drugs used in the ICU

Drug	*Equianalgesic dose IV (mg)*	*Intermittent dose*	*Infusion dose*	*Main adverse effects*
Morphine	10	0.03 mg/kg IV every 15–20 minutes	0.02–0.07 mg/kg per hour	Depressed respiration, hypotension
Buprenorphine	0.3	3 µg/kg	0.01 mg/kg per hour	Same as above
Fentanyl	200	0.35–1.5 µg/kg IV at 0.5–1 hour	0.7–10 µg/kg per hour	Same as above Rigidity with high doses
Pentazocine	50	0.5–1 mg/kg		Depressed respiration, hypotension
Pethidine (Meperidine)	75–100	Not recommended	Not recommended	Same as above Occasionally excitability, tremors, delirium, seizures
Hydromorphone (not available in India)	1.5	10–30 mg/kg per hour	7–15 µg/kg per hour	Depressed respiration, hypotension
Ketorolac		15–30 mg intramuscular (IM) every 6 hours Decreased in elderly patients Avoid in renal insufficiency Do not use >5 days		Platelet dysfunction, Gastrointestinal bleed, renal dysfunction

20

BEDSIDE DEBRIDEMENT OF WOUNDS, OTHER MINOR SURGICAL PROCEDURES IN THE ICU, OR EXCISION OF ESCHAR IN BURNS PATIENTS

Ketamine is a phencyclidine anesthetic which produces dissociative anesthesia, hypnosis and analgesia. It is also an N-methyl-D-aspartate (NMDA) receptor antagonist. When given intravenously in a dose of 2 mg/kg, it acts within 30–60 seconds. Its effect is short-lasting, and it has a plasma half-life of 2–3 hours.[13] This excellent anesthetic allows minor bedside surgical procedures like debridement of painful wounds, to be performed in the ICU. The drug when used intravenously as a short acting anesthetic is also extremely useful in the care of burns patients, particularly for the excision of eschars. Ketamine can also be given intramuscularly in a dose of 5–10 mg/kg, its onset of action then being 3–8 minutes. Ketamine in a dose of 1–2 mg/kg produces analgesia, with little change in the level of consciousness; the degree of analgesia is equivalent to that obtained with opioids. In the ICU, ketamine can be given before intubation, prior to changing a surgical dressing, prior to orthopedic manipulations and for other surgical procedures, such as incision, drainage of an abscess, or a tracheostomy.

The short anesthesia induced by intravenously administered ketamine (provided it is given slowly over 1 minute) is associated with preserved gag and laryngeal reflexes, and a slightly increased skeletal muscle tone. Ventilation is generally not depressed, and the patient does not require to be intubated. Emergence from anesthesia may be associated with excitement and hallucinations, which can be easily controlled by diazepam, or droperidol. Stimulation of the cardiovascular system may result in tachycardia and mild hypertension. Ketamine may induce profuse salivation, and hence an antisialogogue should be administered prophylactically.

ANXIETY, AGITATION AND THE USE OF SEDATIVES IN THE CRITICALLY ILL PATIENTS[14-17]

Anxiety is a feeling of nervousness and apprehension. Agitation is a sense of anxiety plus irritability, restlessness, marked arousal so that rest and sleep are either difficult or impossible.

The ICU is to an extent a hostile environment for critically ill patients. Noxious stimuli include pain, noise, suctioning of oropharyngeal and tracheal secretions, or tragedy involving other patients in the unit. Added to this is the sense of isolation, the difficulty encountered in communication (particularly in patients with an artificial airway), physical restraints associated with immobilization, other distressing sensory inputs, fear, anxiety and often deprivation of sleep. All these features can lead to a stressful situation, eliciting a mental response that ranges from anxiety and depression, to anger, hostility, agitation or even psychosis.

Sedative-hypnotic medications are often necessary to calm the patient and dull the edge of anxiety and fear. The agents most frequently used are the benzodiazepines. Occasionally, propofol and barbiturates are also used; narcotics should preferably be given only for pain, or when pain and anxiety coexist. The present discussion is restricted to the use of benzodiazepines. Ideally, a sedative and anxiolytic agent used in the ICU should have the following features—rapid onset of action, effective response, predictable duration of action, no adverse effects on vital functions, in particular on the respiratory and cardiovascular functions, and ease of administration. The drug should have a good therapeutic index, and, if possible, a specific antagonist should be

Table 3: Richmond Agitation-Sedation Scale (RASS)

+4	Combative	Combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tubes or catheters; aggressive
+2	Agitated	Frequent non-purposeful movement; fights ventilator
+1	Restless	Anxious, apprehensive, but movements not aggressive or vigorous
0	Alert & calm	
−1	Drowsy	Not fully alert, but has sustained (>10 sec) awakening (eye opening/contact) to voice
−2	Light sedation	Drowsy, briefly (<10 sec) awakens to voice or physical stimulation
−3	Moderate sedation	Movement or eye opening (but no eye contact) to voice
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Am J Respir Crit Care Med. 2002;166:1338-44; and from Ely EW, Truman B, Shintani A, et al. Monitoring sedation status over time in ICU patients: reliability and validity of the Richmond Agitation-Sedation Scale [RASS]. JAMA. 2003;289:2983-91.

available in case of overdosage. Benzodiazepines satisfy many of the above requirements. They have sedative and anxiolytic effects, produce muscle relaxation, and have anticonvulsant properties.

The ideal level of sedation is one where the patient sleeps, yet is easily arousable. Severely hypoxic patients on mechanical ventilation or those on neuromuscular paralytic agents may require a higher degree of sedation.

MONITORING SEDATION

No subjective or objective method or technique is ideal for monitoring sedation. Several monitoring protocols have been devised. The Riker Sedation-Agitation Scale (SAS) has proved satisfactory for ICU patients.[18] The Vancouver Interaction and Calmness Scale is also used, and in children a widely used scale is the COMFORT scale.[19] A monitoring scale used in the ICU should be simple, yet should document the degree of anxiety present and the degree of sedation achieved with accuracy.

The Richmond Agitation Sedative Scale (RASS) is discussed in Table 3.

The RASS is a 10-point scale with criteria to distinguish levels of agitation and sedation; it takes very little time to complete. It has been shown that—

- The use of sedation target (i.e. level of desired sedation) through a protocol-based therapy reduces both patient anxiety, agitation, and improves patient outcome.[20,21]
- Daily interruption of sedation should always be part of the protocol to allow careful patient assessment.
- Patient awakening (through interruption of sedation) should be linked with spontaneous breathing trial, if a decision to wean the patient off ventilator support has been made. This has been shown to reduce time on ventilator support and reduce ICU and hospital stay.[22,23]

DIAZEPAM

Diazepam is the most commonly used drug. It binds to specific receptors in the hypothalamic, thalamic and limbic areas of the brain (responsible for sedative effect), and to spinal receptors in the spinal cord, enhancing the inhibitory effects of gamma aminobutyric acid (GABA) and other inhibitory neurotransmitters (responsible for a muscle relaxant effect). An IV dose acts within 1 minute, the maximum effect being observed in 2–5 minutes, and the duration of sedative action lasts for 4–6 hours. The drug is metabolized in the liver by microsomal oxidation and demethylation, its active ingredients being excreted by the kidneys. The drug should preferably not be given intramuscularly as its absorption is then erratic.

Diazepam is chiefly used as an anxiolytic agent which produces sedation and anterograde amnesia for stressful events. It is also used as a muscle relaxant (as in tetanus), and as an anticonvulsant (as in tetanus and in status epilepticus). It is the premedication of choice for cardioversion and for endoscopic procedures, and is also used in the management of addictive drug or alcohol withdrawal.

It is usually given slowly intravenously as a 2–10 mg bolus, and repeated after 6–8 hours, if necessary. For cardioversion, 5–10 mg is given intravenously 5 minutes before the procedure. Status epilepticus is managed by 10 mg bolus doses of IV diazepam, or by an infusion of 30–50 mg of the drug in 500 mL of N-saline. It is important to remember that individual response to the drug varies greatly, so that the dose should always be titrated to the response, particularly in feeble patients, or in the elderly.

Diazepam can produce prolonged drowsiness and impairment of intellectual and psychomotor functions. Respiratory depression and even apnea may occur, particularly if given rapidly. Bradycardia, hypotension, and even cardiac arrest have occurred in patients who are exquisitely sensitive to the drug, or when a large rapid bolus injection is used. The drug should be used with great caution and, as far as possible avoided altogether in patients with liver or renal dysfunction. Milder forms of anxiety are best treated by the oral use of the drug, 5–10 mg thrice daily.

LORAZEPAM

Lorazepam is a benzodiazepine with no specific advantage over diazepam. It acts on the benzodiazepine receptors in the central nervous system and spinal cord, enhancing the function of the inhibitory neurotransmitter GABA, by promoting the binding of this neurotransmitter to its receptors.

It has the same sedative, anxiolytic, muscle relaxant and anticonvulsant properties as diazepam. The duration of action is 6–10 hours, and is longer than that observed with diazepam. The usual IV dose is 0.04 mg/kg. The maximum dose that can be administered is 2 mg intravenously and 4 mg intramuscularly. The bioavailability on intramuscular injection is better and more predictable than with diazepam. The dose however as with diazepam needs to be titrated and individualized depending on the response. In status epilepticus, the drug is given in a dose of 0.1 mg/kg IV up to 4 mg per dose. The dose may be repeated every 10 minutes till seizures stop. It can also be given as a slow infusion of 4–8 mg/hour in 500 mL of normal saline. Currently lorazepam is preferred to valium in the management of status epilepticus.

The side effects are exactly similar to those observed with diazepam. However, venous thrombosis is infrequent with the use of lorazepam.

MIDAZOLAM

The main advantage of this drug over diazepam is its very short duration of action. It is also two to three times more potent than diazepam. On IV use, its action starts within 1 minute, peaks in 5 minutes, and lasts for 30–120 minutes. The drug has a short plasma half-life of 1.5–3 hours. Its metabolism is through mitochondrial oxidation in the liver, and its half-life (as with the other benzodiazepines) is significantly prolonged in liver cell dysfunction.

It is effective both intravenously and intramuscularly in a dose of 0.1 mg/kg, to a maximum of 2.5 mg/kg. Intermittent doses of 2.5–5 mg can be given every 3–4 hours. The drug in some instances can also be given as a slow IV infusion at the rate of 0.5–5 µg/kg per minute. The drug is freely available for use and it appears to have become the benzodiazepine of choice in many ICUs in the West. Its indications are exactly the same as for diazepam, and it has the same side effects. Apnea and severe respiratory depression may occur, particularly in old, feeble patients. Myocardial depression and hypotension are also observed particularly in hypovolemic patients who have received narcotics. A careful watch should be kept on cardiovascular and respiratory function, following its use.

Clinical features of overdosage with benzodiazepines are not uncommon in critical care units. This effect is either due to extreme sensitivity to the drug, or to overuse of the drug. Respiratory depression and hypotension can be life-threatening in some critically ill patients. Flumazenil is the specific antidote for benzodiazepines, and may be given slowly intravenously in a dose of 1 mg. The dose can be repeated up to a total dose of 3 mg.

PROPOFOL (DI-ISOPROPYLPHENOL)

Propofol is both an IV sedative and anesthetic. It is short-acting and rapidly metabolized. When used as sedation, an initial IV dose of 0.5–1 mg/kg is given, followed by an infusion of 25–70 µg/kg per minute. The infusion rate is titrated to the level of sedation required. Patients become awake within 20 minutes of the discontinuation of the drug. The shortness of action and quick arousal after stopping the drug are very similar to that of midazolam.

Propofol comes as a lipid emulsion and strict aseptic technique in administration should be followed for fear of nosocomial infection.

Side effects include hypotension, vasodilation. Sudden death has been reported from metabolic acidosis, particularly in children.[24] Myoclonic jerks have been observed in some patients after drug withdrawal.

BUTYREPHENONES

These drugs inhibit dopamine-mediated neurotransmission in the cerebrum and basal ganglia, resulting in an improvement in abnormal thought patterns; a detachment of the patient from the environment is observed. Haloperidol (the most commonly used butyrephenone) is a useful drug to calm agitated patients. The drug is given parenterally in a dose of 0.5–5 mg; it takes 30 minutes for a full response to be evident. The drug could be repeated if agitation is uncontrolled or recurs. A small maintenance dose at night for 5–7 days may prevent night-time delirium or hallucinations.

Side effects include extrapyramidal signs, dyskinesia and very rarely the neuroleptic malignant syndrome. The drug also causes a prolongation of the QT interval; an electrocardiograph should therefore be monitored, particularly in cardiac patients.

DROPERIDOL

Droperidol is similar to haloperidol but has a greater antiemetic and sedative effect than the latter. It can be combined with opioids to enhance sedation without causing further respiratory depression.

DEXMEDETOMIDINE

Dexmedetomidine is a selective α_2 agonist approved for short-term use in patients receiving mechanical ventilation. It has both analgesic and anxiolytic properties, maintaining easy arousability as well. Side effects include bradycardia and hypotension.

BARBITURATES

They are one of the oldest of sedative hypnotic drugs. They are used chiefly as sedative hypnotics and as anticonvulsants in patients with seizures.

Table 4 lists the IV dose, onset of action, peak action, and duration of action of the commonly used sedatives.

MUSCLE RELAXANTS IN INTENSIVE CARE[25]

Neuromuscular blocking agents are often used in critical care units. They are absolutely indispensable in the management

Table 4: Intravenous dosages, onset of action, peak action and duration of action of commonly used sedatives in the ICU

Drug	*IV Dose*	*Onset of action (min)*	*Peak action (min)*	*Duration of action*
Diazepam	2–10 mg	1–2	2–5	4–6 hours
Lorazepam	0.04 mg/kg	1–5	60–90	6–10 hours
Midazolam	0.1 mg/kg	1–2	2–5	0.5–2 hours
Propofol	1–2.5 mg/kg (maintenance dose 50–150 µg/kg/min)	<1	1–2	5–10 mins
Haloperidol	0.15 mg/kg*	1–5	60–90	4–8 hours

*IM dose

of severe tetanus, and following major neurosurgery, or a head injury where restlessness, agitation and straining are to be controlled, and where sedation is contraindicated for various reasons. Neuroparalytic agents are also indicated in status epilepticus which is uncontrolled or poorly controlled with the usual sedatives and antiepileptics. Mechanical ventilator support is mandatory in patients receiving neuroparalytic agents.

Perhaps the most frequent use of neuroparalytic agents in the ICU is to help in mechanical ventilator support in patients who continue to clash severely with the machine. In such instances, effective ventilation becomes impossible. Neuroparalytic agents should however only be used if all obvious correctable causes of a clash between the patient and the machine are carefully excluded. These causes have been discussed in the Chapter Mechanical Ventilation in the Critically Ill, and include incorrect ventilator settings, hypoxia, alveolar hypoventilation, a blocked airway, pneumothorax, airways obstruction and a decreased compliance of the lungs due to edema, pneumonia or atelectasis. There are however a number of patients where asynchrony between the patient and the ventilator is due to either uncontrolled agitation, or to a strong respiratory drive. The latter is most frequently observed in severe intrinsic lung disease (as in acute lung injury), and can only be abolished by the use of muscle relaxants. The use of inverse ratio mechanical ventilation in acute lung injury also often necessitates the use of muscle relaxants for proper ventilator support. Sedation, and relief of discomfort, pain and agitation with diazepam or narcotics, often enables the physician to offer ventilator support, without ultimately resorting to neuroparalytic drugs.

A patient paralyzed by a neuroparalytic agent has a feeling of extreme helplessness and dependency which leads to fear and anxiety. The use of benzodiazepines as sedatives and anxiolytic agents is mandatory in all such patients, as also the use of an analgesic for pain relief.

DEPOLARIZING AGENTS

Succinylcholine

This is the only clinically available depolarizing neuromuscular blocking agent. On IV administration it acts within 60 seconds, and has a short duration of action (5–10 minutes). It acts by binding to postsynaptic cholinergic receptors causing persistent depolarization and muscle paralysis. The drug however stimulates all cholinergic receptors, including autonomic ganglia, post-cholinergic nerve endings, and cholinergic receptors in the vessel walls.

The following side effects can be observed with succinylcholine—

- Bradycardia sometimes leading to sinus arrest. This is usually seen after administration of a single large bolus dose, or following a second dose of the drug, given approximately 5 minutes after the first dose.
- Persistent muscle fasciculation. This can cause a hyperkalemia which at times can lead to arrhythmias. Hyperkalemia is enhanced in burns, following trauma, crush injuries, and following cerebrovascular accidents. Succinylcholine is therefore best avoided in these conditions.
- Malignant hyperthermia can be triggered following its use.
- A rise in intragastric pressure, which could cause regurgitation of gastric contents, and aspiration pneumonia.
- Increase in intraocular pressure.

The main use of succinylcholine in a critical care setting is to permit endotracheal intubation, when clenching of the jaw or increased muscle tone makes laryngoscopy impossible. The dose used is 1–2 mg/kg intravenously.

NON-DEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS

These agents bind competitively to the postsynaptic cholinergic receptors at the neuromuscular junction, and prevent depolarization of the muscle by acetylcholine. They thereby induce a paralytic state in all voluntary muscles. The drugs chiefly in use are pancuronium, atracurium, vecuronium and rocuronium.

Pancuronium

This is the main neuroparalytic agent easily available in poor countries. It is a long-acting water-soluble, steroidal non-depolarizing agent which is excreted mainly by the kidneys (90%). Its renal clearance depends on the glomerular filtration rate. The drug is also metabolized and broken down into less active metabolites in the liver (10%).

It is administered in a bolus dose of 2–6 mg intravenously (0.06–0.08 mg/kg). Muscle relaxation is observed in 3–4 minutes, and lasts for 40–120 minutes. The intubating dose is 0.08–0.12 mg/kg. Besides its neuroparalytic effect,

pancuronium causes histamine release and has a mild vagolytic effect. It is unnecessary to aim for complete or total paralysis with this drug. The dosage should be titrated in such a manner as to enable the physician to achieve his objective. This does not always necessitate total paralysis. The drug can also be given as a continuous infusion through an infusion pump. We prefer the bolus method because it allows constant easy assessment of the patient, and in our opinion, a better titration of the dosage and frequency of administration of the drug, particularly when used over a long period of time.

Pancuronium in clinical practice has little effect on the cardiovascular system. However, after prolonged use (as in severe tetanus), each bolus dose may be followed by a transient drop in blood pressure due to histamine release. The elimination half-life of the drug is 90–160 minutes, and this is significantly prolonged in patients with hepatic or renal dysfunction. The dosage should be suitably reduced and carefully titrated in these conditions, else it can result in prolonged paralysis.

We have used this drug in patients with severe tetanus for as long as 6–8 weeks, with comparatively few or no side effects.

Atracurium

Atracurium is a non-depolarizing neuromuscular blocking agent, benzylisoquinolinium that has an intermediate duration of action. Renal or hepatic dysfunction does not prolong its half-life; the drug is therefore safer to use when compared to pancuronium in renal or hepatic disease.

The IV dose in adults is 0.5 mg/kg. The onset of action is within 2 minutes, peak action occurs in 3 minutes, and the total duration of action is 20–60 minutes. IV administration should be slow; a rapid bolus can cause significant histamine release and hypotension. It can be given by continuous infusion at a rate of 0.3–0.6 mg/kg per hour; in most instances, recovery is rapid once the infusion is stopped. It is recommended for prolonged neuromuscular paralysis as in tetanus. It is however more expensive than pancuronium.

Vecuronium

Vecuronium is an intermediate acting monoquarternary analog of pancuronium. Its great advantage is that it provokes no histamine release, has no vagolytic effects, and its use is therefore associated with a very stable cardiovascular system. The drug is chiefly metabolized by the liver, and is partially excreted by the kidneys.

In adults, the drug is administered intravenously in a dose of 0.1 mg/kg. Its action starts within 2 minutes, peaks in 3–5 minutes, and duration of action lasts for 20–30 minutes. A continuous infusion of the drug is recommended in patients needing prolonged paralysis. The dose needs to be suitably reduced in patients with hepatic or renal dysfunction. Patients with cardiac disease do not require any adjustment in dosage. In patients with hepatic or renal disease, the duration of its effect may be variable and unpredictable.

Rocuronium

Rocuronium is an intermediate acting steroidal neuromuscular blocking agent. The intubating dose is 0.6–0.8 mg/kg and the duration of action is between 20–40 minutes. It is primarily eliminated by the liver and it is very useful in hemodynamically unstable patients in the ICU.

OTHER NON-DEPOLARIZING NEUROPARALYTIC AGENTS[4]

These include doxacurium, pipecuronium, mivacurium and cisatracurium. Doxacurium and pipecuronium resemble pancuronium, but do not affect the cardiovascular system. Mivacurium has the shortest duration of action, its effect lasting for just 15–20 minutes. We have no experience with these drugs.

COMPLICATIONS FOLLOWING THE USE OF MUSCLE RELAXANTS

Total or near total paralysis can induce fright and panic, hence the imperative need to use sedatives and anxiolytic agents in patients who are given muscle relaxants.

Pulmonary Complications

Paralyzed patients cannot cough. Secretions need to be carefully aspirated through the endotracheal tube or tracheostomy. Suction is often used in conjunction with expert physiotherapy to prevent atelectasis from retained secretions.

Neuromuscular Dysfunction

Delayed recovery from induced paralysis and neuromuscular dysfunction can occur after prolonged use of muscle relaxants.[26] The following clinical syndromes are observed.

The first is a myopathy producing the clinical picture of flaccid quadriparesis. It is typically observed in severe asthmatics receiving high dose corticosteroids and who have been given muscle relaxants during ventilator support. Flaccid paralysis, increased creatinine kinase levels in blood, myonecrosis and slow recovery that can take several months characterize the clinical picture. Pancuronium, atracurium, vecuronium have all been reported to produce this syndrome. Steroid dose and the dose of muscle relaxants should be kept to a minimum. The creatinine kinase level in the blood should be monitored and if the concentration increases, the muscle relaxant should as far as possible be stopped. The incidence of myopathy in asthmatics on both steroids and muscle relaxants, in our experience is between 10% and 20%; the higher the dose of these drugs the greater the risk.

The second syndrome is a motor neuropathy without myopathy, following the long-term use of vecuronium and pancuronium. The neuropathy involves both upper and lower limbs, producing weakness, wasting of muscles and absent

Box 1: Complications associated with the use of muscle relaxants

1. Ventilator failure or circuit disconnection can cause disaster if not promptly recognized
2. Pulmonary complications—
   - Inability to cough—atelectasis
   - Pulmonary infection
   - Retained secretions—atelectasis
3. Prolonged paralysis after stopping muscle relaxant—
   - Persistent neuromuscular blockade
   - Steroid-associated myopathy
   - Motor neuropathy
   - Neuromuscular dysfunction
   - A combination of the above
4. Immobility—
   - Pressure sores
   - Peripheral nerve injuries
   - Deep venous thrombosis
   - Pulmonary embolism

tendon reflexes. Weaning from mechanical ventilation is delayed and recovery may take weeks or even months.

A third syndrome observed following prolonged use of pancuronium or vecuronium is motor weakness of the limbs which on an electromyography (EMG) is related to failed neuromuscular transmission. Recovery occurs over several months.

Finally, a mixed neuromyopathic syndrome may be observed. Notwithstanding the above description, we have been singularly fortunate in using pancuronium for prolonged periods of time in severe tetanus, without significant side effects.

Many sophisticated ICUs find it helpful to titrate the requirement and dose of muscle relaxants by the use of a peripheral nerve stimulator, with assessment of train-of-four (TOF) responses.[27] This is a luxury we have dispensed with. Clinical judgment invariably suffices in adjusting both the dose and the frequency of administration.

Box 1 lists the common complications associated with the use of muscle relaxants in the ICU.

REVERSAL OF NEUROMUSCULAR BLOCKADE

Depolarizing agents have no specific antagonists. Neuromuscular block caused by non-depolarizing drugs can be reversed by anticholinesterase drugs. The drugs commonly used are neostigmine (0.06 mg/kg), pyridostigmine (0.2 mg/kg) and edrophonium (0.5 mg/kg). Atropine (0.01 mg/kg) is given simultaneously to counter the muscarinic side effects of these anticholinesterase drugs.

Sudanimex is a new antagonist of drugs causing nondepolarizing blockade. It is the first selective relaxant binding agent. It produces rapid and effective reversal of even more profound rocuronium induced muscular blockade. Sudanimex is ineffective against succinylcholine and benzylisoquinolinium, neuromuscular blockers such as atracurium, mivacurium and cisatracurium.

Critical Care of the Transplant Patient

- Critical Care of the Transplant Patient

CHAPTER 73

Critical Care of the Transplant Patient

INTRODUCTION

Organ transplantation is an increasingly prevalent form of management in end-organ disease. Renal transplant, heart transplant, lung transplant, heart and lung transplant, liver transplant, and pancreas transplant are the solid organ transplants being practiced in large centers in all Western countries, as also in a few countries in the East. In India, many centers have been carrying out renal transplants for several years. Liver transplants are being performed in special centers in Delhi, Chennai and Hyderabad with results as good as those reported in the West. Mumbai lags behind, but hopefully will do better in the next few years. Heart transplants, heart and lung transplants, and single lung transplants, barring isolated exceptions are unfortunately not being done on an organized scale. There is hope that they too will slowly start to increase in numbers in the years to come. Stem cell transplantation is in a way slightly different from solid organ transplants, and is also being done in few centers in the country.

The reason for organ transplant surgery not keeping pace with countries in the West is twofold. Earlier on, the law in our country did not legally recognize brain death, thereby sharply reducing the donation of heart, lungs, liver and pancreas for transplant purposes. Fortunately, good sense dawned on our lawmakers, and by an act of parliament, brain death has been accepted as a legal definition of death since 1994. There is also a lack of social awareness of the need to donate organs under the right circumstances to save lives. This social awareness has unfortunately yet to be cultivated in our country. The infrastructure and organization necessary for the use of cadaver transplants in India is being increasingly better organized. It is to be ardently hoped that ethical safeguards for donor organs are strictly formulated and followed.

This chapter gives an overview of the critical care of patients receiving solid organ transplants. It deals only with the principles of renal, liver and single lung transplant postoperative care. We have no experience with critical care of patients with heart or both heart and lung transplants. We have included some basic features of critical care of lung transplant recipients because there was one successful lung transplant done at the Hinduja Hospital in Mumbai, and there is hope that more will follow. Even so, there are basic problems common to all solid organ transplant surgeries. These are briefly dealt with below.

There are three major groups of complications in organ transplantation that determine outcome.[1] These complications are common to all solid organ transplants. They include—

1. Technical complications resulting from the surgical procedure of the graft implant and other postoperative complications.
2. Complications due to the effect of immunosuppressive therapy, to poor graft function, or to rejection of the graft.
3. Complications due to infection.[2]

Technical problems are generally observed in the early postoperative period, within the first 10–12 days. Rejection primarily occurs later between 10 and 60 days or even later. Side effects of immunosuppressive drugs can occur early or late. Infectious complications can occur any time after transplant surgery, due to active suppression of the immune system. However, the pattern of infection in these patients in the early postoperative period (1–30 days) is different from the pattern observed in the period from 1 month to 4 months or even later.

Not all patients with organ transplantation require critical care. Renal transplants are not routinely managed

in the intensive care unit (ICU), unless age, background disease or complications discussed below necessitate close monitoring or critical care management. On the other hand, heart transplant, heart and lung transplant, lung transplant, liver transplant and pancreas transplant, all need critical care for a varying period of time after surgery. Many patients may also require critical care in the pre-transplant period for a varying length of time. A preoperative assessment in all potential transplant recipients begins with a proper history, physical examination, electrocardiography (ECG), X-ray chest, a full biochemical and blood profile, and also blood and tissue typing. Patients with evidence of coronary artery disease undergo a more thorough cardiac evaluation, which includes a two-dimensional (2D) echocardiography, and when indicated, a coronary angiography. Critical lesions in the coronaries should be preferably corrected before performing, for example, a renal transplant. Similarly, endoscopy is indicated if there is a history suggestive of peptic ulcer, and transplant surgery is delayed till the ulcer has healed. The assessment of compliance is an important preoperative feature of organ transplant surgery. A work-up prior to transplant surgery includes a study of Hepatitis B and C viral (HBV and HCV) markers, other viral titers, which should include antibodies for the cytomegalovirus (CMV) both in the recipient and donor, tests for human immunodeficiency virus I (HIV I) and HIV II, urine culture, and cultures of a throat swab.

General contraindications for transplant surgery include malignancy, sepsis, manifest HIV infection which has not been correctly treated, history of drug abuse, hepatitis, noncompliance and advanced disease in an organ system, other than the one being considered for transplant.

IMMEDIATE POSTOPERATIVE CARE

The postoperative management of a transplant patient follows the general principles of postoperative care with special reference to monitoring functions of the organ transplanted. Heart, lung and liver transplants will require mechanical ventilation for at least 24 hours. Nasogastric suction through a nasogastric tube is required for intra-abdominal transplants and in patients on ventilator support. Enteral feeds are started as soon as gut function returns.

The emphasis on laboratory data or on other investigational procedures will depend on the organ transplant that has been done. Serial chest X-rays are important in the early postoperative period to assess the lung fields, and to check the placement of various lines and tubes. Common prophylactic measures include the use of antacids or sucralfate to protect against stress ulcers and the ulcerogenic effect of corticosteroids. Parenteral antibiotics in very good units are chiefly used perioperatively for adequate antibacterial cover. Many units in the West use antifungal agents for oral *Candida* prophylaxis, trimethoprim-sulfamethoxazole for prophylaxis against *Pneumocystis carinii,*[3] and ganciclovir for the first 3 months to prevent CMV infection in solid organ transplants. Immunosuppressive therapy is a mandatory postoperative feature of all organ transplant regimes.

CRITICAL CARE IN KIDNEY TRANSPLANT RECIPIENTS

The transplanted kidney is usually placed extraperitoneally in the recipient's right or left iliac fossa with end-to-side anastomosis to the external iliac vessels. It can however also be placed intraperitoneally either in the right or left iliac fossa. The transplanted ureter is reimplanted into the recipient's bladder in a manner to prevent ureteric reflux. Though most patients after renal transplant surgery are managed in the wards, complications arising after surgery may need critical care. The complications may occur in the immediate postoperative period (1–10 days) or a little later (10 days to 1 month) or later still (1–6 months or more). These have been briefly discussed below.

COMPLICATIONS OF RENAL TRANSPLANT SURGERY[3-5]

Urological Complications[6]

Improvement in surgical techniques has sharply reduced the incidence of postoperative urological complications. Currently urological complication rates are 4–8% with a very low mortality rate.

- Urine leaks and urinomas are rare complications and occur during the first few postoperative days (technical problems) or, at the most, in the first few weeks (ureteric necrosis). Extravasation of urine may occur from the renal pelvis, but more often occurs from the ureter at the ureteroneocystostomy site due to ureteric necrosis caused by vascular insufficiency, or to increased urinary pressure caused by obstruction.

Urinomas are usually found between the transplanted kidney and the bladder; they may however occur in unexpected sites as in the labia or the scrotum. A significant urinary leak leads to a decrease in urine output and a wrong diagnosis of graft failure may be entertained. Clinical signs include fullness and tenderness around the graft, swelling of the ipsilateral leg, or scrotal or labial edema.

On ultrasonography, a urine leak appears as a well-defined anechoic fluid collection, which is observed to increase in size fairly rapidly. Drainage of the urinomas with ultrasonographic guidance and estimation of the creatinine content of the fluid proves the diagnosis. Computed tomography (CT) scans, nephroscintigraphy and retrograde cystography are other investigative modes that can prove and outline the extent of a urinary leak.

Minor leaks may spontaneously resolve with Foley's catheter decompression. Recipients with large leaks in the early postoperative period are best explored with reimplantation of the ureter into the bladder.

Large urinomas may rupture to produce urinary ascites, or get infected to form an abscess. A urinoma may also track upward through pores in the diaphragm into the right pleural space.

- Mild hematuria from the distal ureter or the cystostomy is often seen in the immediate postoperative phase, but generally stops within 12–24 hours. Hematuria may, however, lead to a clot formation in the bladder, which in turn can lead to an obstructive uropathy with well-nigh cessation of urine output. Obstructive uropathy is the most common cause of new onset anuria in the immediate postoperative period and should be promptly treated with catheter irrigation. If anuria persists, a Doppler ultrasound should be done to ensure patency of the renal artery and vein, and also rule out a large hematoma causing an obstructive uropathy.
- Hematomas and lymphoceles are early post-transplant complications. They can cause an obstructive uropathy or can compress the iliac veins leading to leg edema and venous thrombosis.
- Ureteric stenosis is a late complication occurring months after transplant. Ureteric stenosis may be secondary to rejection, infection, ischemia or a tight ureterocystostomy. Hydronephrosis is present and detected on ultrasonography. A percutaneous nephrostomy helps to elucidate the location and degree of the ureteric stenosis. A balloon dilatation and placement of a temporary stent generally solves the problem.

Vascular Surgical Complications Leading to Graft Dysfunction and Failure[6]

Vascular complications are surgical complications and occur in the early postoperative period, at times even in the immediate postoperative period. They include vascular thrombosis either involving the renal artery or renal vein. The incidence of vascular thrombosis is from 0.7% to 5%, but it always results in a loss of the graft. The striking clinical feature of *renal artery thrombosis* is a sudden fall in urine output and rise in creatinine. Salvage is only possible if the vascular thrombosis is discovered within the first few hours. If several hours have elapsed, salvage is unlikely and a nephrectomy of the transplant becomes necessary.

Renal artery stenosis can result from the presence of intimal flaps, preimplantation arterial or graft damage, size discrepancy between donor and recipient vessels and hypotension or hypoperfusion during surgery.

Renal vein thrombosis can be caused by kinking of the anastomosis, injury, pressure on the veins due to fluid collection (urinoma, hematoma and lymphocele) or may occur as an extension of iliofemoral vein thrombosis. It usually occurs within the first few days after transplant surgery. It is characterized by the sudden onset of pain, swelling over the graft, hematuria, and if due to extension of an iliofemoral vein thrombosis, it is associated with swelling and edema of the lower limb. A Doppler ultrasound reveals a pulsatile renal artery with reversal of blood flow surrounded

by a hematoma. If thrombosis of the renal vein is total, a nephrectomy is necessary. If the thrombosis is incomplete, a successful thrombectomy may save the graft. As an alternative, thrombolysis with urokinase or treatment with heparin is recommended.

Early Graft Dysfunction

Medical problems that can lead to early graft dysfunction are acute tubular necrosis (ATN), acute rejection and recurrence of kidney disease.

Acute tubular necrosis[4] Acute tubular necrosis is the most common cause of impaired renal function in the immediate postoperative period. It may be observed immediately after revascularization or may have a slightly delayed onset. ATN may last from several days to as long as 6 weeks. The most frequent cause of ATN is prolonged ischemia to the graft. Donor factors, such as age, hypertension, use of vasopressors during procurement of the graft or during the transplant surgery may also contribute to the complication. Ischemia, ischemia-reperfusion injury, drug nephrotoxicity and acute infection are other factors that could precipitate ATN. It has a detrimental effect on later graft function, overall graft survival and on postoperative morbidity.[7] Measures to prevent graft rejection in this early period include volume expansion, avoidance of nephrotoxic drugs and minimizing calcineurin inhibitors during the peritransplantation period. If delayed graft function persists, a biopsy of the transplant kidney is performed within the first 3 weeks of transplantation.

The differential diagnosis of ATN is from other causes of acute oliguria or anuria. The most important differential diagnosis is renal artery or renal vein thrombosis. A Doppler ultrasound can easily establish the integrity of the circulation and blood flow through the renal artery and vein.

Hemodialysis needs to be continued in patients with ATN till such time as graft function recovers. Recovery occurs in over 95% of recipients. If delayed graft function persists, a biopsy of the transplant kidney is performed within the first 3 weeks of transplantation.

Acute or hyperacute rejection of the graft Acute or hyperacute rejection of the graft though rare does occur. Acute antibody-mediated rejection leads to a quick decline in early graft function. It is caused by allo- and autoantibodies formed in the recipient following pregnancy or following blood transfusions received earlier by the recipient because of an earlier organ transplant. These preformed antibodies can target capillary endothelium, activate complement resulting in a quick destruction of the graft. Only a biopsy of the graft can confirm the diagnosis, which should be followed by a surgical removal of the graft. A detailed description of the acute rejection syndrome is outside the scope of this book.

Recurrence of kidney disease[8,9] Acute kidney diseases do not generally recur. Focal segmental glomerulosclerosis (FSGS) can however recur and cause severe early graft dysfunction. Proteinuria more than 3.5/day in a recipient with known FSGS should prompt biopsy of the graft.[8] Similarly, a hemolytic uremic syndrome (HUS) can recur in a transplant kidney or it may even occur de novo in a transplant kidney. The use of tacrolimus, cyclosporine (calcineurin inhibitor) has been implicated when the HUS occurs de novo.[9]

Later Graft Dysfunction-Rejection

Though acute or hyperacute rejection of the renal transplant can occur within the first 10 days, it is much more frequently observed between 10 days and 1 month of surgery. In fact, rejection leading to graft dysfunction is the major complication in this period. There are, however, other important causes of graft dysfunction and it is vital to determine whether the dysfunction is related to rejection or to other causes. Oliguria following a renal transplant can be due to different etiologies. A careful and quick diagnostic evaluation should distinguish between rejection and other causes so that correct management can be promptly instituted. A diagnostic work-up of oliguria after renal transplant surgery is given in Flowchart 1.

A confirmed diagnosis of rejection is best made on histological grounds. An early histological diagnosis of rejection can lead to a suitable modification of immunosuppressive therapy and result in improved graft survival. However, in some renal transplant centers, a diagnostic biopsy is not performed before the first treatment for rejection with corticosteroids. Most centers do a diagnostic biopsy before a second course of treatment or before using antilymphocytic preparations. In renal transplant patients, cyclosporine therapy can unfortunately cause renal dysfunction indistinguishable from renal dysfunction induced by rejection. The need for a kidney biopsy and its correct interpretation helps to distinguish between these two important causes of poor function of a renal graft.

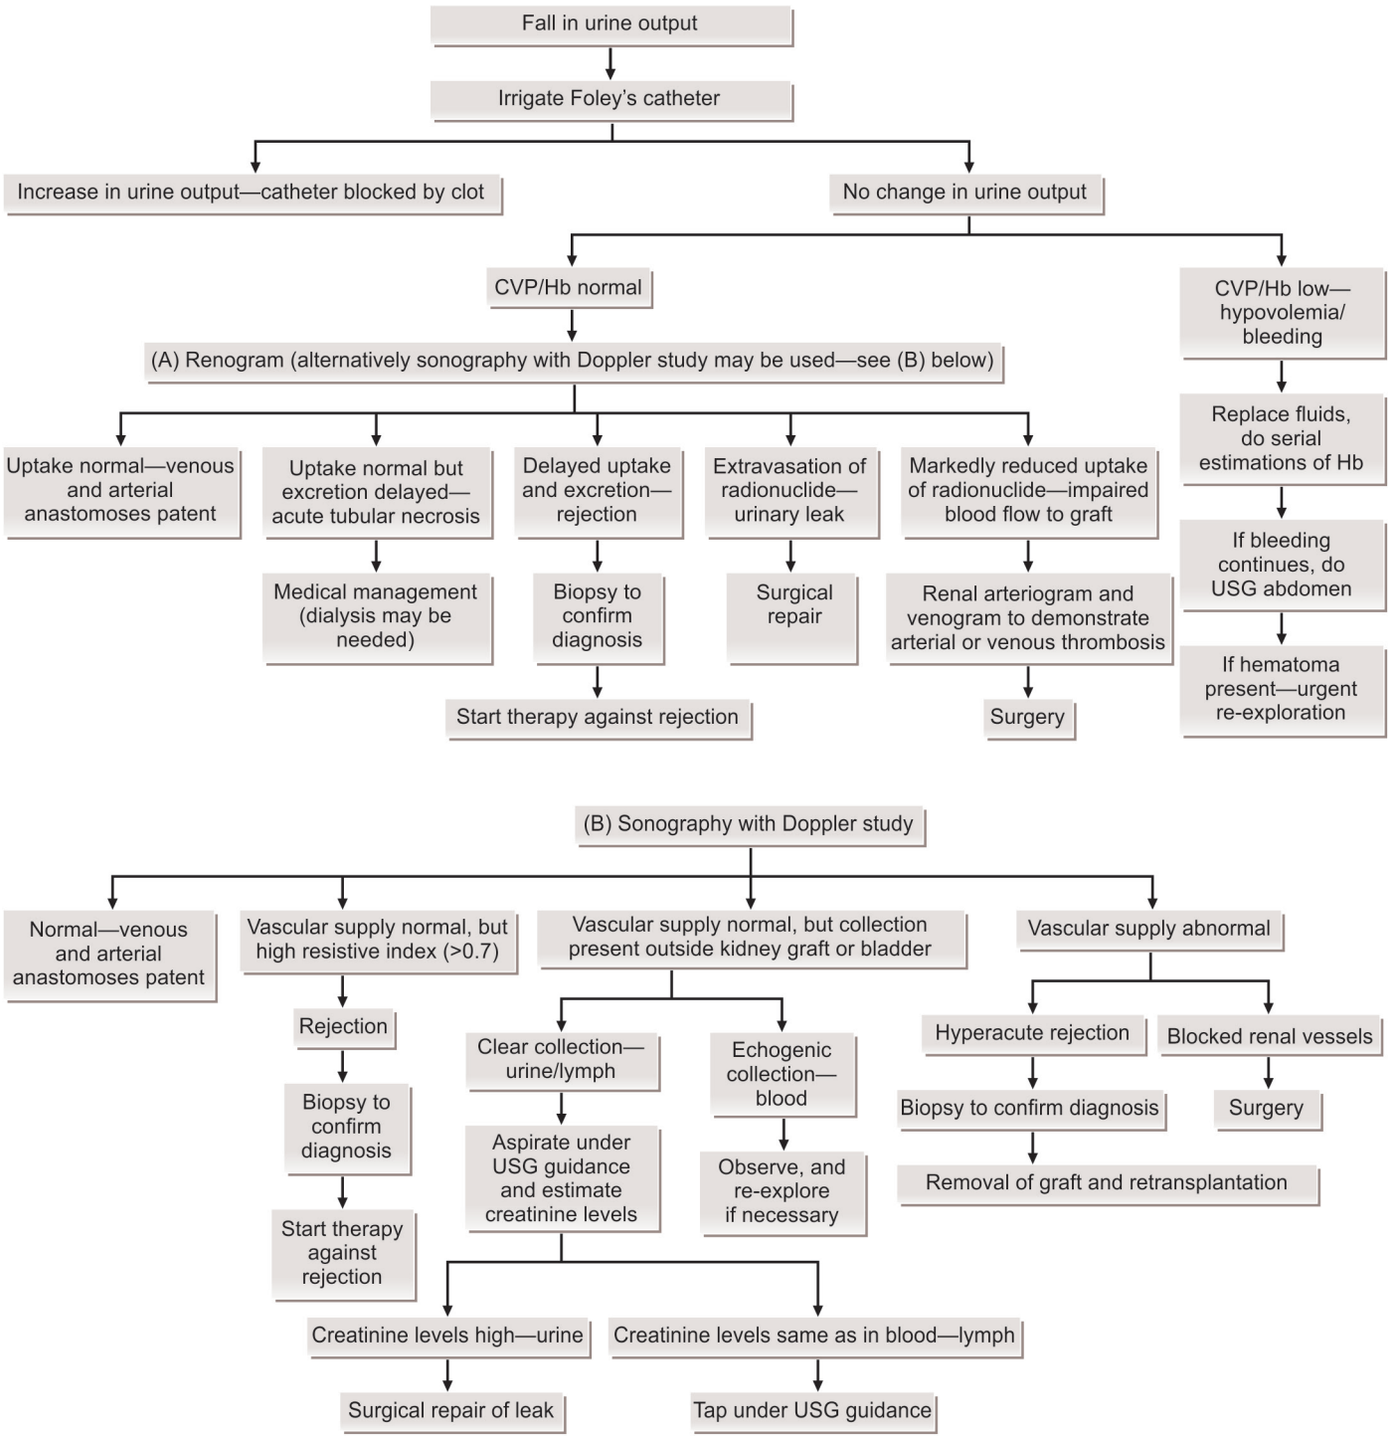
Treatment of acute rejection Treatment consists of the administration of a brief course of high dose corticosteroids [methyl prednisolone 500 mg intravenous (IV) everyday for 3 days). This is followed by the use of oral corticosteroids (0.5–1 mg/kg)] daily for several weeks, slowly tapered to a maintenance dose which is kept at a higher level compared to the preacute rejection period. In most cases, urine output improves, renal blood profile is rectified and serum creatinine is significantly reduced.

Occasionally some patients require a second course of IV steroids or a longer course of increased oral steroid therapy.

It is important to note that ganciclovir prophylaxis (5 mg/kg twice daily) tapered over 6 weeks must be given on initiating anti-rejection therapy for all patients with CMV-disparate DIR status.

Treatment of chronic rejection Chronic rejection is observed later in the natural history of a renal transplant in the 1–6 months period after transplant surgery or any time after 6 months. It is particularly observed in patients who have

Flowchart 1: Approach to postoperative oliguria in a patient with renal transplant: (A) using a renogram, and (B) using sonography with Doppler study



Fall in urine output
Irrigate Foley's catheter
Increase in urine output—catheter blocked by clot
No change in urine output
CVP/Hb normal
CVP/Hb low—hypovolemia/bleeding
(A) Renogram (alternatively sonography with Doppler study may be used—see (B) below)
Replace fluids, do serial estimations of Hb
Uptake normal—venous and arterial anastomoses patent
Uptake normal but excretion delayed—acute tubular necrosis
Delayed uptake and excretion—rejection
Extravasation of radionuclide—urinary leak
Markedly reduced uptake of radionuclide—impaired blood flow to graft
If bleeding continues, do USG abdomen
Medical management (dialysis may be needed)
Biopsy to confirm diagnosis
Surgical repair
Renal arteriogram and venogram to demonstrate arterial or venous thrombosis
If hematoma present—urgent re-exploration
Start therapy against rejection
Surgery
(B) Sonography with Doppler study
Normal—venous and arterial anastomoses patent
Vascular supply normal, but high resistive index (>0.7)
Vascular supply normal, but collection present outside kidney graft or bladder
Vascular supply abnormal
Rejection
Clear collection—urine/lymph
Echogenic collection—blood
Hyperacute rejection
Blocked renal vessels
Biopsy to confirm diagnosis
Aspirate under USG guidance and estimate creatinine levels
Observe, and re-explore if necessary
Biopsy to confirm diagnosis
Surgery
Start therapy against rejection
Removal of graft and retransplantation
Creatinine levels high—urine
Creatinine levels same as in blood—lymph
Surgical repair of leak
Tap under USG guidance

failed to respond adequately to treatment of acute rejection. It presents as a dysfunction of the transplant kidney, leading to progressive renal failure. Chronic rejection is outside the purview of critical care and is treated generally on an outpatient basis.

Unfortunately, there is no satisfactory treatment for chronic rejection of solid organ transplants including kidney transplants. Retransplantation is the only solution to this problem.

Infectious Complications[10]

Infections in the immediate postoperative period are bacterial and are similar to those observed following other major surgery. Wound infections, nosocomial pneumonia, urinary

sepsis related to urinary catheters or infections introduced through central lines are all observed. Gram-negative and staphylococcal infections are most frequently observed. When compared to other solid organ transplants, kidney transplant recipients have the lowest incidence of pneumonia; even so, pneumonia occurs in about 16% of patients and has a mortality of 10%.[4] In the first post-transplant month, the organisms responsible for pneumonia are Gram-negative bacteria (*Klebsiella*, *Escherichia coli, Pseudomonas*) and staphylococci. Though fungal infections (*Candida* and *Aspergillus*) are more often observed after the first month (between 1 month and 6 months), they may occur earlier in patients on a more intensive immunosuppressive regimen or in patients who have received prolonged antibiotic therapy. Bacterial pneumonias are sometimes caused by multidrug-resistant organisms, extended spectrum beta lactamases, methicillin-resistant *Staphylococcus* and vancomycin-resistant Enterococci.

The most common postrenal transplant infection is a urinary tract infection (UTI) with an incidence of 30% during the first 3 months after transplant surgery. UTIs can lead to pyelonephritis and bacteremic sepsis, generally caused by Gram-negative infections.

Most patients undergoing kidney transplants are on hemodialysis and have an indwelling catheter, arteriovenous fistula or arteriovenous graft, all of which could be the source of blood stream infection, generally due to Gram-negative infections.

Opportunistic infections generally occur between 1 month and 6 months of transplant surgery. In developing and poor countries where tuberculosis is endemic, tubercular infection is perhaps the most common and the most important infection to surface after transplant surgery. It can occur at any time frame after transplant surgery but is more often observed after the first month onward. The most frequent site is the lung and the most common mode of presentation is a pyrexia of unknown origin (PUO). A CT chest is mandatory as radiography of the chest may fail to detect the lesion.

Among opportunistic infections, the ones most commonly observed between 1 month and 6 months (after tuberculosis) are viral infections, fungal infections, nocardial infections and cryptococcal infections. *Pneumocystis jirovecii* is observed in the late post-transplant period and causes an interstitial pneumonia. Since the use of trimethoprim/sulfamethoxazole (TMP/SMX) prophylaxis, the incidence of *P. pneumonia* has declined significantly.

The most important viral infection generally occurring between 1 month and 6 months after transplant is CMV infection.[11] The two diagnostic tests in current use are—

- A polymerase chain reaction (PCR) quantitative assay.
- An antigenemia assay based on the identification of the late structural protein pp65.

The clinical features and management of CMV infections are discussed elsewhere.

Other viral opportunistic infections are those due to herpes simplex virus (HSV), varicella zoster virus (VZV) and the Epstein-Barr virus (EBV). EBV infections can present with mononucleosis like symptoms with fulminant widespread post-transplant lymphoproliferative disease—a form of B-cell lymphoma.

Fungal infections are generally due to *Candida* species and *Aspergillus* infections.[12] Oropharyngeal candidasis is the most common fungal infection. Systemic fungal infections (candidiasis, disseminated aspergillosis or *Aspergillus* infection of the lung) are particularly noted in patients on significant immunosuppression or on broad spectrum antibiotics. Systemic fungal infections with respect to their diagnosis and management have been described separately elsewhere.

Nonrenal Post-transplant Complications

Nonrenal post-transplant complications include complications in relation to the following—

Cardiovascular System

Left ventricular failure, congestive cardiac failure, ischemic heart disease, hypertension, hypotension and pericarditis have all been observed.

Respiratory System

Pulmonary edema and ARDS. ARDS is more likely in recipients with poor initial graft function and in those receiving antilymphocyte globulin for inducing immunosuppression. The mortality of ARDS in these groups of patients is well over 50%.

Metabolic Complications

These include fluid and electrolyte disturbances, notably hyperkalemia. Copious diuresis immediately post-transplant may result in hypokalemia. Hypomagnesemia and hypophosphatemia can also occasionally occur following copious diuresis seen immediately post-transplant. Hypomagnesemia is related to drug-related renal wasting (related to the use of cyclosporine, tacrolimus, diuretics and amphotericin B). Hypophosphatemia is secondary to loss of phosphates in the urine caused by secondary hyperparathyroidism; the use of glucocorticoids and antacids contributes to hypophosphatemia.

CRITICAL CARE OF THE LIVER TRANSPLANT RECIPIENT

Liver transplantation is the standard treatment for patients with end-stage liver disease and acute liver failure. Currently, the survival rate after transplantation is 90–95% at 1 year and 70% at 5 years.[1]

Results in India today at the best centers in the country are as good as those reported from the United States.[2] In spite of these encouraging figures, liver transplantation carries with it a significant morbidity. The risk of developing complications and therefore the associated increase in morbidity and mortality is not just related to the inherent major surgical procedure that liver transplantation entails. It is related to the patient's preoperative state of health, the quality of the donor liver, initial graft function and peri- and postoperative anesthetic, and intensive care management.[3]

POSTOPERATIVE CIRCULATORY INSTABILITY[4]

Graft function depends not only on intrinsic recovery of hepatic cell function, but also on hemodynamic stability. Hypovolemia, pulmonary edema and deterioration in gas exchange within the lung can all adversely affect graft function and contribute to increased morbidity and mortality. Hypotension is commonly observed at or soon after surgery. Hypovolemia is an important cause. Acidosis, electrolyte disturbances, hypothermia, underlying ischemic heart disease may adversely affect cardiac function and further hemodynamic instability. Multiple blood transfusions may lead to citrate-induced hypocalcemia and could further depress circulation. Volume loss is often underestimated because of hemorrhage, sequestration of fluid into the third space and continuing formation of ascites. Subclinical pulmonary edema is frequently observed in the first 24 hours after transplantation. The quick relief of vasodilatation following transplantation increases the afterload of the heart and is an additional factor contributing to impaired cardiac function.

The potential cardiac and circulatory instability make it imperative that the postoperative condition is carefully monitored and that measures are taken to maintain or restore an adequate cardiac output, a stable circulatory system and well-preserved pulmonary function to ensure adequate blood supply and oxygenation to the graft.

Monitoring should involve an estimation of the preload and afterload of both right ventricle (RV), left ventricle(LV), cardiac output, central venous pressure (CVP), pressure in the pulmonary artery, intrathoracic blood volume (ITBV) and lung edema index (extravascular lung water). The application of the thermodilution single indicator (PiCCO) system is a monitoring system that allows the above as also other relevant hemodynamic parameters to be monitored.[5] Optimizing cardiac output will help to avoid excessive fluid administration and will prevent both pulmonary edema and congestion within the hepatic sinusoids. A persistent vasodilatory state after surgery may necessitate the use of a judicious combination of fluid plus inotropes and/or vasopressors. Failure to increase systemic vascular resistance or to reduce inotropic/vasopressor support is believed to indicate a poorly functioning graft.

POST-TRANSPLANT SURGICAL COMPLICATIONS

Postoperative Hemorrhage

Bleeding is common in the postoperative period and is due to several causes. Five percent of patients may require a re-exploration to control bleeding in spite of improved postoperative ICU care. Bleeding is from the large raw area left after removing the recipient liver, from collaterals secondary to portal hypertension, and to ongoing coagulopathy due to disturbances in coagulation, fibrinolytic and platelet function. The coagulopathy is further compounded by multiple blood transfusions that may have been necessary. Fresh frozen plasma (FFP), cryoprecipitate need to be given, as also platelet transfusions. Hyperfibrinolysis present during the operative period may continue postoperatively and may necessitate the use of aprotinin.

Vascular Complications

Vascular complications occur in 3–5% of patients.[3] Thrombosis is the most common early complication; stenosis, dissection and pseudoaneurysm formation are less frequent. The hepatic artery is most commonly involved, though any of the vessels involved in vascular anastomosis may be involved.

Hepatic artery thrombosis is the most common vascular complication, the reported incidence being 3–5% in adults and 5–8% in children.

Thrombosis of the hepatic artery in the very early post-operative period leads to acute hepatic necrosis. There is a marked rise in the liver enzymes, septic shock, encephalopathy and overall rapid deterioration. Doppler ultrasound confirms the diagnosis. Prompt exploration and anastomosis is done if the diagnosis is made early.[6] If hepatic necrosis is extensive, a retransplant is indicated.

Hepatic artery thrombosis may present in a less dramatic fashion. The donor bile duct receives its blood supply from the hepatic artery; bile duct ischemia results. The presentation is with a biliary leak, hepatic abscess, cholangitis, sepsis or an evolving biliary stricture. These patients ideally require a retransplant. Till such time as an organ is available, the bile duct needs to be stented.

Hepatic Artery Stenosis

Hepatic artery stenosis occurs in 10% of cases.[3] It can lead to biliary ischemia and hepatic dysfunction. Doppler ultrasonography usually establishes the diagnosis.

Portal Vein Thrombosis and Stenosis

Portal vein thrombosis (PVT) is less frequently observed, occurring in about 2% of patients. Clinical presentation varies. When PVT occurs early, it results in severe liver dysfunction. Ascites develops quickly and variceal bleeding results from raised portal and mesenteric venous pressures. A Doppler ultrasound can assess the patency. Patients with severe liver cell dysfunction need an emergent transplant.

Portal vein thrombosis can also be managed by thrombolysis, anticoagulation and stenting.[7] If PVT occurs late, liver function is usually preserved. Management is conservative with systemic anticoagulation.

Portal vein stenosis (PVS) is an uncommon complication. It should be suspected if there is an increased portal vein pressure on a Doppler ultrasound. PVS is treated by balloon dilatation of the vein or a surgical reanastomosis.

Hepatic Venous/Caval Complications

Hepatic venous thrombosis, stenosis (Budd-Chiari syndrome) is rare, with an incidence of 1% in deceased donor liver transplant and 1–10% in live donor transplant.[8] Presentation is usually with increasing ascites, graft dysfunction and occasionally edema and renal dysfunction. Doppler ultrasound usually demonstrates the hepatic vein thrombosis or stenosis; the findings can be confirmed by a venacavogram.

Balloon dilatation with or without stent placement is the treatment for hepatic vein/caval stenosis.[9] Anticoagulation is required if recurrence of the Budd-Chiari syndrome is to be prevented. Urgent retransplantation is warranted if hepatic venous blood flow is completely or almost completely obstructed.

Biliary Complications

Biliary complications occur in 10–15% of patients.[3] They are generally due to devascularization of the bile duct, technical faults during difficult biliary reconstruction and biliary leaks from the cut surface of a partial liver transplant.

Biliary Leaks

Biliary leaks generally occur within the first 10 days after transplant from the anastomotic site. The leak is due to dehiscence of the bile duct at the anastomotic site related to surgical dissection, which impairs blood supply around that site, or to hepatic artery thrombosis.

Less frequently biliary leaks may occur later than 3 months after transplantation and are usually due to persistence of earlier complications or a late hepatic artery thrombosis.

Anastomotic leaks can be successfully treated in most cases by endoscopic stenting if the leak is localized without major biliary spillage. An intra-abdominal bile collection (biloma) is managed by an ultrasonography (USG) or CT-guided drainage.

If the anastomosis is markedly disrupted or if there is a large biliary leak, surgical revision becomes necessary.

Biliary Strictures

Biliary strictures account for about 30% of biliary complications. They occur most commonly at the anastomotic site due to local ischemia or to technical error. Nonanastomotic strictures can also occur; diffuse intrahepatic narrowing of bile ducts is rare, but carries a worse prognosis. Biliary stricture results in a cholestatic jaundice. Cholangitis may be the presenting feature with fever, leukocytosis and right hypochondriac pain. Cholangitis in liver transplant patients may also be present in the absence of the systemic features described above. USG may be misleading as biliary duct dilatation may not be seen. Cholangiography is the diagnostic test which should always be performed to confirm the presence of a biliary stricture. The treatment of an anastomotic biliary stricture is by percutaneous or endoscopic balloon dilatation and placement of a stent across the stricture. The long-term success rate is close to 70%.

Nonanastomotic strictures resulting from hepatic artery thrombosis have a poorer prognosis. Dilatation of the stricture with stenting should be considered as a bridge to liver transplantation.

Treatment of diffuse intrahepatic strictures is unsatisfactory. Balloon dilatation and stenting of major strictures should be attempted as a palliative measure. Retransplantation is generally required.

Wound Complications

Wound complications are common in liver transplant patients. The most common wound complications are infection and hematoma formation. Direct wound contamination may occur from bile or bowel contents if a bilioenteric anastomosis has been done. Hematomas can form because of large collaterals in the abdominal wall and because of underlying coagulopathy.

Wound infections generally present toward the end of the first week. The infection may cause obvious symptoms and signs, such as fever, leukocytosis, erythema and a purulent discharge. At times, symptoms and signs may be minimal. Treatment of wound infections is the same as in non-transplant patients. Systemic antibiotics may be necessary in some patients.

POST-TRANSPLANT MEDICAL PROBLEMS

Medical problems after transplant fall into the following groups. Problems may arise: (1) due to side effects of immunosuppressive drugs used to prevent graft rejection; (2) due to the residual effects of liver failure which disappear when the graft starts to function well; (3) dysfunction of the transplanted liver and (4) other complications following surgery. These could involve almost any organ system within the body.

Primary Nonfunction of the Transplanted Graft

Technical complications like vascular and biliary complications described earlier can lead to a non-functioning or

poorly functioning graft. However, a dreaded complication after liver transplant surgery is a primary non-functioning (PNF) graft. PNF graft is defined as a syndrome that results from poor or no hepatic function from the time of surgery. It occurs in less than 5% of transplants and has 80% mortality.[10]

The etiology of PNF is not known. Donor risk factors that have been associated with PNF include advanced donor age, increased fat content of the donor liver, prolonged cold ischemia (>18 hours) and reduced size grafts.

The clinical features of PNF are an unstable, clinical condition after hepatic perfusion has been re-established. The patient is hemodynamically unstable, there is increasing acidosis, persistent coagulopathy, poor bile production and poor color of the liver graft. The patients remain unconscious in the ICU; liver cell function is markedly impaired judged by a prothrombin time greater than 20 seconds 4–6 hours after the transplant, increasing hypoglycemia, marked rise in serum transaminases (>5000 IU-L) and persistent coagulopathy. It is important to make an early diagnosis and distinguish PNF from hepatic artery thrombosis, acute or hyperacute rejection of the graft and infection.

The treatment of PNF graft is unsatisfactory. Recipients with a diagnosis of PNF should be on a continuous infusion of prostaglandin E 1 (PGE 1) starting with 0.005 mg/kg per minute increasing if well tolerated to a maximum of 0.03 mg/kg per minute. PGE 1 acts by dilating the splanchnic vascular bed thereby allowing better perfusion of the graft. The drug probably also has an immunomodulatory effect. Ultimately, the patients do far better with a retransplant. The latter should be done early before multiple organ failure develops.

21

Rejection

Hyperacute rejection is uncommon, but the diagnosis should be entertained if graft failure occurs during the first post-transplant week. Acute rejection on the other hand is common after a liver transplant; 30% of patients suffer at least one bout of rejection after 1 week post-transplant. Clinical features of acute rejection are often mild fever, malaise, a rise in serum bilirubin and transaminases is generally observed. A mild asymptomatic disturbance of liver cell function may at times be the presenting feature. The diagnosis is proven by a percutaneous biopsy of the liver graft. Mild rejection is treated by increasing the dose of immunosuppressants. Moderately severe or severe rejection (as judged by histology) should receive IV methyl prednisolone 500 mg daily for 3 days followed by oral prednisolone 0.5–1 mg/kg to start with slowly reduced to a maintenance dose.

Small for Size Syndrome

The diagnosis of small for size syndrome (SFS) is based on hyperbilirubinemia and massive ascites during the early post-transplant phase without evidence of any technical problems.[11] The pathophysiology of the syndrome is hepatocyte damage secondary to portal hyperperfusion. Patients with SFS have a higher incidence of renal, pulmonary and septic complications.

COMPLICATIONS INVOLVING DIFFERENT ORGAN SYSTEMS

Neurological Complications

Decreased conscious level is very often due to the use of sedatives and narcotics. Metabolic encephalopathy due to fluid and electrolyte disturbances, renal insufficiency, and poorly functioning graft could also result in a decreased conscious level. Prolonged postoperative hypotension may result in hypoxic ischemic encephalopathy with obtundation and cognitive impairment.

Fluctuations in serum sodium levels can cause a central pontine myelinolysis; a diagnosis which can be proved by a magnetic resonance imaging (MRI) of the head.

Postoperative generalized seizures can complicate the course of the first 2 weeks of the postoperative period. Seizures could be due to metabolic problems, drugs, cerebrovascular accidents or infective pathologies in the brain (meningitis, encephalitis and brain abscess).

Neurotoxic side effects of calcineurin inhibitors include tremors, mental changes, focal neurological and visual disturbances. Posterior reversible encephalopathy syndrome (PRES) is an uncommon, but well-known complication of immunosuppressive therapy and solid organ transplantation.[12] The syndrome is due to reversible vasogenic edema chiefly involving the occipital cortex, but also involving other areas of the cerebrum. The diagnosis of PRES can be promptly made on an MRI of the head. The calcineurin-inhibitor drug should be stopped immediately.

Cardiovascular Complications

Most intraoperative cardiovascular (CVS) complications occur immediately after reperfusion of the liver. These include arrhythmias, ischemic changes, fluctuations in blood pressure and occasionally cardiac arrest.

The postreperfusion syndrome[13] is characterized by a decrease in the mean arterial blood pressure by at least 30% for 1 minute within the first 5 minutes. Rarely hypotension and bradycardia worsen, and may lead to cardiac arrest. Ventricular tachycardia and ventricular fibrillation have also been described in the early reperfusion phase.

A rare postoperative complication is acute right ventricular failure secondary to severe pulmonary hypertension.[14] The pulmonary hypertension in these patients must have been present prior to the transplant as an uncommon complication of portal hypertension. The underlying pathology in the pulmonary vasculature is a plexiform angiopathy.

Respiratory Complications

Pulmonary complications are invariably present. Early complications during the first week include pleural effusion,

pulmonary edema, atelectasis and ARDS. Complications due to infections predominate after the first week.

Hypoxemia should always be looked out for; all the conditions listed above could cause hypoxemia. Hypoxemia is also present in patients with the hepatopulmonary syndrome.[15] The syndrome is associated with portal hypertension, and is characterized by dyspnea, cyanosis, clubbing and orthorexia. The hepatopulmonary syndrome is reversed in the majority of cases after liver transplantation.

Renal Complications

Renal dysfunction is very common after a transplant. Ten percent have severe renal failure requiring dialysis. Renal failure whether pre- or post-transplant increases the mortality rate of transplant surgery.

Prerenal and renal causes account for most of the renal dysfunctions observed after surgery. Acute tubular necrosis may result from hypotension and prolonged ischemia. Post-transplant new-onset hepatorenal syndrome occurs as a primary manifestation of severe graft dysfunction and often indicates the need for an urgent retransplant.

Once renal dysfunction is diagnosed, diagnosis should be directed to the cause. Hypovolemia should be corrected, hypotension countered by inotropes or vasopressor after correcting the volume status. It is important to avoid nephrotoxic drugs. If renal function worsens, renal support may be necessary in the form of hemodialysis or continuous venovenous hemofiltration (CVVH). Indications for CVVH or hemodialysis include—

- Volume overload with pulmonary edema.
- Persistent worsening hyperkalemia.
- Persistent or worsening metabolic acidosis.

Infectious Complications

Infections[3,16] Incidence of infections is the highest after liver transplants when compared to other organ transplants. This is related to—

- The massive lengthy surgery.
- The poor condition of the recipient before the transplant.
- The potential for biliary and enteric contamination.

All attempts should be made to prevent infection. Prophylactic antibiotics against biliary tract pathogens are important. Other prophylactic drugs include trimethoprim-sulfamethoxazole against pneumocystis infection, acyclovir or ganciclovir against CMV and other herpes family viruses, and fluconazole/voriconazole against fungal infections. Scrupulous attention to central lines, arterial lines and aseptic suction of respiratory secretions through the endotracheal tube is of crucial importance.

As with all other organ transplants, infections during the first month after transplant are chiefly bacterial, but CMV infections may occur even during the first month. Bacterial infections usually involve the abdominal wall and the abdominal cavity. Wound infections, cholangitis, intra- or extra-hepatic abscesses and peritonitis are important intra-abdominal complications. Bacterial pathogens often originate either from the biliary tract or from the small bowel at the time of surgery, or later following a biliary leak or a biliary stenosis. Nosocomial pneumonia may occur particularly if the patient is on ventilator support for a long time.

From 2 to 6 months (at which time immunosuppression has been obtained through immunosuppressive drugs) after a liver transplant, opportunistic infections may necessitate admission to the ICU. Viral infections are frequent particularly CMV infection. Overall, this is the most common microorganism responsible for post-transplant infections. Though it classically appears after the first month, it may well be responsible for infection during the first month. The graft from a seropositive donor transplanted into a seronegative recipient, multiple blood transfusions and the use of anti-lymphocytic serum are risk factors for CMV infection. In the absence of prophylaxis, CMV infection occurs in 23–83% of patients though only 10–30% will develop disease. CMV infection is associated with increased incidence of graft loss and increased post-transplantation mortality.

Other viral infections between the second and sixth months include EBV, recurrence of HCV and adenovirus infections. Fungal infections are also observed. Infections due to *pneumocystis, candida, aspergillus* species and *Cryptococcus* should always be kept in mind.

Mycobacterial infections, either *Mycobacterium tuberculosis* or atypical mycobacteria, are important infections in developing poor countries where tuberculosis is highly endemic.

After the sixth month of surgery, ICU admissions are for acute infections common to non-transplanted patients. Infections in this period affect mainly the respiratory tract and are caused chiefly by the *Pneumococcus* and *Haemophilus influenzae.*

Management

It is important to identify the site of infection and the organism causing the infection. A low-grade fever may be the only manifestation of infection. A careful physical examination, laboratory tests, culture of blood and other body secretions and imaging studies generally allow a correct diagnosis. Treatment depends on the nature and site of infection. At times, particularly when dealing with serious infections, empiric therapy is necessary. Drug interactions between certain antibiotics chosen for treatment and immunosuppressive drugs should be kept in mind.

Gastrointestinal Complications

Gastrointestinal infections include—

- *Gastrointestinal bleed* Upper gastrointestinal (GI) bleeding can be due to several causes—stress, use of steroids, gastroesophageal varices and peptic ulcer disease. Bleeding from varices generally settles down

quickly; if persistent, a portal venous thrombosis is a strong possibility and needs investigation. Ulcerations of the GI tract may be due to infections, esophageal candidiasis and CMV infection.

Lower GI bleeding may be due to infective colitis caused by *Clostridium difficile* or CMV infection. These infections may also cause persistent diarrhea.

- *Ileus* is a common postoperative complication which settles down with time. Intra-abdominal infection is an important cause of ileus.
- *Bowel perforation* is a rare complication. Either the small or large bowel may be involved. Symptoms and signs are often not prominent, probably because of the use of corticosteroids and immunosuppressants. Early diagnosis and surgical repair is crucial. Even so, the mortality is high.

CRITICAL CARE OF THE LUNG TRANSPLANT RECIPIENT

Lung transplantation (single, double lung and heart-lung) is now an established procedure in the West. Major technical complications following lung transplantation are therefore increasingly uncommon due to improvement in surgical techniques and peri- and postoperative management.

Complications following lung transplant surgery are considered under three heads—

- Early complications occurring 0–10 days after surgery.
- Complications in the intermediate postoperative period (10 days to 1 month).
- Late complications (1–6 months).

COMPLICATIONS IN THE IMMEDIATE POSTOPERATIVE PERIOD (0 TO 10 DAYS)

Technical Problems and Other Early Postoperative Complications—

- *Postoperative hemorrhage* severe enough to require re-exploration is indeed rare.
- *Pulmonary artery obstruction* due to anastomotic stenosis or external pressure. Pulmonary hypertension results and this may be the cause of hypoxia.
- *Left atrial anastomotic obstruction* because of faulty anastomotic technique can lead to pulmonary hypertension and unilateral pulmonary edema. CT pulmonary angiography should confirm this diagnosis. Re-exploration and correction of the anastomosis may be necessary.
- *Pleural complications* though not uncommon are of minor significance. These include: (1) pneumothorax which requires intercostal tube drainage. Pneumothorax arising from the lung graft is worrisome as it may denote airway dehiscence being responsible for a communication between the airway and the pleural space; (2) pleural effusions are common, particularly if there is a size disparity between the donor lung and the thorax. Pleural effusions are managed conservatively.
- *Airway complications* The most common airway complication is related to bronchial ischemia. This is because the donor bronchus has to rely entirely on collateral perfusion from the pulmonary circulation in the initial post-transplant period. The airway complications that ensue are partial or complete bronchial dehiscence, bronchial stenosis and bronchial infection. The clinical features of bronchial dehiscence are a persistent air leak observed in the early post-transplant period. Infection at the anastomotic site can lead to peribronchial inflammation, peribronchial abscess or fistula. Bronchoscopy is the preferred method of evaluating bronchial anastomosis. Appropriate antibiotics and/or antifungals should be used if there is evidence of infection corroborated by culture studies. Bronchial dehiscence or infection can lead later to bronchial stenosis. There is progressive increase in airway obstruction, both clinically and on lung function tests. Bronchial stenosis is relieved by balloon dilatation and stent placement. Cryotherapy has also been used; rarely surgical reconstruction becomes necessary.
- *Myocardial infarction* is generally due to pressure overload during the implantation procedure and can be prevented in most patients by promptly initiating cardiopulmonary bypass.
- *Atrial arrhythmias* are common; *ventricular arrhythmias* may also occur. They are managed in the usual fashion.

Complications due to Immunosuppression

Immunosuppression protocols by and large are the same for all solid organ transplants. The complications related to immunosuppression are also therefore similar. At times, the occurrence of dysfunction of the transplanted organ causes difficulty in the evaluation of complications produced by the immunosuppressive drugs. The early side effects of immunosuppressive drugs are renal and neurologic dysfunction due to cyclosporine, hyperglycemia, mental changes, and acute gastroduodenal erosions due to corticosteroids, and leukopenia, and thrombocytopenia from antilymphocyte preparations.

Infectious Complications

Infections in the immediate postoperative period are bacterial, and are similar in nature to those observed following other major surgery. Wound infection, nosocomial pneumonia, urinary sepsis related to urinary catheters, or infection introduced through central lines are all observed.

Bacterial infections are treated with appropriate antibiotics, and by removal of lines that may have triggered the infection. Many units in our part of the world use prophylactic antibiotics after transplant surgery. The danger of superinfection with resistant organisms must always be kept in mind following unnecessary and wrong use of powerful antibiotics.

Bacterial pneumonia is the most commonly acquired infection after lung transplantation and is generally due to Gram-negative infection. It can occur in the early postoperative period, as also at any time during the first 2 months. New pulmonary infiltrates either in the transplant lung or native lung require aggressive evaluation. Flexible bronchoscopic examination and culture of bronchoalveolar lavage (BAL) fluid, and if thought necessary culture of protected brushings are often necessary for diagnosis. Besides routine cultures, smear and culture for acid-fast bacilli (AFB) and fungal cultures should also be sent for.

Gastroesophageal reflux can be an important cause of recurrent aspiration pneumonia, particularly in chronic

Table 1: Degree of postgraft dysfunction

Grade	PaO_2/FiO_2	Radiological findings
1	>400	No
2	>300	Yes
3	200–300	Yes
4	<200	Yes

obstructive pulmonary disease (COPD) patients. Proton pump inhibitors, sucralfate and a propped up position are important for prevention.

Complications with Regard to Graft Function

Postgraft Dysfunction[1]

Postgraft dysfunction (PGD) is perhaps the most serious postoperative problem after lung transplant surgery. Some degree of PGD is observed in 80% of lung transplant patients; it is severe in 15% of patients.[2] This complication occurs hours to within 3 days after lung transplant (LT) and must be distinguished from infection and rejection which occur well after 24 hours. PGD can persist for hours to as long as 8 days after LT.

The syndrome of PGD[3] is characterized by a disturbance in gas exchange which may be sufficiently marked to cause well marked hypoxia. The radiological features include interstitial plus alveolar edema. There is a lowered pulmonary compliance and an increase in pulmonary vascular resistance. In severe cases, a radiographic examination of the chest shows a total or "white out" of the lung, the pathology of which is diffuse alveolar damage.

The degree of PGD can be graded on the basis of gas exchange abnormalities and radiological findings (Table 1).

Management[4]

- Patients who have marked gas exchange abnormalities with the radiological features of acute lung injury or ARDS need ventilator support with the usual lung protective strategies. Inhalation of nitric oxide is reported to decrease both hypoxia and pulmonary hypertension in these patients.
- Extracorporeal membrane oxygenation (ECMO), high frequency ventilation and differential lung ventilation have been used in very severe cases.
- Retransplant has been done on an emergency basis when conservative management has failed, but with very poor outcome.
- Instillation of bovine surfactant immediately after the establishment of the bronchial anastomosis has shown improved oxygenation, reduced incidence of PGD and enhanced post LT recovery.

Several risk factors may predispose to PGD. These include disruption of lymphatics, nerves, bronchial vasculature during surgery, lung injury during preservation or during lung surgery, use of cardiopulmonary bypass, prolonged ischemic time, and use of blood products.

Rejection of the Graft

There are three types of rejections: (1) hyperacute; (2) acute and (3) chronic.

Hyperacute rejection is rare, and if it occurs, does so in the early postoperative period. Hyperacute rejection is mediated by existing antibodies that attach themselves to the endothelium of the blood vessels within the donor lung. Activation of complement causes thrombosis of the vessels with quick rejection of the lung transplant graft.

Acute rejection Though acute rejection may occur in the early postoperative period, it generally does so 10–90 days after LT and is therefore considered later.

COMPLICATIONS IN THE INTERMEDIATE POSTOPERATIVE PERIOD (10 DAYS TO 1 MONTH)

Technical Complications

Though complications due to technical procedures or faults during surgery manifest in the immediate post-transplant period, they may occasionally do so after 10 days. These complications have already been listed earlier and do not require repetition. Complications with regard to various organ systems in the immediate postoperative period may also manifest in the intermediate postoperative period (10 days to 1 month).

Rejection

Acute Rejection

Acute rejection generally occurs from 10 days to 1 month after surgery. It may however occur up to as long as 90 days after lung transplantation. Fifty percent of patients, however, experience it within the first operative month. In fact rejection is the major complication in this period. It leads to graft dysfunction and it is vital to determine whether the dysfunction is related to rejection or to other causes such as infection.

The clinical features of acute rejection of a lung transplant are fever, malaise, cough and increasing breathlessness. The radiological abnormalities observed include a hilar flair, interstitial and/or alveolar shadows, generally diffuse, but occasionally localized, and the presence of a pleural effusion. The pleural fluid is an exudate with predominant lymphocytes. Acute rejection causes hypoxia with a lowered PaO_2 and deteriorating lung functions, characterized by a fall in the forced expiratory volume in the first second (FEV_1), and in the mid and late expiratory flow rates. A transbronchial biopsy shows characteristic perivascular and subendothelial mononuclear cellular infiltrates. A lymphocytic bronchitis or bronchiolitis is also observed. Transbronchial biopsy and a full study of the BAL fluid help to differentiate acute rejection from lung infection. The transbronchial biopsy is assessed according to the degree of perivascular infiltrate present and the degree of airway inflammation (Table 2).[5,6]

Table 2: Classification and grading of pulmonary allograph rejection

Acute rejection	
Grade A0	None
Grade A1	Minimal
Grade A2	Mild
Grade A3	Moderate
Grade A4	Severe
Airway inflammation-lymphocytic bronchitis/bronchiolitis	
B0	No airway inflammation
B1	Minimal airway inflammation
B3	Moderate airway inflammation
B4	Severe airway inflammation
BX	Ungradeable because of sampling problem; infection rate

A confirmed diagnosis of rejection is best made on histological grounds. In both heart and lung transplant, a histological diagnosis of rejection can be made at a point in time when clinical and other functional parameters are barely or only slightly altered. An early histological diagnosis of rejection can therefore lead to a suitable modification of immunosuppressive therapy and result in improved graft survivals. Surveillance transbronchial biopsy is recommended at 3 weeks, 6 weeks, 3 months, 6 months, 9 months and 12 months after surgery for both heart, lung and isolated lung transplant. This is because rejection can occur with minimal clinical symptoms or signs. Also clinical symptoms and signs and/or a fall in FEV_1 can be due to other causes besides rejection, as for example, following infection. Bronchoscopy, a BAL study and a transbronchial biopsy may therefore be necessary for other reasons as well.

Treatment of acute rejection Treatment consists of administration of a brief course of high dose corticosteroids (methyl prednisolone 500 mg IV daily for 3 days). In most patients lung function and radiographic improvement occurs in 48–72 hours. The intravenous (IV) therapy is followed by oral prednisolone (0.5–1 mg/kg per day) for several weeks, the dose being gradually tapered ultimately to prerejection levels. The dosage of immunosuppressants in use should also be suitably increased. Occasionally some patients require a second course of IV steroids therapy. If clinical features of rejection persist in an LT patient in spite of the above, a repeat bronchoscopy for BAL and a transbronchial biopsy is advised. In patients who have features of a persistent acute rejection, cytolytic therapy with OK T3 and antithymocytic globulin (ATG) should be considered.

It is important to note that ganciclovir prophylaxis (5 mg/kg twice daily tapered over 6 weeks) must be given on initiating antirejection therapy for all patients with CMV disparate D/R status.

Infection

Bacterial infection mentioned in the immediate postoperative period can continue up to 1–2 months after surgery. Bacterial pneumonia is an important complication after lung transplant.[7] It is generally due to Gram-negative bacteria and responds to antibiotic therapy. Depending on the microorganisms involved, aerosolized antibiotic therapy may also help.

Cytomegalovirus infection[7-9]can also occur during this period of time after a solid organ transplant. The incidence of CMV transplant is related to the serological status of both donor and recipient. Recipients who are negative for CMV and receive a CMV negative solid organ transplant should not develop CMV infection, provided they are not transfused with CMV positive blood products. Recipients positive for CMV who receive a CMV positive donor transplant generally rarely develop CMV infection because of their preoperative immunity. However, if a CMV positive recipient receives a solid organ transplant from a seronegative donor, reactivation of the recipient's CMV can cause CMV infection in the donor transplant. Again if a CMV negative recipient receives a transplant from a seropositive donor, reactivation of CMV in the donor transplant may well occur. In both the last two scenarios systemic CMV infection with a CMV viremia may result. In some of these immunosuppressed patients the serology for CMV may be negative though the PCR for CMV may be strongly positive.[9] Systemic CMV infection[7,8] is a potentially fatal infection characterized by fever, pneumonia, hepatitis, chorioretinitis and hemorrhagic colitis. The incidence of CMV infection in transplant patients has been significantly reduced by: (1) the prophylactic use of ganciclovir before, during and after transplant surgery; (2) the use of blood products which do not show the presence of CMV infection and (3) testing for CMV infection both in the recipient and donor through a serological test. Treatment of CMV infection has been dealt within a separate chapter.

Oral candidiasis[10] is not infrequently observed following the use of broad spectrum antibiotics and the use of immunosuppressants. Candidal esophagitis and fungal infections of the urinary tract are also observed. Topical antifungal agents can be used as prophylaxis against oral candidiasis. Fluconazole is of use in oral moniliasis and candidal esophagitis. It can, however, cause an elevation of cyclosporine levels, which need to be carefully monitored. There are a number of antifungal agents available for systemic use in patients with invasive candidiasis. Amphotericin B is the drug most frequently used in poor developing countries. It should, however, be noted that systemic fungal infections generally do not occur within the first month of transplant surgery unless induced by the prolonged use of broad spectrum antibiotics to treat bacterial infection, or the use of high dose steroids as a counter to acute rejection.

LATE COMPLICATIONS AFTER LUNG TRANSPLANT SURGERY (1 TO 6 MONTHS OF LUNG TRANSPLANT SURGERY)

A detailed discussion of late complications is outside the purview of this chapter as these do not generally merit critical care. However, acute rejection when it occurs late or chronic rejection may occasionally necessitate intensive care.

Technical Complications

Bronchial stenosis may manifest at this point in time and has already been discussed.

Rejection

As mentioned earlier, acute rejection occurs generally between 10 days and 1 month after surgery. It may appear later. *Chronic rejection* may be observed particularly in patients who have failed to respond adequately to treatment for acute rejection. Chronic rejection of the lung graft[11] is synonymous with bronchiolitis obliterans (BO).[12] This entity is characterized by cough, breathlessness and an otherwise unexplained fall in expiratory flow rates.[13]

Bronchiolitis obliterans, also called obliterative bronchiolitis is defined clinically by severe airways obstruction and histologically by obliteration of the terminal bronchioles.[11-13] It is the single leading cause of death more than 1 year after transplantation. It generally occurs 16–20 months after surgery, but has been reported to occur as early as 3 months after transplantation. Its incidence ranges between 35% and 50%.[11-13]

The most consistent risk factor is acute rejection, particularly acute rejection with an incomplete response to treatment, or recurrent acute rejection. Other risk factors include CMV infections, other community-acquired viral infections, gastroesophageal reflux disease, PGD, human leukocyte antigen (HLA) mismatches, older donor age and bronchiolitis obliterans (BO) with organizing pneumonia.[13]

Clinically BO may exhibit no clinical symptoms and is then diagnosed on lung function tests by the presence of airways obstruction, a lowered FEV_1 and reduced mid-expiratory flow rates. When it does produce symptoms, it generally manifests as an upper respiratory infection, with fever, cough and breathlessness, and is not uncommonly mistaken for one.[11,12]

An X-ray chest may not be of help, but CT chest may help in diagnosis. Air trapping during expiration in a high resolution computed tomography (HRCT) of the chest is a sensitive sign. HRCT of the chest may also show decreased peripheral vascular marking, tree in bud appearance, mosaicism and bronchial dilatation.[11,12]

Transbronchial biopsy is used both for diagnosis and to exclude other causes. The diagnosis is often not proven by a transbronchial biopsy. The International Society of Heart and Lung Transplantation (ISHLT) has established a staging system for BO.[12] This system is based on reduction in the FEV_1 of more than 20% from the baseline after transplantation and a fall in the FEF 25–75% with or without pathological changes observed on a transbronchial biopsy.[12]

Treatment of BO is high dose IV methyl prednisolone followed by tapering doses of oral corticosteroids. ATG, OKT, alemtuzumab, basiliximab are tried in patients who do not respond. *The purpose of treatment is to stabilize the rejection phase as long as possible.* Methotrexate, sirolimus, aerosolized cyclosporine, total lymphoid radiation and newer immunosuppressants have been tried with the above purpose in mind.

There is no permanent cure for chronic rejection. Retransplantation has been performed with comparatively poor outcome.

Complications due to Immunosuppresion

The chronic complications of immunosuppressive drugs during the late phase are cyclosporine nephrotoxicity, hypertension, lymphomas and skin cancer. The most common malignancy seen after lung transplant is B-cell lymphoid proliferation termed post-transplant lymphoproliferative disorder (PTLD) which appears to be related to EBV infection. When it occurs within one year of the transplant, the disease is localized and responds to a temporary reduction in immunosuppressants. If it occurs after a year of the transplant, if does not respond to reduction in immunosuppressants and needs cytotoxic therapy. The mortality for lymphoma in these patients is 70%.

Infection[14,15]

Tuberculosis and opportunistic infections predominate after 1 month of transplant surgery. In our part of the world, tuberculosis is the most frequently observed infection. It generally presents as a PUO and may be difficult to prove. Pleural effusion, lymphadenopathy within the chest or abdomen are most often due to tuberculosis. Investigations include a BAL study for AFB in patients with obscure lung shadows, and imaging studies to detect mediastinal hilar or intra-abdominal adenopathy. A therapeutic trial with antituberculosis drugs is at times necessary when all investigations have drawn a blank.

Important opportunistic organisms[14,15] causing infections in this phase are fungal infections (in particular, aspergillosis), *Nocardia, Pneumocystis carinii* infection, *Toxoplasma* and cryptococcal infections. Possible viral infections include CMV, HCV, EBV and papavoadenovirus.[7] Prophylaxis with trimethoprim-sulfamethoxazole is advised to prevent *P. carinii* infection. Flowchart 2 illustrates the time span for different infections following transplant surgery.

Flowchart 2: Time span for occurrence of common infections in the organ transplant recipient

IMMUNOSUPPRESSION THERAPY IN ORGAN TRANSPLANTS[1-3]

Immunosuppressive drug regimes have been responsible for the great success of transplant surgery, and for the long-term survival of transplants. The critical care physician must be aware of the side effects of these drugs for two reasons—firstly they may be serious enough to necessitate critical care; secondly they need to be distinguished from other complications that follow transplant surgery.

The most important immunosuppressive drug in use today is cyclosporine. The drug is almost always used in combination with prednisolone. Some centers also add azathioprine to this immunosuppressive combination. A triple drug regime is often used in the hope that side effects from any one drug are lessened, and the combination may have an additive or even synergistic immunosuppressive effect.

IMMUNOSUPPRESSIVE DRUGS

Cyclosporine[4,5]

Cyclosporine is the chief immunosuppressant in use today. It prevents rejection, but is of little use in treating rejection once this has occurred. It is used intravenously in the immediate postoperative period, but, after gut function returns, the drug is given orally. IV administration carries a greater risk of nephrotoxicity than the oral use of the drug. The drug inhibits the production of intrarenal prostaglandins, and thereby induces renal vasoconstriction. The IV drug dosage can be profitably reduced by the use of antilymphocytic preparations in the early post-transplant period. This schedule prevents rejection, and will allow the kidneys to recover function after surgery.

Sandimmune is the original oil-based cyclosporine preparation. Almost all units use the newer microemulsified preparation, neoral. Sandimmune requires the presence of bile salts for absorption. Neoral is less dependent on bile salts for absorption. Absorption of cyclosporine from the gut may prove a problem after liver transplantation, as bile is diverted from the gut by a T-tube. The drained bile should be refed through the nasogastric tube, thereby allowing absorption of the orally administered drug.

Drugs such as phenobarbitone, warfarin, phenytoin, rifamycin, which increase the activity of the P450 system, lead to increased metabolism of cyclosporine, with inadequate blood levels of the drug. On the other hand, ketoconazole, fluconazole, and erythromycin lead to increased blood levels of the drug.

Cyclosporine levels should be ideally estimated in the blood either by immunoassay or by the high performance liquid chromatography method. The immunoassay method is generally adequate, though it overestimates blood levels of the drug in the presence of cholestasis and jaundice.

The most important side effect of cyclosporine is renal dysfunction. It can occur early in the post-transplant period, and needs to be distinguished from renal dysfunction due to rejection of the graft. A biopsy of the renal graft is generally necessary for this purpose. Other side effects include headache, seizures, myoclonus and hypertension. Gingival hyperplasia, hirsutism and hypercholesterolemia may also be observed. Hyperkalemia is an important side effect, and is related to hypoaldosteronism.

Tacrolimus [6]

Tacrolimus, like cyclosporine, is used to prevent acute rejection. It is protein bound, does not require bile salts for absorption and is given orally. Dose adjustments in patients with renal insufficiency are not necessary. As with cyclosporine, drug interactions between tacrolimus and other drugs can occur, thereby altering the blood level of tacrolimus. Side effects include hypertension, nephrotoxicity, tremors, abdominal pain and hyperglycemia.

Corticosteroids[1]

Corticosteroids are useful both for prevention and treatment of rejection. At surgery a large dose of methylprednisolone 15–20 mg/kg is given. This is progressively tapered to a maintenance dose of 0.1–0.2 mg/kg within 2 months.

The important immediate side effects of corticosteroids are hyperglycemia and mental changes severe enough to cause a psychosis. The hyperglycemia lessens once the steroid dose is reduced; it may however need a titrated dose of insulin for its control. The long-term side effects of corticosteroids are numerous—obesity, cushingoid features, hypertension, osteoporosis, peptic ulcer, premature cataracts and growth retardation in children.

Azathioprine[1]

This is useful in the prevention of rejection, but has no effect once rejection has occurred. Some units use azathioprine in their protocol from the outset; others use it after one episode of rejection has occurred. The major side effects are depression of the bone marrow and liver toxicity. The white blood cell (WBC) count is best kept more than 3,500/mm^3, and the liver functions should be monitored at periodic intervals.

Antilymphocytic Preparations[7,8]

These preparations are antibodies to lymphocytes, whose functions are thereby inhibited. They are used to both prevent and treat rejection. The two preparations available are: OKT3, a monoclonal preparation; and ATG, a polyclonal preparation.

In the immediate postoperative period, these drugs are given in sequential regimens with the purpose of delaying the initiation of cyclosporine therapy. Sequential therapy consists of an initial use of an antilymphocyte preparation, enabling renal function to improve and stabilize after surgery. Cyclosporine is added subsequently. The risk of renal dysfunction due to cyclosporine toxicity in the immediate postoperative period is thereby reduced.[9] This regime was initially used in kidney transplants, but its use has now been extended in some centers to include other solid organ transplants, where renal dysfunction is a possibility due to intraoperative insults, or to pre-existing renal disease. ATG is initially used in preference to OKT3. This is because OKT3 appears to be more effective in treating rejection, and can be given via a peripheral vein on an outpatient basis. The early use of OKT3 may lead to sensitization that may hinder the future efficacy of the drug in treating rejection, if and when rejection occurs.

Antilymphocytic preparations, besides preventing rejection, are used to treat rejection in patients who have not responded to prior steroid therapy. ATG and OKT3 are associated with significant side effects related to cytokine release from lymphocyte activation. These include fever, hypotension, bronchospasm and respiratory failure. The side effects can be controlled by the prior administration of methylprednisolone in a dose of 15–20 mg/kg. The antibodies in ATG can cross react with leukocytes (other than lymphocytes) and platelets, causing leucopenia and thrombocytopenia. A late hazard of antilymphocytic preparations is the development of lymphomas.

NEWER IMMUNOSUPPRESSIVE DRUGS

Several newer drugs are under trial and will probably come into use for post-transplant immunosuppressive therapy. One of the newer drugs in clinical use is sirolimus. Further experience should decide whether sirolimus should be used as a first line drug together with other immunosuppressants, or whether it should only be reserved for patients who are at high risk for renal dysfunction, or for those who have developed nephrotoxicity following the use of cyclosporine and tacrolimus. The drug is administered orally, and has a half-life of 60 hours. It is metabolized in the liver; dose adjustments need to be made in patients with hepatic dysfunction, but not in patients with renal dysfunction. Like cyclosporine and tacrolimus, sirolimus is metabolized by P450 enzyme systems. Drug interaction may occur with the use of drugs that interfere with this system. The main advantage is its comparative lack of nephrotoxicity. Side effects include hypercholesterolemia, hyperglyceridemia, anemia, leucopenia and thrombocytopenia have also been observed.[10]

Critical Care in Pregnancy

- Introduction
- Critical Illness Not Specific to Pregnancy
- Critical Illness Specific to Pregnancy

CHAPTER 74

Introduction

The critical care aspects of a pregnant patient have four differentiating features compared to the critical care of one who is not pregnant. First, there are specific differences in the physiology between the gravid and nongravid patients. The physician or the intensivist has to be aware of these changes if he is to distinguish the "normal" from the "abnormal". Secondly, critical care of the pregnant patient includes care not only of the woman but also of the fetus. Thirdly, diagnostic procedures, interventions and drug therapy that may be optimal for the patient may pose actual or potential hazards to the fetus. Finally, pregnant patients in critical care units could present with emergencies observed in non-pregnant women, and also with grave problems peculiar to the pregnant state.

This section first gives a very brief overview of the relevant physiological changes in pregnancy followed by relevant observations on critical illnesses in the obstetric patient not specific to pregnancy. It then goes on to describe the major critical illnesses requiring critical care that are specifically related to the pregnant state. These illnesses are—

- Preeclampsia-eclampsia and their variants—the hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome and the hemolytic uremic syndrome (HUS).
- The acute fatty liver of pregnancy.
- Amniotic fluid embolism.
- Septic abortion.

PHYSIOLOGICAL CHANGES IN PREGNANCY[1,2]

Physiological changes in pregnancy should be looked upon as an adaptive process which provides maximum support for the fetus and minimizes the stress on the mother. Support to the fetus consists of ensuring an adequate placental blood flow, thereby providing enough oxygen and nutrients to the fetus. Reduction in maternal stress is chiefly through an expanded maternal blood volume, which acts as a buffer to compensate for substantial blood loss that always accompanies even a normal delivery. This expanded blood volume is responsible both for an increased cardiac output and an increased flow through the placental vessels.[2]

CHANGES IN THE CARDIOVASCULAR SYSTEM

A rise in the diaphragm that accompanies advancing pregnancy causes the heart to be more horizontally placed so that the apex is shifted to the left. The cardiac silhouette often appears larger than normal on an X-ray of the chest.

Hemodynamic changes are characterized chiefly by an increase in cardiac output by 30–50%, most of which occurs by the first trimester. The increase in cardiac output is due to both an increase in stroke volume and cardiac rate. After about 6 months of pregnancy, the cardiac output may decrease by over 20% in the supine position because of pressure of the gravid uterus on the inferior vena cava; this results in a reduced venous return and a fall in cardiac output.

Peripheral vascular resistance and also pulmonary vascular resistance decrease during pregnancy. The hyperdynamic circulatory state in pregnancy is characterized by tachycardia, an increased cardiac output, and an increased pulse pressure with warm peripheries. There is a prominent third heart sound at the apex and a systolic flow murmur, which is generally best heard over the pulmonary area. There is also, to start with, a decrease in systemic blood pressure which reaches its nadir by the sixth month; the pressure then gradually increases, but

should not be greater than non-pregnant levels at any time during pregnancy.

Labor and delivery are associated with even greater stress. Cardiac output increases by over 40%; there is an additional 15% increase in cardiac output with each uterine contraction. Delivery of the fetus is associated with an even further increase in cardiac output, presumably because of autotransfusion of blood contained in the uterus. This extra cardiac stress can lead to decompensation in patients with background heart disease, or could induce a sharp rise in left atrial pressure, resulting in acute pulmonary edema in patients with mitral stenosis.

CHANGES IN THE RESPIRATORY SYSTEM

Several aspects of pulmonary function change during pregnancy. There is an increase in tidal volume by about 40% and a fall in residual volume by 20%, as also a fall in the expiratory reserve volume. The forced vital capacity is unaltered.

The total oxygen uptake is increased by 30–40 mL/minute and there is a disproportionate increase in minute ventilation by about 50% at full-term. This hyperventilation in pregnancy is probably hormonally mediated and results in a $PaCO_2$ <30 mm Hg.

In view of the increased oxygen consumption by pregnant women, the physiological changes in ventilation during pregnancy, and the fetal oxygen dissociation curve, higher parameters for oxygen are necessary in the presence of respiratory distress or failure. The goal should be to maintain an O_2 saturation above or equal to 95% to ensure adequate oxygenation to the fetus.

CHANGES IN RENAL PHYSIOLOGY

There is an increase in glomerular filtration rate, an increase in the creatinine clearance and lowered serum creatinine values (below 0.9 mg/dL). A serum creatinine of say 1.4 mg/dL which would be considered normal in a non-pregnant female would indicate significant renal impairment in a pregnant female. As pregnancy progresses, there is a reduced sensitivity to endogenous vasopressors; this is responsible for decrease in the systolic and diastolic arterial pressures and the widened pulse pressure.

CHANGES IN GASTROINTESTINAL PHYSIOLOGY

Most of the changes in the gastrointestinal tract are caused by progesterone-related alteration of smooth muscle relaxation. Decreased lower esophageal sphincter tone leads to gastroesophageal reflux. There is also a hormone-related generalized hypomotility of the GI tract.

The abdominal viscera are pushed laterally upward and posteriorly by the enlarging uterus. The displacement of viscera may lead to problems in the interpretation of physical signs associated with common inflammatory abdominal pathologies. Thus, as pregnancy advances, Mcburney's point and Murphy's sign do not have the same relevance as in non-pregnant patients.[3]

HEMATOLOGICAL CHANGES

These include an increase in plasma volume by 40–60%, and an increase in red blood cell mass by 25%. There is therefore often a dilutional anemia with an Hb concentration of 11 g/dL at 24 weeks of pregnancy. Biochemical changes include a fall in serum osmolarity and a slight decreased concentration in the serum levels of sodium, potassium, calcium and magnesium. The total proteins and serum albumin level are lowered in proportion to the degree of volume expansion. The levels of cholesterol and triglycerides may double in pregnancy.

The levels of clotting factors are altered. The fibrinogen level is as high as 600 mg/dL. Fibrin degradation products can be detected in traces. The risk of thromboembolism increases with a relative risk of 1.8 in gestation and 5.5 during puerperium. Increased venous stasis may contribute to the increased risk of thromboembolism.

IMMUNE SYSTEM

Pregnant women are at risk for certain infections. Reactivation of viral diseases and of tuberculosis appears more common in pregnancy. Varicella and pyelonephritis occurring in pregnancy are associated with more severe complications. The reason for this immune dysfunction has not been elucidated.

CHAPTER 75

Critical Illness Not Specific to Pregnancy

INTRODUCTION

Serious illnesses necessitating critical care afflict pregnant and nonpregnant females equally. However, the pregnant state can at times influence the incidence, occurrence and clinical manifestations of both medical and surgical problems that require intensive care. The intensivist needs to focus attention not only on the pregnant patient but also on the unborn fetus. Emergencies characterized by hypoxia or fulminant infections increase fetal mortality and morbidity. Fetal monitoring in critical illness is therefore mandatory, particularly in conditions which affect maternal pulmonary or cardiovascular function. Auscultation of the fetal heart rate is an easy method to monitor the presence and degree of fetal distress. Continuous fetal heart monitoring by an electronic monitor is indicated in the viable or near viable fetus (beyond 23 weeks) during crisis situations or during surgical procedures when hypotension, anesthesia can lead to fetal compromise.

A very brief account of the possible influence of pregnancy on important critical illnesses[1] (not specific to pregnancy) is given below.

RESPIRATORY DISEASE[1,2]

The important causes of acute respiratory failure in pregnancy are acute severe asthma, pulmonary embolism, community-acquired pneumonia, aspiration pneumonia, pulmonary edema, and occasionally acute lung injury and acute respiratory distress syndrome (ARDS).

In our experience, acute severe asthma is the commonest medical emergency encountered in pregnancy. In asthmatic patients, pregnancy causes a worsening of the asthmatic state in about one-third of patients. The asthma remains unchanged in another third and may improve in the remaining third. Other than the influence of high dose corticosteroids on the fetus, there is no evidence that the use of beta-agonists or theophylline increases the morbidity or mortality of the fetus. Management of acute severe asthma in pregnant patients should be no different from that in the nonpregnant patients.

Pulmonary embolism is more frequent in the pregnant women as compared to the nonpregnant women, the risk factor being 1.8. This is because of hematological changes described earlier. The presentation most frequently observed is acute breathlessness. More often than not, there are no relevant physical findings and the patient is dismissed as "functional". Acute cardiorespiratory failure with hypotension and even shock is another presenting feature that is obviously promptly noticed. A computed tomography pulmonary angiography needs to be done and subcutaneous low molecular weight heparin in the usual dose should be promptly administered and continued through pregnancy. Warfarin is contraindicated in pregnancy because of the danger of an intracranial bleed in the fetus and because of its proven teratogenicity. Heparin should also be used for deep vein thrombosis even in the absence of pulmonary embolism. Patients with extensive deep vein thrombosis extending into the iliac veins or in patients who suffer from repeated pulmonary emboli, consideration should be given to the insertion of an inferior vena caval filter.

Community-acquired pneumonia is caused by the usual organisms, but treatment of pneumonia in the pregnant patient should include an awareness of the potential toxic effects of antibiotics on the fetus. Consideration should also be given to the harmful effects of diagnostic imaging involving the

use of X-rays. Hypoxia caused by severe pneumonia or acute severe asthma should be corrected adequately and promptly; close monitoring for fetal distress is mandatory. The arterial oxygen saturation should be kept more than 94–95% to avoid fetal compromise.

Aspiration as a cause of pneumonia is frequent in the pregnant patients because of the hormonally induced reduced tone of the lower esophageal sphincter and the increased transdiaphragmatic pressure due to the gravid uterus.

The causes of noncardiogenic pulmonary edema are the same as in the nonpregnant women. However, the use of tocolytic agents to retard the progression of labor is associated with an increased incidence of pulmonary edema. Also, pulmonary edema induced by tocolytic agents is observed to be at times more resistant to conventional therapy.[3,4]

Ventilator management of pregnant patients is no different from that of the nonpregnant patients. Attention should be directed to the avoidance of both high inflation pressures and of respiratory alkalosis. The objective is to prevent hypoxia in the mother and the fetus; yet a high maternal PaO_2 (>100 mm Hg) may lead to oxygen toxicity in the fetus. Higher than usual inflation pressure may, however, be necessary in late pregnancy to allow adequate minute ventilation. Management of ARDS in late pregnancy is distinctly more difficult than in the nonpregnant women.

CARDIOVASCULAR DISEASE[1,2]

The commonest cardiovascular disease in pregnancy necessitating intensive care is rheumatic heart disease with cardiac failure. Mitral stenosis is the most frequent cardiovascular problem meriting intensive care. Acute pulmonary edema in mitral stenosis is often related to the tachycardia and high output state which is the normal physiology of the pregnant patients. Pulmonary edema is worsened in the presence of atrial fibrillation with a fast ventricular rate. Digitalis and diuretics are safe during all stages of pregnancy.

Major cardiac surgery is best avoided during pregnancy unless absolutely necessary. The surgical procedure that may be lifesaving is a valvular commissurotomy for a tight mitral stenosis. However, coronary artery bypass surgery, valve replacement and repair of great vessels have all been performed at good centers with excellent results. Acute cardiomyopathy, though rare, is a recognized complication during the postpartum period. The cause is unknown and the treatment is as for any acute congestive cardiomyopathy.

RENAL DISEASE[1,2]

Pregnant patients are particularly prone to acute pyelonephritis. The latter may take a fulminant course, causing overwhelming sepsis, acute renal failure and multiple organ dysfunction syndrome.

The specific causes of acute renal failure related to pregnancy are dealt with later.

NEUROLOGICAL DISEASE[1,2]

Serious neurological problems are common to both pregnant and nonpregnant patients. However, cortical venous thrombosis with thrombosis of the intracranial venous sinuses is more frequent in the pregnant state and the puerperium. It often presents with seizures and is often wrongly diagnosed as epilepsy, or stoke or meningitis.

Myasthenia gravis may undergo remission or exacerbation during pregnancy. It may also be associated with transient neonatal myasthenia from transplacental passage of acetylcholine antibodies.

AUTOIMMUNE DISEASES[1,2]

Autoimmune diseases may remit or exacerbate during pregnancy. The two important autoimmune diseases which may need critical care during pregnancy are systemic lupus erythematosus and the antiphospholipid syndrome (APS). The latter syndrome is associated with an increased rate of abortion, fetal loss and maternal mortality.[4] Thrombocytopenia and the propensity to arterial and venous thrombi characterize this syndrome. Aspirin and the use of heparin are advocated in the management of APS presenting as an emergency meriting critical care.

ENDOCRINE DISEASE[1,2]

Control of insulin-dependent diabetes is more difficult in the pregnant state, yet ketoacidosis is uncommon. Gestational diabetes is characterized by reduced glucose tolerance initially diagnosed during pregnancy. Early gestational diabetes (before 20 weeks) often necessitates the use of insulin for proper control. There is also an increased risk of overt diabetes after pregnancy in these patients.

The features of thyrotoxicosis occurring in pregnancy may be wrongly attributed to the altered physiology in pregnancy. Tachycardia, palpitation and heat intolerance are common both to hyperthyroidism and to the pregnant state. Antithyroid drugs readily cross the placental barrier; they should be used with caution to prevent fetal hypothyroidism.

SURGICAL EMERGENCIES

Surgical emergencies occur with the same frequency as in the nonpregnant women and include in the main, acute appendicitis, acute cholecystitis, biliary colic, peptic ulcer disease, intestinal obstruction and inflammatory bowel disease.

Acute appendicitis is the most frequent surgical emergency requiring operative intervention. The risk of conservative management clearly outweighs the risk of surgery at all stages of pregnancy. Progressive enlargement of the uterus may displace the cecum upward, so that maximal tenderness may not be elicited over Mcburney's point. Ultrasound examination

is of great help in atypical presentations. Laparoscopic appendectomy is perhaps best confined to the first trimester; laparoscopic identification is difficult at full term.

Acute cholecystitis, particularly in the first and last trimester, is treated conservatively unless there are clinical features suggesting impending gangrene of the gall bladder. Surgical emergencies, like intestinal obstruction and volvulus, are difficult to diagnose particularly in advanced pregnancy. Surgery is indicated only after failure of medical management.

A surgical emergency that can be missed for a time is peritonitis due to accidental bowel perforation during the performance of a cesarean section. Abdominal guarding and rigidity are markedly reduced in these patients because of the stretching and laxity of the abdominal musculature caused by a fully gravid uterus. Persistent pain, free fluid within the abdomen and fever are warning signs that should not be ignored.

DRUGS USED DURING PREGNANCY

Drugs used for the mother can produce dangerous effects on the unborn fetus. The clinician must therefore be aware of the teratogenicity and toxic effects of drugs on the fetus. Though the mother's safety and life come first, the intensivist must consider possible alternative therapies which may be less dangerous to the fetus. Yet, the principle underlying the choice of a drug or therapeutic modality is that the anticipated advantage to maternal health and recovery far outweighs the theoretical risk to the fetus. Thus, the use of a lifesaving drug for which there is no good alternative is indicated in spite of its potential teratogenicity or toxicity to the fetus.

CARDIOPULMONARY RESUSCITATION IN THE PREGNANT WOMEN

If cardiac arrest occurs in a pregnant woman, resuscitative measures are exactly as routinely recommended.[5] Closed chest compression, defibrillation, use of adrenaline, vasopressors and other drugs should be carried out exactly as one would in a nonpregnant patient. It is often necessary to displace the uterus from the large abdominal vessels by a right hip wedge. If cardiopulmonary resuscitation is unsuccessful, the performance of perimortem cesarean section may be performed under appropriate circumstances, in the hope of extracting a live fetus.

CHAPTER 76

Critical Illness Specific to Pregnancy

PREECLAMPSIA-ECLAMPSIA

GENERAL CONSIDERATIONS

Preeclampsia is an important and common complication of pregnancy. It generally becomes evident in the second half of pregnancy, during labor, or for the first time in the immediate puerperium, without there being preceding evidence of the disease. The disease is typically characterized by hypertension [blood pressure (BP) >140/90 mm Hg], significant albuminuria (≥300 mg/day) and generalized edema, which however may be more apparent on dependent areas, such as the feet. The disease always resolves over a period of time after delivery. The etiology of preeclampsia is obscure. The disease can be mild, moderate or severe, or graduate from mild to severe. The moderately severe and severe forms constitute a grave hazard to both mother and fetus, and necessitate critical care.

Eclampsia is characterized by generalized seizures (for which there is no other cause) in a woman with preeclampsia. However, eclampsia may strike suddenly in a pregnant woman who may often have no complaints or who exhibits mild to moderate hypertension very briefly before the onset of seizures.

It is best to consider preeclampsia–eclampsia as belonging to one clinicopathological spectrum extending from the milder forms of preeclampsia to the severe form of eclampsia.

INCIDENCE AND PREDISPOSING FACTORS

The incidence is probably about 1 in 20 or 30 pregnancies. It is more frequent in primigravidas than in multigravidas. Increasing maternal age, obesity, a history of previous preeclampsia and a family history of preeclampsia are also additional risk factors. Medical disorders that add to the risk of preeclampsia are pre-existing chronic hypertension, chronic renal disease, diabetes, antiphospholipid antibody syndrome, background connective tissue disease and severe migraine.

Placental/fetal factors contributing to an increased risk of preeclampsia include advanced gestational age, multiple pregnancy, poor placentation, hydatidiform mole, placental hydrops, trisomy 13 and triploidy (Box 1).

Box 1: Factors predisposing to preeclampsia

- Maternal factors—
  - Primigravida
  - Increased maternal age
  - Obesity
  - History of previous preeclampsia
  - Pre-existing hypertension
  - Chronic renal disease
  - Diabetes
  - Antiphospholipid antibody syndrome
  - Connective tissue disease
- Placental factors—
  - Advanced gestational age
  - Multiple pregnancy
  - Poor placentation
  - Hydatidiform mole
  - Placental hydrops
  - Trisomy 13
  - Triploidy

PATHOPHYSIOLOGY[1]

The pathophysiology remains obscure. The presence of the placenta is crucial to the development of preeclampsia. There appears to be a relative ischemia due to changes in the uteroplacental circulation. The changes are twofold. There is a partial lack of significant dilatation of the spiral arteries supplying the intervillous spaces; this dilatation is necessary to accommodate the expanded uteroplacental flow in the second half of pregnancy. There is also an obstruction of these spiral arteries by fibrin, platelets and lipid-laden macrophages. Whether this impoverished uteroplacental circulation due to changes in the spiral arteries are primary features or merely associated features of preeclampsia is not clear.

The pathology in the maternal circulation has excited a great deal of interest. The full picture of preeclampsia–eclampsia is not just a primary hypertension problem, but is the consequence of diffuse endothelial dysfunction which results in disturbed functioning of various organ systems, widespread changes in the walls and lumen of arteries and arterioles, and coagulation abnormalities. The current belief goes a step further in postulating that the endothelial dysfunction is merely one aspect of a generalized systemic inflammatory response that also involves leucocytes, clotting factors and other components of the inflammatory system. This systemic inflammatory response in a very mild asymptomatic form is believed to be present in the last trimester of normal pregnancy. Preeclampsia results when this pregnancy induced inflammatory response for any reason accelerates and leads to decompensation of one or more organ systems.[2] In other words, if this concept is indeed proven true, preeclampsia is merely an exaggeration or an aberration of a phenomenon present in every normal pregnancy.[2] It is the decompensation of various organ systems in severe preeclampsia that is responsible for complications that could easily lead to death.

CLINICAL FEATURES[2,3]

The minimum criteria for the diagnosis of preeclampsia are: (1) sustained BP elevation of 140 mm Hg systolic or 90 mm Hg diastolic in a previously normotensive woman after 20 weeks of pregnancy; (2) proteinuria of at least 300 mg in a 24-hour urine collection. Edema is frequent but is not included as an essential feature because some degree of pitting edema is often observed in the last trimester of a normal pregnancy. However, a sudden increase in body weight and edema often presages the occurrence of preeclampsia.

Hypertension is the essential feature and is caused by increased peripheral vascular resistance due to generalized endothelial dysfunction. The BP is typically unstable. The circadian rhythm is often altered, with initially a loss of the normal fall of BP at night, and later a paradoxical marked increase in BP during sleep.

Severe preeclampsia is associated with dysfunction of various organ systems.[3] It is of utmost importance to realize that changes in organ functions do not necessarily correspond with the degree of rise in BP.

Box 2: Organ system involvement in severe preeclampsia–eclampsia

- Maternal—
  - Central nervous system-cortical blindness, cerebral hemorrhage, grand mal seizures
  - Acute renal tubular necrosis
  - Acute cortical necrosis
  - Generalized edema, laryngeal edema
  - Acute left ventricular failure
  - Acute lung injury, acute respiratory distress syndrome
  - Disseminated intravascular coagulopathy
  - Hepatic infarction, intrahepatic hemorrhage and hepatic rupture
- Fetal—
  - Intrauterine death
  - Intrauterine asphyxia
  - Placental abruption

Generalized edema can occur but is inconsistent. Renal dysfunction could progress to acute tubular necrosis. Central nervous system (CNS) dysfunction takes the form of cortical blindness, cerebral hemorrhage and/or seizures (eclampsia). Involvement of the respiratory system can result in laryngeal edema and acute lung injury/acute respiratory distress syndrome (ARDS). Disturbances in the coagulation profile can lead to varying degree of disseminated intravascular coagulopathy (DIC). Hepatic dysfunction is characterized by right hypochondrial pain, tenderness, elevated liver enzymes, and rarely by hepatic infarction or even hepatic rupture. Left heart failure with pulmonary edema is also observed.

Fetal crises are frequently observed. They include fetal distress, fetal asphyxia, abruptio placenta and intrauterine fetal death.

Complications associated with severe preeclampsia–eclampsia are listed in Box 2.

Preeclampsia is best classified as mild to moderate or severe. Severe preeclampsia is characterized by at least one of the following additional criteria: (1) BP more than 160 mm Hg systolic or more than 110 mm Hg diastolic; (2) proteinuria more than 5 g in 24 hours; (3) serum creatinine more than 2 mg/dL; (4) noncardiogenic pulmonary edema (ARDS); (5) oliguria less than 500 mL/24 hours; (6) microangiopathic hemolytic anemia; (7) thrombocytopenia; (8) hepatocellular dysfunction; (9) symptoms of end-organ involvement (cortical blindness, severe headache, severe abdominal pain); (10) fetal growth restriction and (11) eclampsia (seizures in a pregnant woman for which there is no other cause).

ECLAMPSIA[2-4]

Eclampsia is merely the severe end of the spectrum of preeclampsia. The term is applied to grand mal seizures in

a patient with preeclampsia, in whom the seizures cannot be attributed to any other cause. As mentioned earlier, it can strike suddenly with the patient being unaware of having preeclampsia. Also the features of preeclampsia may antedate eclampsia by a very short period of time (less than a day or two). Seizures are often preceded by severe persistent headache. The occurrence of seizures is not necessarily related to the degree of hypertension, but is related to microangiopathic changes in cerebral vessels. Visual disturbances are frequent and often include cortical blindness. Cerebral edema, cerebral hemorrhage, DIC and ARDS are in our experience more often observed with eclampsia than in non-eclamptic patients.

There are two other syndromes which are currently considered complications or variants of the preeclampsia-eclampsia state. These are the syndromes characterized by hemolysis anemia, elevated liver enzymes and lowered platelets (HELLP syndrome) and the other characterized by hemolysis and uremia [the hemolytic uremic syndrome (HUS)].

HELLP SYNDROME[5]

There is still controversy as to whether this syndrome is a separate entity or falls within the spectrum of preeclampsia. The hemolytic anemia is due to a microangiopathic hemolytic process and rarely requires packed cell infusion. Thrombocytopenia is moderate and platelet counts less than 30,000/mm^3 are only rarely observed. The elevated liver enzymes that characterize the HELLP syndrome are due to hepatocellular injury, perhaps caused by vasospasm and microangiopathic changes involving vessels supplying the liver cells. The rise in hepatic serum enzymes may be associated with hepatic infarction, intrahepatic hemorrhage, subcapsular hemorrhage, and in rare instances hepatic rupture. The latter is an acute emergency needing prompt surgery. The maternal mortality in the HELLP syndrome is estimated to be 1–2%.

22

HEMOLYTIC UREMIC SYNDROME

This syndrome is believed to be a variant of thrombotic thrombocytopenic purpura (TTP) without the presence of neurological features which typify TTP. It is rare in pregnancy and though considered to fall within the spectrum of preeclampsia may well be in our opinion, a separate rare entity. The HUS is characterized by renal dysfunction with high creatinine levels, an increase in the serum lactate dehydrogenase levels (>1000 U/L), and decreased haptoglobin levels. The direct Coombs test is negative. Coagulation studies are within normal limits.

Differential Diagnosis[3]

Hypertension occurring in the second half of pregnancy may be due to causes other than preeclampsia. These include chronic hypertension (pre-existing hypertension antedating pregnancy), gestational hypertension (pregnancy-induced hypertension with proteinuria), and elevated BP seen in pregnant patients with acute fatty liver. Acute glomerulonephritis or pyelonephritis complicating pregnancy can also cause hypertension.

Coagulation abnormalities can be caused by conditions other than preeclampsia. These include amniotic fluid embolism and acute fatty liver of pregnancy.

A combination of elevated liver enzymes and thrombocytopenia may occur with viral infections such as dengue, falciparum malaria and by other causes of hepatitis.

Management[1,2,6,7]

Severe preeclampsia merits critical care. The patient should be closely monitored with regard to vital signs and with regard to laboratory tests to evaluate functions of different organ systems. A central venous line is inserted before any serious disturbance in the coagulation profile occurs. A careful monitoring of the arterial BP is imperative. Arterial pH and blood gases are done and repeated as and when necessary. A close intake-output chart is vital and if possible the patient should be weighed daily.

Delivery

The definitive treatment of preeclampsia is delivery of the fetus. In severe preeclampsia, this should be undertaken promptly. The features of severe preeclampsia are then relieved and subside over a period of time. If, however, the mother's condition has stabilized and there is little or no organ dysfunction, conservative management with antihypertensives and support to all organ systems may be tentatively continued, only if the fetus is very immature. This is however controversial and should be entertained only when the anticipated benefit to the fetus is far greater than the risk to the mother or to both the mother and the fetus.

Control of Hypertension

The BP should be kept below 140/90 mm Hg. We use a combination of hydralazine, alpha-methyldopa and nifedipine to control BP. When systolic BP is more than 180 mm Hg or diastolic more than 110 mm Hg, hydralazine in a dose of 5–20 mg is given intravenously. An alternative is the use of labetalol, 20 mg intravenously given as a bolus. The drug is repeated, if necessary, at a higher dose of 30–40 mg every 15 minutes till a suitable fall in BP results.

Oral or sublingual nifedipine has been reported to produce a sharp fall in BP, but we have used this drug safely without any untoward effect. A carefully titrated and closely monitored infusion of nitroglycerine or sodium nitroprusside can also be used to control severe hypertension. Both drugs however cross the placental barrier and could exert toxic effects on the fetus.

It is debatable whether control of hypertension can reverse or delay maternal organ damage or increase fetal salvage rates. Hence, the dictum that prompts delivery is the treatment of choice in patients with severe preeclampsia.

Support to All Organ Systems

Oliguria (<30 mL urine/hour) can be due to a depleted intravascular volume, to cardiac failure or to isolated renal arteriolar spasm. Each of these requires appropriate treatment. Low-dose dopamine infusion at 2–4 µg/kg per minute may help to improve urine output, particularly in the presence of renal arteriolar spasm.

Pulmonary Edema

Pulmonary edema may be precipitated by volume overload, by left heart failure or by damage to the alveolar capillary membrane (acute lung injury). Hypoalbuminemia may contribute further to pulmonary edema. Diuretics, use of oxygen, use of digitalis for heart failure and ventilator support for acute lung injury become necessary.

All other organs deserve efficient support; cerebral edema is countered by the use of mannitol, and coagulation disorders by the proper replacement of coagulation factors. Patients with severe preeclampsia should be given seizure prophylaxis with intravenous magnesium (see below).

MANAGEMENT OF ECLAMPSIA[2,4,6,7]

Management consists of control of seizures, control of hypertension with drugs and prompt delivery.

Seizures are controlled best by administering a 4 g intravenous bolus of magnesium sulfate over 10 minutes, followed by a continuous infusion of 2 g/hour. The infusion rate is titrated so as to keep the serum magnesium level between 4.5 mg/dL and 8 mg/dL. If the patient has already been on intravenous magnesium as a prophylaxis (in severe preeclampsia), or if a recurrent seizure occurs after the initial seizure, a further 2 g bolus is administered.

Magnesium sulfate is undoubtedly the drug of choice for eclamptic seizures. If the latter are difficult to control in spite of the use of intravenous magnesium, a titrated infusion of diazepam (20–50 mg in 500 mL glucose) and intravenous dilantin sodium in an appropriate dose should be added to the therapy.

All organ functions need support, in particular the CNS, renal and hematological systems. Close monitoring of all vital parameters and of organ functions is imperative. Arterial pH and blood gases need to be frequently monitored; oxygen is almost always indicated. In patients with severe or recurrent seizures, or in obtunded patients, the airway should be promptly secured by endotracheal intubation. Mechanical ventilator support is indicated in the presence of hypoxia, recurrent or prolonged seizures, in the presence of pulmonary edema, and when the patient is heavily sedated to suppress seizure activity.

Nosocomial infections should be quickly diagnosed and treated with appropriate antibiotics.

MANAGEMENT OF HELLP SYNDROME[5]

The hemolytic anemia in this syndrome rarely needs packed cell infusions. Thrombocytopenia is generally not so marked as to require platelet infusions. Liver cell function should be supported by the use of intravenous glucose, vitamins and adequate nutrition. The latter may be difficult to achieve in the presence of right hypochondrial pain and vomiting. Symptomatic treatment for vomiting includes the use of phenergan, prochlorperazine and ondansetron.

Dexamethasone 10 mg intravenously 12 hourly usually results in clinical improvement and in a reversal of laboratory abnormalities. This therapy may permit some delay in delivery if the fetus is far too premature. Dexamethasone also promotes lung maturation in the fetus. The abnormalities however all return when dexamethasone is discontinued.

MANAGEMENT OF THE HEMOLYTIC UREMIC SYNDROME

The current treatment is the administration of plasma transfusions. Initially, 30–40 mL/kg of plasma is infused, followed by a reduction to 15–20 mL/kg once stabilization occurs. If improvement is not seen, plasmapheresis should be promptly used. Corticosteroids (100–200 mg hydrocortisone intravenously 8 hourly), dipyridamole, immunoglobulins, and immunosuppressants have all been tried with limited success. Platelet infusion should be avoided except perhaps when there is marked thrombocytopenia with severe bleeding, as platelets tend to promote further intravascular thrombosis.

ACUTE FATTY LIVER OF PREGNANCY

GENERAL CONSIDERATIONS

This is a very rare but catastrophic complication of pregnancy. Its incidence is believed to be 1 in 10,000 to 1 in 20,000 deliveries. It is characterized by severe hepatic dysfunction with massive fatty infiltration within the hepatocytes occurring either during the last trimester of pregnancy or in the immediate postpartum period.[1] There are many who believe that this entity is a variant of preeclampsia, as the disease is frequently associated with hypertension and is more prone to occur in first pregnancies and with twin gestation.[2] Earlier, the mortality in acute fatty liver of pregnancy was reported to be over 70%. Currently, the mortality is close to 20–30% partly because less severe forms of the disease are recognized and partly because of early diagnosis and treatment.

The etiology of acute fatty liver in pregnancy is unknown. It is possible that the disease is more likely to occur in mothers who carry fetuses which have a genetic defect in the oxidation of fatty acids.[3]

CLINICAL FEATURES[1]

The clinical features are characterized by nausea, vomiting and increasing anorexia for 4–7 days. This is followed by jaundice and a tender enlarged liver. The serum bilirubin is raised to a varying extent; liver enzymes and alkaline phosphate are raised. Hypertension is frequently present and may be associated with albuminuria and edema.

In severe cases, there is progressive deterioration of liver cell function characterized by hypoalbuminuria, ascites, hepatic encephalopathy and a progressive worsening coagulopathy. Hypoglycemia due to worsening liver cell function, hepatorenal failure and metabolic acidosis are observed. Death, when it occurs, is due to severe multiple organ failure.

Pancreatitis is a noted complication and is associated with worsening abdominal pain and with elevation of serum amylase and lipase. Diabetes insipidus is a reported association; it may result in hypernatremia.

Improvement in the patient's condition generally occurs following delivery of the fetus. There is an increased incidence of fetal deaths from uteroplacental insufficiency, if delivery is delayed.

The *differential diagnosis* is from other causes of acute or fulminant hepatitis, in particular, viral hepatitis and drug-induced hepatitis. The diagnosis can be confirmed by a liver biopsy which demonstrates microvesicular fat within the hepatocytes. An ultrasonography of the abdomen demonstrates increased echogenicity of the liver due to a marked increase in fat content; a computed tomography (CT) or magnetic resonance imaging reveals decreased attenuation of the liver parenchyma.

MANAGEMENT

Critical care is required for patients with acute fatty degeneration of the liver.

Monitoring

Close monitoring of the patient and the fetus is imperative. Fetal heart sounds should be continuously monitored to detect fetal distress or compromise. Liver functions, blood chemistry, blood glucose and functions of all organ systems need careful monitoring, in particular, the renal and coagulation profiles. A central line should be inserted to help measure central venous pressure and guide fluid replacement early in the natural history of the disease.

Stabilization

Critically ill patients should be urgently stabilized. Hepatic encephalopathy should be treated on the usual lines (see Chapter Critical Care in Acute Hepatic Failure). Hypoglycemia poses a danger to both mother and fetus. Fluid and electrolyte disturbances are common and need to be restored to normal. Alteration of the coagulation profile should be countered by appropriate infusions of fresh frozen plasma, platelets and cryoprecipitate as indicated. Renal dysfunction is present in critically ill patients, necessitating fluid restriction and occasionally renal replacement therapy. Hypertension is frequently present and may require the use of hydralazine and other antihypertensives indicated earlier. If acute fatty degeneration of the liver is associated with other features of severe preeclampsia, magnesium sulfate should be used prophylactically (in the dose indicated earlier) to prevent seizures.

Delivery

Once the patient is stabilized, delivery is done preferably through a cesarean section. Spinal or epidural anesthesia should only be risked if the coagulation profile and platelets have returned to normal. General anesthesia is otherwise used, taking care to avoid agents which are hepatotoxic.

Following Delivery

Management involves meticulous multiorgan support, particularly to the liver. Proteins are avoided or sharply reduced in planning nutritional support. Calories should consist chiefly in the form of carbohydrates given as

intravenous glucose or through a nasogastric tube. Branched-chain aminoacids intravenously help to supply proteins (see Chapter Nutritional Support in the Critically Ill Adult). Lactulose 30 mL three or four times a day helps to reduce ammonia production and absorption from the large bowel. A bowel wash using metrogyl is also of help.

Fluid and electrolyte balance is important. Vitamin K should be administered daily and the coagulation profile kept normal through proper blood product replacement therapy. Nosocomial infection is frequent, particularly in ventilated patients; it needs the use of appropriate antibiotics.

AMNIOTIC FLUID EMBOLISM

GENERAL CONSIDERATIONS

Pulmonary embolism is a dreaded complication during pregnancy, at labor or in the puerperium. The source of embolism is generally the deep veins of the lower limbs, occasionally the pelvic veins or the large uterine venous sinuses. Women particularly at risk are those confined to bed because of preeclampsia or eclampsia, or those who have had a cesarean section. Venous thromboembolism is considered an important cause of death in the above situations.

In contrast, amniotic fluid embolism is rare, but catastrophic. It was first described in 1926. The overall incidence is unknown, but is believed to be 1 in 8,000 to 1 in 80,000 deliveries.[1] The maternal mortality can be as high as 85%; the fetal mortality is less, about 20%. Although very rare, it remains the third leading cause of maternal deaths in the United Kingdom after thromboembolism and hypertensive disorders of pregnancy.[1]

This catastrophic emergency is associated with increased maternal age, multiparity, protracted difficult labor, placental disruption and signs of fetal distress as evinced by meconium-stained amniotic fluid. It has been reported as a complication of termination of pregnancy in the first or second trimester, during normal pregnancy and the puerperium. The greatest risk is during labor. The emergency is caused by the escape and release of amniotic fluid into the maternal pulmonary circulation, blocking the pulmonary vasculature and triggering an inflammatory host response mediated by leukotrienes and other arachidonic acid metabolites. Activation of the coagulation pathways leads to DIC.

CLINICAL FEATURES[2]

Massive amniotic fluid embolism is characterized by a sudden progressive deterioration in the clinical condition of the mother, characterized by hypotension, dyspnea, hypoxia, cyanosis, culminating in cardiac arrest.

If the patient survives the immediate catastrophe, the clinical features are those of ARDS. Hypoxia, tachypnea and crackles over both lungs with bilateral shadowing on the X-ray of the chest are observed. Tachycardia and hypotension are generally present.

A third presentation, generally associated with ARDS, is the occurrence of DIC probably triggered by the inflammatory response induced by the contents of amniotic fluid. DIC may occur in 40–50% of patients.

DIAGNOSIS

The diagnosis is suspected from the clinical presentation. There is no confirmatory diagnostic test during life. The classic autopsy finding is the presence of fetal squamous cells in the maternal pulmonary circulation.

MANAGEMENT

Treatment is supportive. It includes cardiopulmonary resuscitation, and circulatory support through volume infusions plus the use of inotropes and vasopressors. Intubation with mechanical ventilator support is mandatory. ARDS is managed on conventional lines as discussed in an earlier chapter (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome). Coagulopathy should be treated with infusion of appropriate blood products. Prompt delivery of the fetus through a cesarean section should be considered if there is a cardiopulmonary arrest, which does not respond to resuscitative efforts.

SEPSIS IN OBSTETRICS

GENERAL CONSIDERATIONS

Conditions leading to sepsis in nonpregnant females can also produce sepsis in pregnant females. Diagnosis is rendered difficult in the presence of a gravid uterus and by constraints on imaging techniques that could be potential hazards to the fetus. Management of sepsis unrelated to pregnancy and delivery is the same as in the nonpregnant females. Surgery is technically more difficult in the presence of a gravid uterus and surgical interference can pose a danger to the fetus.

The most important condition causing sepsis directly related to pregnancy is septic abortion; this section briefly deals with this entity.

Septic abortion is sepsis associated with the spontaneous or induced termination of a recent pregnancy. Septic abortion is much more frequent in poor, developing countries where abortion is often performed by quacks in filthy conditions and by crude and dangerous methods. The chances of complications are greater when abortions are attempted in later pregnancy and when dilatation of the cervix and evacuation procedures are performed.

Maternal sepsis can also occur after the delivery of a child at full-term, particularly if labor is conducted improperly with unsterile instruments. Maternal sepsis is also a feature of a dead, retained, macerated fetus within the uterus.

CLINICAL FEATURES[1,2]

In a patient with a recent history of instrumentation to end pregnancy, the cardinal features of sepsis are fever, lower abdominal and pelvic tenderness, tenderness of the uterus on vaginal examination and a serosanguinous or purulent vaginal discharge. Vaginal bleeding, sometimes exsanguinating, may at times be the presenting symptom.

Fever and tachycardia are invariably present. Tachypnea, hypotension and the features of increasing septic shock can evolve with frightening rapidity. Disturbances in organ function become manifest early. Elevated liver enzymes, a modest rise in serum creatinine and a slight prolongation of the prothrombin time are forerunners of multiple organ failure. In severe cases, DIC sets in with bleeding from various sites, in particular, from the uterus. Death occurs from hypotensive shock and/or multiple organ failure.

LABORATORY EXAMINATION

Blood, urine and cervical secretions should be sent for routine examination and culture. Leukocytosis is frequent, but severe leukopenia often accompanied by thrombocytopenia is also an indication of sepsis. Gram stain of cervical secretions may guide initial therapy before culture reports are available. This is of utmost importance in the early diagnosis of infection with *Clostridium perfringens* The latter appear as Gram-positive rods on Gram stain of cervical secretions or of curetted material. Imaging studies may reveal gas in the myometrium and in fulminant cases, a crepitus can be felt in the soft tissues of the vagina and vulva.

X-ray of the abdomen may also detect perforation of the uterus or bowel which may complicate the use of dangerous procedures to achieve abortion.

An ultrasound of the abdomen may reveal the presence of retained products of conception as also inflammatory pathologies and abscesses within the pelvis and in the adnexa. A CT of the abdomen and pelvis would help to define and localize an abscess even better than an ultrasound. It would also clearly reveal the presence of gas in the myometrium and soft tissues of the pelvis in clostridial infection.

Laboratory investigation should include determination of function of various organ systems; these parameters should be repeated as and when necessary. A coagulation profile is imperative as is the estimation of arterial pH and blood gases. An X-ray of the chest may reveal acute lung injury or even ARDS.

MANAGEMENT[1,2]

Principles of management have already been outlined in the Chapter Sepsis and Septic Shock.

Immediate intravenous use of appropriate antibiotics, which cover Gram-negative, Gram-positive organisms and also anaerobes, is mandatory. Antibiotic therapy may subsequently be tailored according to culture sensitivity reports. Clostridial infections are treated with 2 million units of penicillin G 4 hourly, intravenously. Hysterectomy may be lifesaving in serious clostridial infection.

All organ systems need support; the coagulation profile should be restored by infusion of appropriate blood products. Cardiorespiratory support is vital and seriously ill patients need to be intubated and kept on mechanical ventilation. Details of management have been discussed in the Chapter Sepsis and Septic Shock.

Pelvic surgery may be necessary to drain abscesses or collections of infected blood. Retained products of conception should be removed by careful curettage as they contribute to further infection. Close cooperation between the intensivist and the obstetrician is mandatory for patient survival.

compression by two hands like in adults. The ratio of chest compression to breathing is 5:1 at all ages.

In case of airway obstruction due to a foreign body, the child should be encouraged to cough. Relief of obstruction is attempted only if coughing is ineffective or respiratory difficulty worsens with increasing stridor. In children, the Heimlich maneuver consisting of subdiaphragmatic abdominal thrusts is tried, while in infants, back blows and chest thrusts are attempted, so as to avoid injury to abdominal organs. Following such maneuvers, rescue breathing is attempted, and if this is found to be unsuccessful, the procedure is repeated.

If breathing cannot be initiated and maintained by rescue breathing, bag and mask ventilation with oxygenation is necessary. Well-fitting masks of proper size, with a good seal around the nose and mouth are necessary. Smaller bags of 250–750 mL volume are used in children to deliver small tidal volumes. The pressure applied has to be just sufficient to inflate the chest. In neonates, two to three fingers are used to squeeze the bag, while in bigger children, the bag is squeezed by one hand. Gentle pressure is sufficient, and care should be taken to avoid a pneumothorax.

In most situations, basic life support is enough to resuscitate infants and children. In newborns, before initiating CPR, drying of the skin surface and providing optimal warmth, as also gentle tactile stimulation by rubbing the back or sole, are necessary to establish breathing. Suction of the nostrils and the oral cavity generally clears the airway. If breathing is not established, oxygen delivered by a catheter placed 1 cm from the nostrils is often adequate. In majority of cases, breathing is established by such maneuvers; if not, CPR is begun.

If breathing cannot be adequately maintained by bag and mask ventilation, endotracheal intubation (using an uncuffed tube) may become necessary. A laryngoscope with a straight blade is preferred in infants and small children. A proper-sized tube is selected as per the baby's size—this varies from 2.5 in premature babies to 3–3.5 in full-term neonates, and proportionately larger sizes subsequently. Tube size as depicted by the internal diameter (ID) may be approximated by the formula:

$$\text{ID (mm)} = \frac{16 + \text{Age in years}}{4}$$

Proper-sized suction catheters varying in size from French 5 upward are used. Various oxygen delivery systems may be used, including an oxygen hood. Oxygen is toxic especially in preterm neonates, and may lead to retrolental fibroplasia and bronchopulmonary dysplasia; hence, it should be used judiciously.

Vascular access is often difficult in infants and children. In newborns, the umbilical vein may be used for a short period, till a peripheral vein can be secured. In infants and children, intraosseous infusions of fluids may be tried in the tibial bone, and as soon as the circulatory state improves, a peripheral vein is secured. Emergency drugs may be administered through the endotracheal tube, though such an access may pose special problems. The amount infused through the endotracheal tube must be limited to 5 mL to prevent atelectasis due to altered or destroyed surfactant. Any drug that is administered through an endotracheal tube may form an intrapulmonary depot of the drug as it is not washed off quickly, and hence the drug may have a prolonged effect.

Fluids may have to be infused to maintain an adequate circulatory volume. A bolus of 20 mL/kg body weight of isotonic fluids like Ringer lactate or normal saline are administered as the first step in resuscitation of volume. Further infusions are decided by the circulatory status.

Certain medications may be required in the last step of CPR. As endotracheal intubation is often planned in children, premedication with atropine is ideal. A minimum dose of 0.1 mg of atropine is used at any age; the actual dose works out to be 0.02 mg/kg body weight. This is to avoid smaller doses which often cause a paradoxical central nervous system-mediated bradycardia. Other medications required are similar to those used in adults, and include sodium bicarbonate to counter acidosis, and inotropes for circulatory support. Thus dopamine, dobutamine, isoproterenol or epinephrine infusions may be necessary. The pediatric dosages of inotropes are as follows: dopamine infusion at 2–20 µg/kg per minute; dobutamine infusion at 5–20 µg/kg per minute; epinephrine 0.01 mg/kg (0.1 mL/kg of 1:10,000 solution) stat, followed by an infusion at the rate of 0.1–1 µg/kg per minute; isoproterenol infusion at 0.1–1 µg/kg per minute. Ventricular extrasystoles and rhythm disturbances are often due to hypoxia, and are thus abolished by oxygen administration. Lidocaine in the dose of 1 mg/kg stat, followed by an infusion at a rate of 20–50 µg/kg per minute may however be necessary. Fluid and electrolyte abnormalities are common in the pediatric age group, and the use of dextrose, dextrose saline and Ringer lactate infusions should be carefully monitored.

CHAPTER 78

Respiratory and Hemodynamic Monitoring in Children

Mahesh V Balsekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital, Sir Hurkisondas Nurrotamdas Hospital, Mumbai, Maharashtra, India*

INTRODUCTION

Serious illness in children often goes unrecognized. Since children have immature cardiorespiratory and renal compensatory mechanisms, children can deteriorate rapidly unless appropriate treatment is initiated promptly. It is therefore vital that clinicians caring for children are trained to identify serious illness in the early stages.

The principles of cardiorespiratory assessment in children are similar to those in adults. This chapter has highlighted only the important differences in the assessment and monitoring of children compared to adults. A full discussion on procedures, techniques of monitoring and calculation of various monitoring parameters is done in other chapters in the book.

CLINICAL ASSESSMENT

Identification of serious illness in a child is essentially clinical. The American Academy of Pediatrics has proposed a guideline, the *Pediatric Assessment Triangle (PAT)* to rapidly identify children in need of immediate supportive care.[1,2] The three observations in the PAT are *appearance, breathing* and *circulation*. The American Heart Association has proposed an approach in the pediatric advanced life support (PALS) guidelines[2] where the child is assessed in the format of *airway, breathing, circulation, disability* and *exposure.*

Appearance and Breathing

The assessment of airway and breathing is to evaluate oxygenation and is evaluated by assessing the respiratory rate and pattern.

Respiratory Rate

Vital signs are interpreted in the context of age-related norms for children. Table 1 illustrates the vital signs according to the age groups in children. Tachypnea is a basic sign of respiratory distress and a respiratory rate above 60 minutes is always abnormal. While assessing respiratory rate, it is important to note that respiratory pauses may occur in children less than 3 months of age and are usually less than 5 seconds. Pauses often occur in groups of three or more are separated by less than 20 seconds, and usually resolve by 6 months of age.[3]

Respiratory Pattern

Respiratory distress is often the first clue to an impending respiratory failure. Scoring systems, like the *Wood-Downes* score [4] (Table 2) and *Becker Pulmonary Index* score for asthma,[5] are often used to monitor patient progress. There are other scoring systems which include blood gases and pulse oximetry. It is however noteworthy that respiratory failure can occur without respiratory distress in central hypoventilation, and in metabolic disorders there may be tachypnea without respiratory disease.

The assessment of adequacy of breathing is given in Box 1.

Circulation

The assessment of circulation is done by a clinical assessment of peripheral perfusion and a record of blood pressure (BP).

Peripheral Perfusion

Capillary refill time (CRT) This is assessed by a firm pressure on the forehead, sternum or tibia and on the soles of feet in neonates.

Table 1: Normal vital signs according to age

Age	*Heart rate (beats/min)*	*Blood pressure (mm Hg)*	*Respiratory rate (breaths/min)*
Premature	120–170	55–75/35–45	40–70
0–3 months	100–150	65–85/45–55	35–55
3–6 months	90–120	70–90/50–65	30–45
6–12 months	80–120	80–100/55–65	25–40
1–3 years	70–110	90–105/55–70	20–30
3–6 years	65–110	95–110/60–75	20–25
6–12 years	60–95	100–120/60–75	14–22
12+ years	55–85	110–135/65–85	12–18

Table 2: Wood-Downes Score

Score	*Wheezing*	*Retraction*	*Respiratory rate*	*Heart rate*	*Ventilation*	*Cyanosis*
0	No	No	<30	<120	Good symmetrical	No
1	End expiratory	Sub/Intercostal	31–39	>120	Regular symmetrical	Yes
2	All expiration	Supraclavicular/nasal	40–60		Very reduced	
3	Inspiration and expiration	+ intercostal + suprasternal			Silent thorax	

Source: Wood DW, Downes JJ, Lecks H, et al. A clinical scoring system for the diagnosis of respiratory failure. Am J Dis Child. 1972:123(3):227-8.

Box 1: The assessment of adequacy of breathing

The work of breathing—
- Respiratory rate
- Recession
- Inspiratory and expiratory noises
- Grunting
- Accessory muscle use
- Flare of ala nasi

Effectiveness of breathing—
- Breath sounds
- Chest expansion
- Abdominal excursion

Effects of inadequate respiration—
- Heart rate
- Skin color
- Mental status

Normally the blanched area disappears in less than 3 seconds and more than 5 seconds is considered significantly abnormal. Despite its simplicity and utility, the CRT is not very specific or sensitive.[6]

Cardiovascular signs When peripheral perfusion is inadequate, the cardiovascular compensatory system gives rise to tachycardia, diminished pulse volume and decreased peripheral pulses compared to central pulses.

Core-peripheral temperature gradient This is a useful sign to detect hypoperfusion. The core temperature is recorded in the mouth, rectum or tympanic membrane and the peripheral temperature is recorded on the skin over the peripheries. A normal core-peripheral temperature gap is below 2°C, and a gap of more than 5°C implies marked hypoperfusion.

Systemic manifestations Hypoperfusion of brain and kidney can give rise to altered mental status and oliguria.

American College of Critical Care Medicine has defined shock in pediatric patients as tachycardia with peripheral signs, decreased peripheral perfusion, including decreased peripheral pulses compared to central pulses, CRT above 2 seconds, altered alertness, mottled extremities and decreased urine output. It is important to note that in pediatric patients, a fall in BP is not required to make a diagnosis of shock.[6]

Blood Pressure

Blood pressure is taken in the right upper limb, but in infants it is important to also check the BP in the legs to rule out the possibility of coarctation of the aorta. BP measurements are done by age appropriate cuffs standardized to the circumference of the arm as outlined in Table 3. The British Hypertension Society (BHS) recommends choosing from three cuff sizes: (1) 4 × 13 cm, (2) 8 × 18 cm and (3) 12 × 35 cm (adult cuff) and putting on the widest cuff that will fit the arm [National High Blood Pressure Education Program, American Heart Association (NHBPEP, AHA)].[7] The Korotkoff sound technique is recommended as the standard for children older than 1 year. In infants the best indirect measurement technique is an ultrasonic flow detector[6] since sounds are difficult to hear in infancy.

The lower limit of systolic BP should be below 60 mm Hg for neonates and below 70 mm Hg for 1 month to 1 year olds.

Table 3: Cuff sizes recommended by the American Heart Association

Cuff	*Arm circumference (cm)*	*Bladder width (cm)*	*Bladder length (cm)*
Newborn	<6	3	6
Infant	6–15	5	15
Child	16–21	8	21
Small adult	22–26	10	24
Adult	27–34	13	30
Large adult	35–44	16	38
Adult thigh	45–52	20	42

Box 2: The assessment of adequacy of circulation and perfusion

Cardiovascular status—
- Heart rate
- Pulse volume
- Capillary refill
- Blood pressure

Effects of circulatory inadequacy on other organs—
- Respiratory rate and character
- Skin appearance and temperature
- Mental status
- Urine output
- Mental status

Table 4: Categorization of hemorrhage and shock in pediatric trauma patients

System	*Compensated shock, mild hemorrhage, simple hypovolemia (<30% blood volume loss)*	*Decompensated shock, moderate hemorrhage, marked hypovolemia (30–45% blood volume loss)*	*Cardiopulmonary failure, severe hemorrhage, profound hypovolemia (>45% blood volume loss)*
Cardiovascular	Mild tachycardia Weak peripheral pulses Strong central pulses Low-normal blood pressure [SBP >70 mm Hg + (2 × age in years)] Mild acidosis	Moderate tachycardia Thready peripheral pulses Weak central pulses Frank hypotension [(SBP <70 mm Hg + (2 × age in years)] Moderate acidosis	Severe tachycardia Absent peripheral pulses Thready central pulses Profound hypotension (SBP <50 mm Hg) Severe acidosis
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Neurologic	Irritable, confused	Agitated, lethargic	Obtunded, comatose
Integumentary	Cool extremities, mottling Poor capillary refill (>2 seconds)	Cool extremities, pallor Delayed capillary refill (>3 seconds)	Cold extremities, cyanosis Prolonged capillary refill (>5 seconds)
Excretory	Mild oliguria, increased specific gravity	Marked oliguria, increased blood urea nitrogen	Anuria

Abbreviation: SBP, systolic blood pressure.
Source: Adapted from Advanced Trauma Life Support Course. Chicago, American College of Surgeons.

For children between 2 and 10, the PALS recommends the fiftieth percentile for systolic BP as 90 + (2 × age in years) and the fifth percentile as 70 mm Hg + (2 × age in years). A BP below the fifth percentile is considered as hypotensive. A classification of pediatric shock is given in Table 4.

The assessment of adequacy of circulation and perfusion is given in Box 2.

DISABILITY

Disability is assessed by a neurological evaluation. A change in the level of consciousness is often a result of direct injury to the brain but can be a manifestation of cerebral hypoxia due to cardiorespiratory compromise. The alert/verbal/pain/unresponsive (AVPU) scale (Table 5) and the Glasgow Coma Scale (GCS) (Table 6) are used to assess neurological status. GCS is widely used method to evaluate neurological function. Patients with a GCS score below or equal to 8 require aggressive treatment including airway management and intubation.

Table 5: AVPU neurologic assessment

A	The child is awake, alert and interactive with parents and care providers
V	The child responds only if the parents or care providers call the child's name or speak loudly
P	The child responds only to painful stimuli, such as pinching the nail bed of a toe or finger
U	The child is unresponsive to all stimuli

EXPOSURE

This is the final step in the assessment of the child where the child is undressed and a full general and systemic examination is carried out, to look for coexisting illnesses, injuries and medical issues. In children, it is important to note that the general examination often gives much more important information than a systemic examination. An experienced clinician can identify a "sick" look in a child with a serious illness. This "look" has been described by the mnemonic *TICLS*.[1] The observations include: Tone, Interactiveness (playfulness), Consolability, Look (gaze) and Speech (cry). A child who is not seriously sick would have a good tone, respond to the mother and be comforted and playful. A sick child in contrast would be limp, irritable, and listless and have a weak cry.

Table 6: Glasgow Coma Scale

Eye opening	*Points*	*Motor response*	*Points*
Spontaneous	4	Obeys	6
To voice	3	Localizes pain	5
To pain	2	Withdraws	4
None	1	Flexion	3
		Extension	2
		None	1
Verbal response (older children)	Points	Verbal response (infants and young children)	Points
Oriented	5	Appropriate words; smiles, fixes and follows	5
Confused	4	Consolable crying	4
Inappropriate	3	Persistently irritable	3
Incomprehensible	2	Restless, agitated	2
None	1	None	1

MONITORING

Monitoring is essential to identify serious illness in a child, assess response to treatment, decide on the need for hospitalization and monitor during hospitalization. There is a gamut of devices for monitoring a critically ill child. The choice of device is dictated by the clinical assessment of the child, keeping in mind cost and availability of devices and available medical skills. Excessive dependence on technology is clinically confusing,[8] and there is no hard evidence that extensive monitoring improves clinical outcome.[9] Monitoring will be discussed under two heads: (1) assessment of gas exchange and (2) hemodynamic monitoring.

Assessment of Gas Exchange

Pulse Oximetry

Pulse oximetry is now referred to as the "fifth vital sign" in critical care assessment.[10] As a readily available noninvasive device to monitor oxygenation, the use of the pulse oximeter is now almost a part of clinical assessment. In general, most children have SaO_2 above 97%, but SaO_2 above 95% is considered reassuring. SaO_2 below 90% on room air suggests hypoxia and a red flag that these children need to be monitored carefully.

Pulse oximetry is used in any situation where hypoxia is suspected because clinical signs are not reliable in predicting hypoxia. In pediatric patients, a clinical assessment of hypoxia had a sensitivity of only 33% and the presence of respiratory distress had a sensitivity of only 74% in predicting hypoxia.[10] Patient management was changed 91% of times when SaO_2 was known. Pulse oximetry has therefore become an essential tool for assessing any child requiring cardiorespiratory monitoring.

Pulse oximetry is used to detect a hypoxic patient populations in a variety of clinical settings. It is routinely used to detect hypoxia during pediatric procedures, particularly when sedation is required, including dental care. The American Academy of Pediatrics recommends continuous pulse oximetry in patients receiving sedation and analgesia.[3,11] In the emergency room, reassuring saturations reduce the length of observations and permitted early discharges. It is also useful to assess the response to treatment as well as the need for hospitalizations.[12,13] In the ICU, continuous monitoring with the pulse oximeter is routinely advised. Pulse oximetry reduces the number of blood gases required in an ICU setting without compromising outcome.[13,14] Oximetry may be less prone to error and more accurate in the assessment of oxygenation in patients with cardiopulmonary disease when compared with arterial blood gas (ABG) measurement.[13] It is an important tool to assess the response to cardiopulmonary resuscitation in neonates and children.[1] Routine screening with pulse oximetry of newborns before discharge is an effective tool to identify newborns with congenital heart disease.[15] In pediatric patients where obtaining ABG is difficult or when blood gas facilities are not available, pulse oximetry is invaluable.

Pulse oximetry is also useful for hemodynamic monitoring.[3] Recording the BP in infants can be difficult. Pulse oximeters that display waveforms can be used to measure the systolic BP in infants. The disappearance of the waveform on inflation of the cuff as well as the reappearance of the waveform on deflation of the cuff may be used to record the systolic BP. Alternation in the waveform has also been found to correlate with pulsus paradoxus.

Pulse oximeters have several limitations and readings can be inaccurate due to motion artifacts, presence of COHb and MetHb and errors in transmitted light. Some of the newer oximeters overcome many of these errors. The development of reflectance oximeters, which do not rely on transmitted but on reflected light, are under way. Other technologies are being developed[12,14] to assess tissue oxygenation and brain oxygenation and perfusion.

Pulse oximetry remains the most commonly used monitoring device in children. A clinician aware of its limitations can use it effectively to monitor children noninvasively with reasonable accuracy.

Arterial blood gas It is the traditional method for assessing oxygenation (PaO_2), ventilation ($PaCO_2$) and acid-base status (HCO_3, pH) and remains the gold standard for assessing respiratory status in a critically ill child. It is used intermittently to confirm blood gas status in a child being monitored noninvasively through pulse oximetry. Arterial cannulation is preferred when one anticipates the need for frequent blood gas sampling and when continuous BP monitoring is required in a critically ill child. Arterial blood sampling is sometimes necessary when venous blood sampling is difficult due to vascular collapse.

An ABG analysis is the best indicator of the physiological status of the cardiorespiratory system. The PaO_2, $PaCO_2$ and the pH/HCO_3 give the best indicator of the oxygenation, ventilation and the acid-base status in the critically ill patient. The blood gases can be assessed by the arterial or venous blood gases and transcutaneous blood analysis. Values of arterial PaO_2 below 85 mm Hg are usually abnormal for a child breathing room air at sea level. Values of arterial $PaCO_2$ above 45 mm Hg usually indicate hypoventilation, severe lung disease or a compensatory response to metabolic alkalosis.

Venous blood gas Venous blood gas (VBG) sampling is performed when arterial sampling is difficult since central venous access is usually available in a critical care setting. A VBG can be performed using a peripheral venous sample (obtained by venipuncture), central venous sample (obtained from a central venous catheter), or mixed venous sample (obtained from a pulmonary artery catheter). A VBG measures the venous oxygen tension (PvO_2), carbon dioxide tension ($PvCO_2$), acidity (pH), oxyhemoglobin saturation ($S\dot{v}O_2$), and serum bicarbonate (HCO_3) concentration. $PvCO_2$ and venous pH are used to assess ventilation and acid-base status, but measurement of PvO_2 is unreliable. A VBG is therefore often used in conjunction with pulse oximetry. Venous blood gases from a central vein or pulmonary artery ($S\dot{v}O_2$) are used to guide resuscitation during septic shock.

Transcutanous blood gas determination This involves measurement of PO_2 and PCO_2 by monitors placed on the skin electrochemically. Electrodes are attached to the skin on non-bony well-perfused areas like the abdomen, inner thigh and chest.[11] The monitors have a heating element which warms the skin up to 42–44°C and therefore arterializes the underlying skin. It is therefore reliable only when the BP and perfusion are normal. It is noninvasive, permits continuous monitoring of blood gases and reduces the need for frequent blood gases. The main advantage is in neonates where its readings are accurate over a wide range of PaO_2 values.[15,17] The disadvantage is that the instrument needs frequent calibrations and frequent site change to avoid skin burns[16,17] and an overestimated PaO_2 in the hypoxic range. Due to these limitations, these monitors are rarely used in the pediatric intensive care unit (PICU).

Capnography Capnography is the noninvasive measurement of CO_2 in the exhaled breath ($ETCO_2$). Capnogram refers to the graphic representation of CO_2 as a waveform over a period of time. CO_2 monitors can be either mainstream or sidestream.[13,17] Mainstream monitors are attached to the endotracheal tube and are generally used in ventilated patients. Sidestream monitors detect CO_2 from a nasal or oral cannula and can be used in the ventilated or in spontaneously breathing patients. In sidestream monitors, high flows and increased dead space make monitors less reliable in children. This problem has now been overcome by low flow microstream capnometers which require a minimal sample flow rate (50 mL/minute) enabling its use even in neonates and infants.

The normal $ETCO_2$ value is usually 2–5 mm Hg less than the $PaCO_2$.[14] The correlation between arterial $PaCO_2$ and $ETCO_2$ is reliable when the lungs are normal, and the problem is with ventilation or perfusion. In patients with pulmonary disease or mixed ventilation and perfusion illnesses or metabolic derangements, results are difficult to interpret, and $ETCO_2$ is useful only to document trends over a period of time.

The use of capnography in children is similar to its use in adults.[14,18] In intubated patients, capnography is of greatest value for emergency departments and emergency medical services for confirming placement of endotracheal tubes, continuous monitoring of tube position during transport, assessing the status of patients in cardiac arrest, and monitoring the respiratory status of patients undergoing procedural sedation. In spontaneously breathing patients, capnography can be helpful in monitoring the status of patients with seizures, acute respiratory distress, unconsciousness and metabolic acidosis.

Hemodynamic Monitoring

Electrocardiography

Heart rate is the most common parameter monitored in the PICU. Children increase cardiac output more by increasing the heart rate than increasing the cardiac contractility, and an increase in heart rate is an important sign of circulatory insufficiency. Trends in heart rate can often guide fluid requirements and choice of inotropes. ECG can also assist in detecting rhythm disturbances, hyperkalemia or ischemia.

Noninvasive Blood Pressure Measurement

Automated BP devices which measure BP noninvasively through the oscillometric method are now routinely used in PICUs.[14] These devices have reduced the errors associated with manual methods. Using the correct cuff size improves accuracy.[7,14] A narrow cuff produces a high pressure and a wide cuff produces a low pressure. The American Heart Association recommends that the width of the inflatable bladder be 40% of the mid arm circumference of the limb and the length should be twice the width. Slow deflation further improves accuracy. Noninvasive BP devices are widely used in PICUs since inserting and maintaining arterial cannulas in young children is often difficult. One should however be aware that the accuracy of noninvasive monitors is reduced in the presence of hypotension, dysrhythmias and limb edema. The readings are falsely elevated in hypotension and reduced in hypertension. It is therefore recommended to monitor BP continuously through invasive arterial cannulation in the critically ill child.

Arterial Blood Pressure Monitoring

Children admitted to an ICU need an accurate assessment of circulatory status. Clinical signs of circulatory insufficiency are seen long before a fall in BP and indicate the need for accurate BP monitoring. Due to technical difficulties in arterial cannulation, noninvasive BP monitoring is frequently

practiced in the PICU. It should be emphasized however that direct BP readings are 5–20 mm Hg higher than indirect measurements[19] and intra-arterial recordings are considered the standard of care for monitoring BP in a critically ill child.

The technique, monitoring and complications of arterial cannulation are the same as in adults.[20] The radial artery is the most commonly used site in children. In newborns, the umbilical arteries are used in the first week of life. In infants with patent ductus arteriosus, the right radial artery represents the preductal oxygenation and the left radial represents postductal values. Other sites used for cannulation include: ulnar, axillary, femoral, dorsalis pedis and posterior tibial.

Central Venous Pressure Monitoring

Indications for central venous access include insertion of central venous catheters for administration of medications or fluid, parenteral nutrition, hemodynamic monitoring, plasmapheresis or hemodialysis. Central venous access may be necessary in patients with poor peripheral venous access.[21]

Central venous pressure (CVP) monitoring is used to guide fluid therapy in patients with shock, myocardial impairment or severe pulmonary disease. In adults, the flow directed balloon tipped pulmonary artery catheter has somewhat replaced central venous pressure monitoring because it is more reliable in patients with pre-existing cardiac and pulmonary disease.[20] In children, however, CVP monitoring continues to have a role to guide fluid therapy. In the specific setting of septic shock, CVP monitoring is an important component of "goal directed therapy". Measurement of central venous oxygen saturation is a part of the treatment of septic shock.

The normal CVP is 1–5 mm Hg. A CVP greater than 7–10 mm Hg is considered high. The determinants of CVP are ventricular function, intravascular volume and pulmonary vascular resistance.[20,22] A low CVP indicates low return of blood to the right atrium and indicates the need for more fluids. Low CVP is also seen in sepsis and spinal cord injury due to reduced vasomotor tone. Unlike adults, children usually have good cardiac reserve and tolerate fluid challenges well. Pediatric intensivists resort to CVP monitoring only if adequate fluid challenges do not restore BP. A high CVP indicates that there is cardiac dysfunction and the heart is unable to pump the blood or that there is fluid overload.

Left Atrial Pressure Monitoring

The CVP offers effective guidelines for fluid therapy only when the myocardial contractility and lung functions are normal. In critically ill children, particularly after cardiac surgery, the CVP is a poor predictor of LV end-diastolic pressure, and these children need a surgically placed left atrial catheter. These lines are used infrequently in children and are usually removed within 2 days to reduce complications.[20]

Cardiac Output

Cardiac output is the volume of blood ejected by the heart each minute, measured in liter/minute. Assessment of cardiac output can be done indirectly or directly. Direct assessment of cardiac output can be done noninvasively by echocardiography or by invasively by cardiac catheterization. Cardiac output is determined by the following factors: heart rate, preload, cardiac contractility and afterload.[20] Indirect assessment of cardiac output involves assessing each of these factors. An accurate evaluation of the physiologic status of the circulatory system helps in the choice of medications to support cardiovascular insufficiency.

Invasive cardiac output monitoring is usually needed only in cardiac cases. Cardiac output can be measured by different techniques including thermodilution, CO_2 rebreathing and dye dilution. The common variables calculated include cardiac index, stroke index, pulmonary and systemic vascular resistance, stroke work index and oxygen delivery. A detailed discussion on these values is beyond the scope of this chapter.

Noninvasive assessment of cardiac function is routinely done at the bedside by echocardiography.[14,23] Cardiac contractility is assessed by the SF (Shortening Fraction) and the EF (Ejection Fraction). The SF or the percent change in ventricular diameter gives a measure of the global systolic function. The normal SF values are 29–41%. The EF uses the percent change in end diastolic volume to assess cardiac contractility. The normal EF value in children is 60% ± 7%. The echocardiography also gives an estimate of the diastolic function and afterload.

Assessment of Intravascular Volume

Optimum fluid therapy is crucial in intensive care, particularly in children. Half the patients will improve their cardiac output and oxygen delivery when given appropriate fluid challenges.[20,24] Traditionally intravascular volume is assessed by static parameters (CVP and left atrial pressures) but more recently there is considerable interest in measuring dynamic parameters to improve accuracy.

Static measurement of intravascular volume Despite its limitations, a commonly used marker for the assessment of the preload is the CVP (right atrial pressure). The pulmonary artery wedge pressure (left atrial pressure) is usually monitored only in cardiac surgical cases or critically ill children with lung disease. If fluid challenges do not improve cardiac output, it means that inadequate fluid has been administered or that there is impaired cardiac contractility.

Dynamic assessment of intravascular volume Dynamic measurements evaluated include systolic pressure variation (SPV), pulse pressure variation (PPV) and stroke volume variation (SVV).[14,24] A difference of greater than 13% in maximum and minimum values during inspiration and expiration has been shown to be highly sensitive and specific in identifying hypovolemic patients who are fluid responsive. These values are however sensitive only in the sedated ventilated patients in sinus rhythm. In non-ventilated patients, a fall in CVP by 1 mm Hg during inspiration is a predictor on the need for additional fluid challenges. In ventilated patients, a collapsibility of the inferior vena cava greater than 12% during respiration has been shown to predict response to fluid boluses.

Assessment of Tissue Oxygenation

A functional end-point for cardiac output is to assess whether there is adequate oxygenation of the tissues. The markers used to assess tissue oxygenation are the *mixed venous oxygen saturation* and the *blood lactate*.[14,20] The normal mixed venous oxygen saturation is 73% (65–75%) and the average arteriovenous oxygen saturation difference is 20–33%. An elevated blood lactate usually indicates anaerobic glycolysis in the skeletal muscles due to circulatory insufficiency. Elevated lactates are also seen in sepsis due to tissue dysoxia.[20] A mixed venous saturation below 60% is clearly abnormal and a value below 50% indicates a worse outcome. Normally, the serum lactate is below 2 mmoL/L. Serum lactate above 4 mmoL/L indicates worse outcome.

In circulatory insufficiency, blood supply to vital organs is maintained at the cost of perfusion to the skin and splanchnic areas. Splanchnic hypoperfusion can be identified by *sublingual capnometry* and *gastric tonometry*, and skin hypoperfusion can be identified by *transcutaneous CO_2 estimation*. Newer techniques like *orthogonal polarization spectroscopy* and *near-infrared spectroscopy*[14,20] attempt at direct assessment of microcirculation but are not yet in clinical use.

CONCLUSION

Monitoring is an important aspect of critical care and improves patient care. In recent years there has been an explosion in medical technology and it is now imperative that clinicians approach monitoring in a rational manner. The basic question an intensivist needs to ask is whether monitoring is justified and likely to improve outcome.[8,25] Clinicians are increasingly aware that monitoring should be done in a clinically appropriate manner, taking into account need, cost, accuracy and safety of monitoring techniques.

CHAPTER 79

Approach to Shock in the Pediatric Intensive Care Unit

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

Shock is defined as a state of circulatory dysfunction that results in failure to provide adequate oxygen and other nutrients to meet the metabolic demands of the tissues. This is usually due to a reduction in cardiac output, maldistribution of regional blood flow, or a combination of both factors. Rarely it may occur due to increased metabolic requirements or impaired oxygen utilization at the cellular level. Such cellular oxygen deficiency leads to altered metabolism and decreased energy production, which, if uncorrected, may result in death.

Everchanging metabolic demands of tissues are met with primarily by adjustments in the cardiac output, which is the product of stroke volume and heart rate. In infants and young children, it is mainly the increase in the heart rate which tries to maintain the cardiac output, whereas in older children (as in adults), stroke volumes can be efficiently increased to improve cardiac output, without significant change in the heart rate. Thus infants and young children are at high risk of decompensation at an earlier stage as compared to older children. Besides suitable modification of cardiac output, the metabolic demands of a particular organ can be met by augmenting the regional blood flow by appropriate changes in the vasomotor tome mediated through neurohumoral mechanisms. When such physiological changes fail to meet the metabolic requirements, shock ensues. In pediatric practice, shock is a common accompaniment of many disease states; however, the pathogenesis of shock varies depending upon the nature of disease. The different clinical forms of shock are briefly enumerated below—

- *Hypovolemic shock* results from decreased circulating blood volume commonly due to loss of fluids from the extravascular or intravascular compartment; it may also be due to third space fluid losses associated with the capillary leak syndromes.
- *Distributive shock* results from maldistribution of blood flow due to widespread abnormalities in vasomotor tone. Vasodilatation leads to venous pooling with decreased preload and shock ensues. Septic shock represents this type of shock. Other etiologies, like central nervous system injury, anaphylaxis and drug intoxication, may also result in distributive shock.
- *Cardiogenic shock* results from decreased myocardial contractility. It may occur in patients with congenital heart defects, in whom shock is preceded by congestive cardiac failure, or in children with previously normal hearts who have suffered hypoxic injury or metabolic derangements.
- *Obstructive shock* results from mechanical obstruction to venous inflow to the heart, as seen in cardiac tamponade, or to tight ventricular outflow as in pulmonary embolism.
- *Dissociative shock* occurs in conditions like methemoglobinemia and carbon monoxide poisoning where oxygen is not released from hemoglobin to the tissues, in spite of normal tissue perfusion.

The first three types of shock are quite common while the last two varieties are rather rare.

PATHOPHYSIOLOGY OF SHOCK[1]

Reduced cardiac output is the main factor in the evolution of shock. Hypovolemic shock results from a decrease in preload due to contraction of the intravascular volume as a result of blood or fluid loss. In septic shock, decrease in preload is the result of much more complex mechanisms. In sepsis, bacterial products interact with the reticuloendothelial cells to produce

a wide variety of mediators, which exert a potent effect on vascular tone and permeability leading to maldistribution of blood flow. Activated complement components promote leukocyte and platelet aggregation in capillaries, resulting in mechanical obstruction to blood flow. These changes in microcirculation which are the hallmark of septic shock also depress myocardial function, which further reduces cardiac output, as in cardiogenic shock. Thus, diminished cardiac output and resultant lowering of blood pressure trigger a series of changes that are characteristic of the clinical shock states.

Compensated Stage

With the onset of shock, the body tries to compensate for the reduced cardiac output by sympathetic discharge which leads to vasoconstriction, thereby increasing the heart rate and myocardial contractility. This results in improved cardiac output and blood pressure. However, if the basic condition leading to shock is not controlled quickly, continued sympathetic overactivity beyond a certain limit proves detrimental to the patient, precipitating the decompensated stage of shock.

Decompensated Stage

Increasing heart rate leads to reduced myocardial perfusion and excessive oxygen consumption, which results in lowering of cardiac output. Hence the very mechanisms which are compensatory in the early stage of shock prove to be detrimental at a later stage, perpetuating tissue ischemia, impairing cell function and ultimately resulting in cell death. Tissue ischemia releases biochemical mediators which exert potent effects on capillary endothelium and other cellular elements, thereby aggravating existing damage.

Cellular Response to Ischemia

Tissue ischemia with resultant lack of oxygen gives rise to anaerobic cell metabolism. Only 2 moles of adenosine triphosphate (ATP) are produced per mole of glucose, instead of 38 moles produced by aerobic metabolism. Cellular ATP levels fall leading to failure of energy-dependent processes. Anaerobic glycolysis with excess of lactate production and increased organic phosphates from ATP hydrolysis results in extracellular and intracellular acidosis. This leads to influx of sodium, calcium and water into the cell, and efflux of potassium out of the cell; this damages the cell membrane and further impairs cell-ion regulation. Such changes impair energy production and promote release of acid hydrolases, which in turn cause tissue inflammation and injury.

Chemical Mediators in Shock

In all types of shock, but particularly in septic shock, mediators play an important role in initiating and sustaining impairment in tissue perfusion.[2] These agents cause vasospasm, platelet aggregation and thrombus formation; they also increase capillary permeability, and promote maldistribution of blood flow.

A variety of arachidonic acid metabolites have been implicated as being modulators of shock. Thromboxane A_2 is the most important of these compounds. It is mainly formed by the platelets and also by vascular smooth muscle, lung and the spleen. It is a potent vasoconstrictor and has platelet aggregating thrombogenic properties. These effects further reduce blood flow in an already compromised microcirculation, producing extension of tissue ischemia and death. Vasoactive prostaglandin-F (PGF) alpha-2 is also formed by the platelets and is a potent vasoconstrictor. Prostacyclin is believed to neutralize the deleterious effect of thromboxane and is produced by healthy capillary endothelium. However, as the capillaries are damaged, insufficient prostacyclin is produced and hence the shock state is perpetuated. Leukotrienes are produced by different types of cells like leukocytes, macrophages and mast cells. They enhance capillary permeability, produce intense vasoconstriction and have a myocardial depressant action. Intrinsic myocardial depression exists in all types of shock, mediated through several hemodynamic mechanisms. Irrespective of these factors, a small peptide released from pancreatic acinar cells due to ischemia is known to exert a negative inotropic effect, and is named the myocardial depressant factor. This mediator depresses myocardial function even in the presence of normal coronary flow, preload and afterload. This factor also causes pancreatic ischemia, as well as depression of the reticuloendothelial system. Endogenous opiates, most widely implicated in the pathogenesis of shock, are released from the pituitary in response to stress.

CLINICAL APPROACH

In vulnerable clinical settings, one must suspect and watch for early signs of shock. Much before clinical signs manifest clearly, there may be early clues, raising a suspicion of shock. Disproportionate tachycardia and tachypnea indicates systemic inflammatory response and is a forerunner of impending sepsis. An increase in the difference between the core and skin temperatures, and postural hypotension may suggest impending shock. Subsequently typical clinical signs develop which consist of increasing tachycardia, increasing tachypnea, low or normal blood pressure, cool and mottled extremities, poor color and prolonged capillary refill, more than 2–3 seconds. In the early stage of distributive shock, patients may be febrile with a dry hot skin, and normal blood pressure often referred to as warm shock. Urine output is an excellent indicator of renal perfusion and must be monitored on an hourly basis. A depressed neurological state may ensue later. All the above-mentioned clinical signs must be periodically assessed; however, they have to be supplemented by appropriate biophysical and biochemical parameters.

Septic shock[2] is a clinical challenge for early diagnosis and prompt management. Though Gram-negative bacterial infections are more commonly the causative factors in the evolution of septic shock, Gram-positive bacterial infections as well as viral infections, parasitic infections (like malaria),

and even myobacterial and fungal infections may lead to septic shock in children. In fact, any infection in a vulnerable setting constitutes a potential threat to develop into septic shock. It is the sound knowledge of interactions between host factors and infections that guide a clinician to anticipate the outcome in a given infection. If an infection, instead of localizing, threatens to spread, a competent host develops a systemic inflammatory response syndrome (SIRS). SIRS is a measure of a counter-regulatory process, clinically evident by disproportionate tachycardia and tachypnea. This stage represents early sepsis. If infection further worsens, the counter-regulatory mechanisms fail to maintain the body's homeostasis. This corresponds to a stage of severe sepsis. On further deterioration, organ failure ensues and this heralds the development of septic shock. In unfavorable conditions, a patient may pass through these stages rapidly within 12–24 hours, giving little time for action. Hence clinical anticipation and early monitoring are key factors for successful management.

For the sake of understanding, three distinct phases (early sepsis, severe sepsis and septic shock) may be defined; each phase however overlaps the other, and there are no clinical or investigatory parameters for their precise diagnosis.[3] It is the continuous monitoring of vital parameters together with periodic biochemical monitoring that predicts the trend in a given disease state. A single record of any parameter is of much less significance that the trend observed over a period of time. Besides continuous display of heart rate, respiratory rate, core and skin temperatures, and noninvasive blood pressure readings, arterial oxygen saturation, and end-tidal PCO_2 monitoring help in optimum management. Central venous pressure (CVP) monitoring helps in the infusion of adequate amount of fluids especially in septic shock. Children with septic shock need very large amounts of fluid and are in constant danger of both under- or overperfusion, in the absence of proper monitoring facilities. Sophisticated monitoring may entail the study of metabolism at cellular level, and assessing both oxygen delivery and consumption.[4]

MANAGEMENT

Early rapid infusion of fluids to replenish the intravascular volume, often decides the ultimate outcome of a patient in shock.[5] In septic shock the source of sepsis should be promptly identified and eradicated. The earlier this is done, the better the prognosis. Empiric use of antibiotics in patients where the nature of infection cannot be immediately proven is on the same principles as in adults.

Diagnosis of early shock should be followed by volume challenges of at least 20 mL/kg body weight of Ringer lactate. If this produces improvement in vital parameters, then appropriate infusions are continued and the patient is monitored clinically. However, if there is no adequate improvement on such a challenge, then further infusions should be planned by CVP monitoring. Crystalloids are commonly used; they may be safely infused to an amount equivalent to 50% of circulating blood volume, beyond which point peripheral tissue and pulmonary edema may develop. Colloids like plasma, blood or dextran are administered under close monitoring, as they are likely to expand the intravascular space by a volume greater than that infused, and may cause circulatory overload. Dextran solutions have an advantage of improving microcirculation by decreasing RBC aggregation and improving oxygen transport; however, their administration should not exceed 20 mL/kg per day. In hypotensive patients dopamine may be required to augment cardiac output, whereas in low cardiac output states with normal blood pressure, dobutamine may be the drug of choice. Vasodilators may be indicated in the late stages of shock where vasoconstriction is the prominent feature. Cardiac failure and rhythm disturbances may need appropriate therapy.

If in spite of adequate replacement, hypotension and hypoperfusion persist, CVP monitoring alone may not suffice, and further invasive monitoring is often required to assess the right and left atrial pressures and cardiac output; however, this is not routinely required. In case of renal hypoperfusion, diuretics should be used only after adequate volume expansion.

Metabolic status including oxygenation should be periodically evaluated and adequate steps are necessary to correct abnormalities. Hypoxia at the cellular level is the key factor in the pathogenesis of shock, and hence adequate oxygenation is mandatory in every patient. Blood gas determinations should guide timely interventions, including mechanical ventilator support.

The use of corticosteroids in the management of shock is controversial. Though theoretically steroids are supposed to exert a beneficial effect through various mechanisms, controlled studies have not found statistically significant benefits, and hence no definite recommendations can be made. Many other drugs have been tried, like the opiate antagonist naloxone, and thyrotropin, but as yet these cannot be recommended for routine use. Future drugs used

Box 1: Resuscitation in shock

Goal of therapy—
- To maintain normal blood pressure and keep mixed venous O_2 saturation >70%

Management—
- Recognize poor perfusion—reduced urine output and mental status
- Maintain airway and secure vascular access
- Aggressive volume replacement—
  - Push 20 mL/kg body weight of isotonic saline in 20 minutes—if need be repeat two more pushes over next 40 minutes
  - If fluid refractory shock—establish central venous pressure and start dopamine
  - If fluid refractory and dopamine resistant shock—epinephrine for cold shock and norepinephrine for warm shock
  - If catecholamine-resistant shock—hydrocortisone

in shock would essentially antagonize the actions of the numerous chemical mediators involved in shock. Till then, early recognition, maintenance of a satisfactory circulatory and metabolic state, and above all, prompt eradication of the underlying pathology remain the mainstays of management (Box 1).

CHAPTER 80

Hypertensive Emergencies in Pediatrics

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

In children, severe hypertension is almost always secondary. In fact, primary hypertension is mild and asymptomatic. About 80% of children with hypertension have underlying kidney disease, two-thirds of them mesoparenchymal and one-third renovascular. Ten percent of patients suffer from hypertension due to coarctation of aorta or aortoarteritis of various etiologies. The remaining patients comprise of endocrinal disorders and other miscellaneous causes.

Hypertensive emergencies may occur in patients with known kidney disease. However, at times hypertension may be the only presenting feature, often manifesting with vague nonspecific symptoms that may suggest primary central nervous system (CNS), cardiovascular or ocular disease. Hence in any seriously ill child who presents with ill-defined encephalopathy (headache, vomiting, irritability and change in sensorium), cardiac failure, or visual disturbances of unknown etiology, the blood pressure must be recorded. Accurate measurement of blood pressure is difficult in children and demands a proper size cuff, correct technique and patience on the part of the clinician. As the blood pressure is markedly elevated in hypertensive emergencies, a small error in the blood pressure recording does not change the interpretation or the management.

It is the sudden rise in the blood pressure that presents as an emergency, rather than chronically elevated blood pressure which has fewer symptoms. The child may present with convulsions and demonstrate various neurological abnormalities mimicking intracranial infection. Fundus examination may show evidence of papilledema or retinal hemorrhages. Sudden onset of left ventricular failure, especially in the presence of overhydration may be a manifestation of acute glomerulonephritis and may be mistaken for myocarditis or bronchopneumonia.

MANAGEMENT[1-3]

The main aim of therapy is to reduce the blood pressure to a safe level, control various complications like seizures, cardiac failure and airways obstruction, and treat the primary cause when feasible. Reduction of blood pressure should be achieved over 3–4 days to a level of 95th percentile appropriate for the age. A sudden precipitous fall in blood pressure may be associated with development of neurological signs and impairment of cerebral and renal blood flow. Several drugs are available for prompt reduction of blood pressure. Diazoxide and labetalol are not easily available, and nifedipine is the drug most often used in our setup. Though sublingual administration is known to lead to a sudden fall in blood pressure, in our experience it occurs rarely. Sodium nitroprusside is an excellent drug for continuous infusion; it is extremely potent and needs careful titration of the dose by constant monitoring. Hydralazine is another drug, but is rather slow in action. In case of accompanying fluid overload, diuretics like furosemide can be used; otherwise, diuretics may in fact be harmful as they may lead to volume depletion and hypotension. Dosage of drugs commonly employed in the treatment of hypertensive emergencies are given in Table 1.

Supportive measures include control of seizures by diazepam 0.3 mg/kg per dose, and antifailure treatment in case of cardiac failure. Surgical intervention may be necessary at times. Maintenance therapy for hypertension can be continued orally.

Table 1: Drugs commonly used (with route of administration and dosage) for treatment of hypertensive crisis in the pediatric age group

Drug	*Route of administration*	*Dosage*
Nifedipine	Sublingual	0.5 mg/kg every 4–6 hours
Sodium nitroprusside	IV infusion	0.5 µg/kg per minute
Labetalol	IV	1–3 mg/kg
Diazoxide	IV	1–5 mg/kg every 4–6 hours
Hydralazine	IV	0.2 mg/kg every 4–6 hours
Furosemide	IV	2–5 mg/kg

Abbreviation: IV, intravenous.

CHAPTER 81

Heart Failure in Neonates and Children

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

Cardiac failure is a state in which the heart cannot maintain adequate output to sustain metabolic demands of the body. In the early stages, the heart tries to maintain optimum output by physiological adjustments; however, after a certain point, compensatory mechanisms fail, and decompensated stage of cardiac failure ensues. Clinical manifestations vary a great deal between neonates and older children. No age is exempted from cardiac failure, but the etiological factors are so diverse in the different age groups that prompt recognition of cardiac failure and diagnosis of its etiology, often pose a challenge to the clinician. Moreover, the majority of these patients present as medical emergencies, with very rapid decompensation. This is due to the limitations of physiological compensatory mechanisms in children. Unlike adults, where stroke volume can be modified to a considerable extent by appropriate changes in myocardial contractility, preload and afterload, in children it is mainly changes in the heart rate that try to maintain cardiac output, without much change in the stroke volume. However, increase in the heart rate beyond an optimum level, in fact, results in poor coronary filling, and increased oxygen consumption leading to early decompensation. Thus early recognition of cardiac failure is far more important in young children.

In our experience, 10% of patients in any pediatric intensive care unit (ICU) manifest with significant cardiac problems. Though congenital defects and acquired heart diseases presenting with cardiac failure are common to all age groups, certain conditions predominate in specific age groups. Besides congenital defects like hypoplastic left heart, transposition of the great vessels and large left to right shunts, birth asphyxia is an important cause of cardiac failure in newborns. Occasionally, a baby is born with hydrops fetalis is as a result of cardiac failure due to severe anemia caused by isoimmune hemolytic disease. Severe anemia in the newborn may also be caused by fetomaternal transfusion, hemorrhage due to birth injury or a bleeding diathesis. In infants and young children, cardiac failure may result from large left to right shunts, endocardial fibroelastosis, cardiomyopathy, viral myocarditis and hypertension, including coarctation of the aorta. In older children above 5 years of age, rheumatic heart disease is a major cause of cardiac failure in our country. Other important conditions include infective endocarditis, viral myocarditis, diphtheritic myocarditis and pericardial effusion due to tuberculosis or other infections. Acute hypertension often presents with cardiac failure in this age group. Cor pulmonale, thyrotoxicosis and beriberi, are rare in children.

CLINICAL FEATURES[1]

Newborns and infants present with varied and vague symptoms that are often unrelated to the cardiovascular system. Poor feeding, vomiting, diarrhea may be initial symptoms while restlessness, excessive sweating and crying may offer clues to the diagnosis of cardiac failure. Tachypnea, chest retractions and tachycardia are invariably present. Hepatomegaly is a constant feature, though tenderness and the hepatojugular reflux are difficult to elicit. Normally, the liver is palpable in newborns and young infants, and has a clearly defined edge. In case of cardiac failure, the liver edge becomes rounded and is a good clinical pointer to a pathological liver. Edema of feet is often absent. Marked tachycardia, gallop rhythm and murmurs, if present, are commonly observed clinical signs.

In older children, symptoms and signs are similar to those seen in adults, and hence easily detected. Breathlessness, edema on dependent parts, right hypochondrial pain, and oliguria are the classical symptoms. Besides tachycardia and tachypnea, a tender, enlarged liver with a positive hepatojugular reflux, cardiomegaly, basal crepitations in the lungs, soft heart sounds and murmurs, if any, are the characteristic clinical signs. Signs of cardiogenic shock may ensue at any stage.

INVESTIGATIONS[1]

In newborns and young infants, mild cardiomegaly is difficult to assess radiologically. Echocardiography (ECG) needs proper-sized chest leads, and interpretations are essentially age-dependent. Two-dimensional ECG with Doppler study is very useful in delineating anatomical defects, as well as assessing the functional state of various chambers and valves. Vegetations can be picked up easily in cases of active rheumatic carditis as well as in infective endocarditis. Other relevant investigations include serum electrolytes, acid-base balance and oxygenation status.

MANAGEMENT[2-5]

Cardiac failure is an emergency which especially in infants and young children needs prompt management. Nonpharmacological measures are as important as drug treatment. A proper position (ideally propped up) is comfortable for older children, but infants may have to be managed even on the mother's lap. Humidified oxygen is given by a hood in an infant, at the rate of 8–10 L/minute; this may be administered by mask or nasal prongs in older children. Adequate sedation may be necessary at times in young children, either with chloral hydrate (20–25 mg/kg per dose orally) or in very sick infants with pulmonary edema, even with morphine (0.1 mg/kg per dose subcutaneously). Adequate hydration and nutrition need to be maintained by suitable methods, either orally or intravenously. Salt-restricted diet with sufficient calories and appropriately restricted fluids may have to be planned to meet the increased energy requirements, without overloading the child with salt and water.

Cardiac output may be increased by using inotropic drugs combined with diuretics and vasodilators as and when necessary. Digoxin is an important drug in the control of cardiac failure.[2,3] In pediatric patients, rapid digitalization (0.04–0.05 mg/kg) over 24 hours is generally required; however, in certain conditions in older children, slow digitalization over a week may be ideal. Later, a maintenance dose of 0.01 mg/kg per day is administered. Other inotropes like dopamine and dobutamine are used in cardiogenic shock, asphyxia and postsurgical conditions. Diuretics like furosemide (1–2 mg/kg per day), thiazides (1–2 mg/kg per day) and spironolactone (1–2 mg/kg per day) are used judiciously in combination with digoxin, starting with a low dose and titrating the same as per the clinical state. Vasodilators like captopril (0.5–2 mg/kg per day) may be useful in cases of pulmonary edema due to mitral or aortic regurgitant lesions, as well as in postoperative patients with cardiac failure. Precipitating factors like anemia, electrolyte disturbances, arrhythmias and infective endocarditis must appropriately be treated for successful management of cardiac failure.

CHAPTER 82

Acute Respiratory Failure in Children and Hyaline Membrane Disease

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

ACUTE RESPIRATORY FAILURE IN CHILDREN[1]

Respiratory failure, either impending or manifest, is a significant threat in many patients in pediatric practice. In our experience, 20% of patients in a pediatric ICU are admitted for primary respiratory emergencies, though in many other conditions, secondary respiratory problems ensue, needing prompt respiratory care. Such diseases include cardiac failure, peripheral nervous system disorders as in the Guillain-Barré syndrome, poliomyelitis, myopathies, central nervous system (CNS) disorders and shock states. Thus, respiratory dysfunction is a common denominator in many, pediatric ICU patients.

Common pulmonary diseases presenting with respiratory failure include pneumonia, severe asthma, acute bronchiolitis,[2] pulmonary edema, and the croup syndrome. Other problems causing acute respiratory failure include foreign body obstruction and hydrocarbon poisoning. Epiglottitis causing upper respiratory obstruction is rarely seen in our country. The important causes of acute respiratory failure in the pediatric age group are listed in Box 1.

Neonates may present with hyaline membrane disease, meconium aspiration, persistent pulmonary hypertension, congenital malformations, like diaphragmatic hernia and lobar emphysema, as well as pneumonias, birth asphyxia and pulmonary hemorrhage. Extrapulmonary conditions include CNS infections and cardiac diseases. The important causes of acute respiratory failure in neonates are given in Box 2.

Acute respiratory failure in terms of arterial blood gas estimation is defined as arterial carbon dioxide tension ($PaCO_2$) more than 50 mm Hg and/or arterial oxygen tension

Box 1: Important causes of acute respiratory failure in the pediatric age group

- Pulmonary causes—
  - Pneumonia
  - Severe asthma
  - Acute bronchiolitis
  - Pulmonary edema
  - The croup syndrome
  - Obstruction by foreign body
  - Epiglottitis causing upper respiratory obstruction
- Nonpulmonary causes—
  - Cardiac failure
  - Neuromuscular disorders, e.g. Guillain-Barré syndrome, myopathies
  - Central nervous system disorders, e.g. poliomyelitis
  - Shock states

Box 2: Important causes of acute respiratory failure in the neonates

- Pulmonary causes—
  - Hyaline membrane disease
  - Persistent pulmonary hypertension
  - Congenital malformations, e.g. diaphragmatic hernia, lobar emphysema
  - Pneumonia
  - Pulmonary hemorrhage
  - Birth asphyxia
- Extrapulmonary causes—
  - Central nervous system infections, e.g. neonatal tetanus
  - Cardiac diseases (generally congenital heart disease)

(PaO_2) less than 55 mm Hg, while breathing room air. It may be clinically classified into pump failure (disorders of mechanics of respiration), and lung failure (diseases of airways and lung parenchyma). Pump failure is characterized by an increase in $PaCO_2$ and a fall in PaO_2; whereas lung failure is characterized by a decreased PaO_2 with a normal or low $PaCO_2$. Later in the natural history of lung disease, the occurrence of alveolar hypoventilation or of respiratory muscle fatigue can cause a gradual rise in the $PaCO_2$. The above classification has an implication both in relation to etiology and management. Thus an increase in $PaCO_2$ in pump failure may well be an indication for initiating mechanical ventilator support. On the other hand, a decrease in PaO_2 with a low $PaCO_2$ may respond to an increase in the fraction of inspired oxygen (FiO_2), if hypoxia is chiefly due to a ventilation-perfusion (V/Q) mismatch produced by lung disease. If however a decrease in PaO_2 is chiefly due to a right to left shunt within the lungs, increase in FiO_2 will not produce a significant increase in the PaO_2. Ventilator support will be required in these patients, as also in those who ultimately show a progressive increase in the $PaCO_2$.

Pathophysiology involves five mechanisms of hypoxemia—reduced PiO_2 (as in high altitude), hypoventilation, V/Q mismatch, shunt and a diffusion abnormality. (It is least important as at sea level, there is rarely a problem of diffusion as there is enough time for red blood cells to exchange gases and even in case of diffusion abnormality, it is coexistent V/Q mismatch and shunt that is more responsible for hypoxemia.) Hypoxemia in hypoventilation is accompanied with normal A-a difference and a high $PaCO_2$. V/Q mismatch can be differentiated from shunt as hypoxemia in V/Q mismatch can be easily corrected by a slight increase in inspired O_2 concentration while hypoxemia in shunt is not corrected easily by oxygenation and even an FiO_2 of 1 may only modestly increase PaO_2 in a shunt.

In newborns and young children respiratory failure can develop rapidly due to various unfavorable anatomical and physiological factors, like poor compliance of the lungs, easy blockage of air passages, immaturity of the cough reflex and the higher centers, and poor respiratory reserve with early fatigability of respiratory muscles.

Clinical Features

It is important to realize that respiratory distress may occur in the absence of respiratory disease or failure. Conversely, respiratory failure may be present without respiratory distress as in patients with muscular weakness or CNS depression. Diseases, like encephalitis and Reye's syndrome, as well as diseases causing metabolic acidosis may present with hyperventilation, which may be mistaken for respiratory distress. Apnea may be the manifestation of respiratory failure in neonates. Respiratory distresses, with activity of accessory muscles of respiration, along with chest retractions, stridor, grunting or wheezing, are important clinical manifestations. Symptoms and signs of hypoxemia manifested by restlessness, confusion, hypotonia and cyanosis may supervene. Muscle fatigue may be evident by paradoxical breathing and see-saw movements of the chest and upper abdomen. Convulsions, shock and cardiorespiratory failure ultimately supervene.

The clinical features of neonatal tetanus are characterized by difficulty in suckling and swallowing due to spasm and rigidity of the muscles of the face and of deglutition. Risus sardonicus with the characteristic tetanus fancies is diagnostic of the disease. In neonatal tetanus, skeletal and truncal rigidity is quickly followed by convulsive seizures. Breathing is impaired; atelectasis is frequent and acute hypoxemic respiratory failure results. Death generally results from cardiorespiratory failure.[3]

Diagnosis

The clinical diagnosis of respiratory failure should be supplemented by relevant investigations. Arterial blood gas estimation defines the type and severity of respiratory failure. This can be further monitored by noninvasive parameters, like SaO_2, transcutaneous PO_2 and capnography. These noninvasive methods certainly have limitations, but are very useful for defining the trends in progress. Chest X-ray is helpful in evaluating the cause, progress and complications of respiratory disease. Ultimately, cardiac, CNS and other organ dysfunctions need to be monitored by appropriate tests.

MANAGEMENT

Pump failure is rather easy to manage. Mechanical ventilation is required with an increasing $PaCO_2$ due to ventilatory failure. In our experience, patients with ventilatory failure who, to start with, have normal lungs, tolerate prolonged mechanical ventilation for several weeks without any complications. We have had a newborn with congenital amyelinosis, and a 6-week-old infant with severe poliomyelitis who, despite being on mechanical ventilation for longer than 12 weeks, presented no problems in management. However, lung failure is a challenge to the clinician.[4] It is in this type of failure that skilful management may change the outcome, because in lung disease, there exists a high risk of inflicting further damage by the use of both high inflation pressures and high concentrations of inspired oxygen. The aim of management is to maintain blood gases and acid-base status within the optimum range. This is primarily done by adequate oxygenation and ventilation. Humidified oxygen is administered at suitable flow rates depending on the method of delivery used—be it by oxygen hood, mask or nasal prongs. In pediatric practice, Venturi mask is rarely required as we do not encounter patients with chronic respiratory disease, dependent on the hypoxic central drive. Except in preterm neonates, where FiO_2 needs to be stringently monitored, short-term high oxygen concentrations are well tolerated.

In children, ventilatory settings depend on the age and body size. Table 1 details the standard ventilator settings used in infants and children. However, these may be modified depending on the disease and its pathophysiology. Pressure-limited time-cycled ventilation is ideal for newborns and

Table 1: Standard ventilator settings in neonates and older children

Settings	*Newborns and infants*	*Older children*
Tidal volume	10 mL/kg	10 mL/kg
Respiratory rate	25–30/min	20/min
Peak inspiratory pressure	15–20 cm of H_2O	20–25 cm of H_2O
PEEP	2 cm of H_2O	2 cm of H_2O
Inspiratory: Expiratory ratio	1:2	1:2

Abbrreviation: PEEP, positive end-expiratory pressure.

infants, whereas older children require volume-control ventilation. The peak inspiratory pressure should not exceed 15–20 cm H_2O in neonates and infants, and 20–25 cm H_2O in older children. Positive end-expiratory pressure (PEEP) is often used in children to improve oxygenation, though too much PEEP is harmful. Square wave pressure generation with prolonged inspiration time may be ideal to improve oxygenation in acute lung disease.

Continuous positive airway pressure is an intermediate method between mechanical ventilation and spontaneous breathing. It is normally delivered through an endotracheal tube, though it may also be employed to some extent through a nasopharyngeal tube, or even through a tight-fitting mask in small children. Specific treatment of the underlying disease and management of dysfunction of other organ systems are as important as the primary management of respiratory failure.

Orotracheal intubation with proper length and size of endotracheal tube is a prerequisite. Nasotracheal intubation is technically difficult in small children, and its long-term use is known to be associated with higher incidence of middle ear infections. In children, mechanical ventilation is required for a short time in most cases. The size of the endotracheal tube should be such as to allow a small leak under positive pressure. Tight-fitting tubes with a tight seal may lead to tracheal stenosis. At the same time, too large a leak may hamper adequate ventilation. The formula of [(16 + age in years) ÷ 4] is a useful guide for determining the size of the endotracheal tube. An endotracheal tube of a small diameter in pediatric patients is prone to get blocked by thick secretions, and hence proper humidification of the respiratory tract is an important yet often neglected aspect of management. On the other hand, enthusiastic over humidification may lead to absorption of considerable amount of water. Frequent suction by sterile techniques is necessary in many ventilated children. Bag and tube ventilation with 100% oxygen prior to suctioning prevents hypoxemia. Suction should be done whilst withdrawing the catheter gradually over 8–10 seconds. Between each suctioning, 100% oxygen is administered by bagging. An end-hole catheter is preferred to a side-hole one, to avoid trapping of respiratory mucosa. Development of bradycardia is indicative of hypoxemia and suctioning must be immediately stopped, and the patient ventilated with 100% oxygen. Infection must be prevented by proper asepsis including hand washing, use of disposables and proper sterilization of equipments including ventilators. Delicate parts of the ventilator circuits, like transducers, are chemically sterilized in alcohol. Colonization of ventilators, humidifiers and endotracheal tubes by Gram-negative organisms, including pseudomonas infection, is a major problem in management. Scrupulous attention must be paid to prevent infections. Respiratory tubings must be changed every 2–3 days, or more frequently in the presence of colonization.

Patients needing mechanical ventilation often require some form of sedation or muscle relaxants. We use pancuronium bromide in the dose of 0.15–0.2 mg/kg intravenously, as an initial dose and repeat this every 2–4 hours as required. Paralyzing patients for prolonged periods may cause a gradual fall in the compliance of the lungs, and sudden accidental disconnection of the ventilator may be fatal in a paralyzed child.

HYALINE MEMBRANE DISEASE (RESPIRATORY DISTRESS SYNDROME)[5]

Hyaline membrane disease occurs primarily in premature neonates. Its incidence is inversely proportional to the gestational age—60% to 80% in infants less than 28 weeks of gestation, and rare in term babies. The incidence is also increased in infants born to diabetic mothers and in those delivered by cesarean section.

Absence of surfactant results in high surface tension and keeps the alveoli atelectatic. Along with atelectasis, formation of hyaline membrane and interstitial edema make the lungs poorly compliant. High compliance of the chest wall in preterm infants offers less resistance against the tendency of the lungs to collapse. This results in poorly ventilated, though well-perfused alveoli, leading to hypoxia. Poor lung compliance and alveolar hypoventilation, increased dead space, small tidal volumes and extra work of breathing, all contribute to hypercarbia. A combination of hypoxia, hypercarbia and acidosis results in pulmonary vasoconstriction leading to right to left shunting, reduced pulmonary flow and ischemic injury to alveolar cells, thus worsening the vicious cycle.

Clinical presentation occurs early at birth, or within a few hours after birth, with tachypnea, chest retraction and cyanosis. This may progress over the next 24–48 hours to cause severe hypoxic injury leading to shock, hypotension, myocardial failure and renal dysfunction. Persistent hypoxemia in a typical setting, with diffuse lung infiltrates on chest X-ray, clinch the diagnosis of hyaline membrane disease. Pulmonary infections are difficult to exclude. Complications, besides acute respiratory failure and shock, include air-leak syndromes and shunting through a patent ductus and foramen ovale.

Management is aimed at improving oxygenation and reducing hypercarbia and acidosis by proper oxygenation and ventilation. Artificial surfactant can be instilled into the air passages through the endotracheal tube, which helps in reverting early pathological changes. Other drugs may be necessary to deal with accompanying problems—tolazoline

for persistent fetal circulation, aminophylline and doxapram to counter respiratory depression.

Prevention of hyaline membrane disease is possible by administering steroids to mothers 24–48 hours prior to delivery, especially before 32–34 weeks of gestation, trying to prevent preterm labor, and controlling maternal diabetes throughout pregnancy.

Surfactant Therapy

Exogenous surfactant therapy is widely used in preterm neonates with respiratory distress syndrome (RDS) and it is increasingly used in other respiratory conditions as well. There are two types of surfactants—natural and synthetic. The predominant and most efficient phospholipid in these products is DPPC (dipalmitoylphosphatidylcholine). However, DPCC adsorbs very slowly to the air-liquid interface.[6] Its adsorption is enhanced by other lipids and proteins contained in these products, including four major apoproteins—SP-A, SP-B, SP-C and SP-D.[6] They provide defense against inhaled pathogens. Among them SP-A is most efficient in regulating lowering of surface tension. None of the presently available preparations contain SP-A. Synthetic surfactants lack many of the components of natural surfactant.[7] Use of natural surfactants is preferred, though it needs refrigeration for storage. Synthetic surfactant is available in lyophilized form, can be stored at room temperature and reconstituted with sterile water before use.

While use of surfactant in preterm neonates is well established, there used to be a debate over timing of its use and number of doses required. However, in recent times, such a controversy is settled. In a neonate at risk of developing RDS, prophylactic use of surfactant immediately after stabilization is preferred to "rescue" therapy employed after development of RDS, even though such practice may result in the use of surfactant in a small number of neonates who may not have required it.[8,9] In those neonates who do not receive prophylactic surfactant therapy, early administration before 2 hours of age has better outcome than at later age. In patients who demonstrate good response to the first dose but deteriorate after some time, multiple doses are administered—3 to 4 doses over the first 72 hours. Such a strategy has proved to be useful.[8,9]

Current evidence suggests that surfactant administered through double-lumen endotracheal tube or a catheter passed through suction valve appears to be more effective and minimizes related adverse effects (including hypoxia) as compared to administration through the use of a simple catheter or side-port.

Adverse effects are few and not serious. Long-term follow-up of these neonates who receive surfactant is reassuring.

With the knowledge that surfactant deficiency occurs in many acquired disorders leading to acute lung injury, surfactant has been tried in such diseases with varying benefits.[8] Evidence suggests that preterm neonates with bronchopulmonary dysplasia and prolonged mechanical ventilation also experience surfactant dysfunction; however, exogenous surfactant therapy beyond the first week of life has not been well studied. Surfactant replacement therapy has been studied for use in other respiratory disorders including meconium aspiration syndrome and pneumonia.[8] Commercial surfactant preparations currently available are not optimal, given the variability of surfactant protein content and their susceptibility to inhibition. Further progress in the treatment of neonatal respiratory disorders may include the development of "designer" surfactant preparations.

Recently, natural exogenous surfactant replacement has been used in experimental models and clinical trials for the treatment of severe respiratory syncytial virus (RSV) disease. It has been shown that surfactant therapy improves gas exchange and respiratory mechanics and shortens the duration of ventilatory support and intensive care unit stay in infants with severe RSV-induced respiratory failure.

There is strong evidence that alterations in the pulmonary surfactant system play an important role in the pathophysiology of lung disease, including acute respiratory distress syndrome (ARDS). Although it is still unclear whether mortality and morbidity of ARDS will be reduced, surfactant replacement therapy has been shown to improve oxygenation and improve lung compliance, and decrease need for ventilator support. Further studies will also be needed to elucidate the optimal timing and dosage regimen for different disease processes. Some evidence supports the measurements of surfactant protein levels as markers for predicting the onset and outcome of ARDS and perhaps providing a window for early treatment of patients at risk to develop ARDS. Continued investigation into the role of surfactant in the immune regulation of the lung may also provide additional information to support the efficacy of surfactant replacement in lung disease.

However, meta-analysis of various trials has shown that exogenous surfactant administration has proven inconsistent as a therapeutic modality for patients with ARDS. This is because of severity of the injury at the time of treatment and because of variable surfactant preparations, dosing regimes, and delivery methods used in the different trials. Moreover, with the recognition that surfactant also plays an important role in host defense, the future for surfactant therapy is exciting.

In summary, role of surfactant is well established in preterm neonates suffering from RDS and it has now been a standard therapy to institute prophylactic therapy. However, its use in other conditions has met with varying success and at present cannot be recommended as a standard form of treatment. Its benefit to improve host defense may find favorable indications in future.

High Frequency Ventilation

High frequency ventilation (HFV) is a form of mechanical ventilation that uses small tidal volumes, sometimes less than anatomical dead space and extremely rapid ventilatory rates. Inherent too many modes of HFV are the small pressure swings during the respiratory cycle, which allow for higher mean airway pressures than those safety achieved with conventional mechanical ventilation (CMV). This has

the potential to reduce lung injury by limiting volutrauma, whereas maintaining bigger lung volumes at end-expiration may reduce atelectrauma. HFV has an ability to provide adequate gas exchange using lower proximal airway pressures in the lung already injured by barotraumas and volutrauma. It also enables preservation of normal lung architecture, even when high mean airway pressures are required. Normally efficient gas exchange depends upon adequate alveolar volume ($V_A = V_T - V_D$). It is quite perplexing and intriguing that tidal volume as small as anatomical dead space used in HFV can provide effective gas exchange.

The increasing understanding of the pathogenesis of acute lung injury, including concepts such as volutrauma, barotraumas, oxytrauma and atelectrauma has led to a renewed interest in the role of HFV in lung-protective ventilation strategies.

There are three types of HFV—high frequency positive pressure ventilation produced by conventional or modified CMVs operating at rapid rates, high frequency jet ventilation (HFJV) that delivers high velocity jet of gas into airways and high frequency oscillatory ventilation (HFOV) produced by a device that moves gas back and forth through airway opening.[10] HFJV and HFOV enhance both distribution and diffusion of gases. HFO is the only mode with an active expiration phase. This characteristic, combined with superior gas conditioning, may make HFO a promising ventilatory strategy for adults. Although a significant amount of data exists in the literature to support the application of HFO in infants and children who have acute respiratory failure, clinical data on the use of HFO in adults is only now emerging.

High frequency oscillatory ventilation is a new mode of ventilation using lung protective strategy and the safer use of mean airway pressure that is higher than that generally used during CMV. HFOV can achieve oxygenation and ventilation while maintaining maximal lung recruitment on the deflation limb of its pressure-volume curve.[11] The primary theoretical advantages of HFOV over CMV in the management of acute lung injury are that HFOV allows adequate alveolar ventilation with minimal peak-trough pressure changes, provides lung recruitment, and avoids end-inspiratory over distension of the relatively compliant nondependent lung. Taken together, the results of studies in animals, preterm and term neonates, and older pediatric patients reveal that an open-lung strategy, with the goal of a high end-expiratory lung volume is safe and superior to CMV in both the short term (rapidly improved oxygenation and/or ventilation) and long term (lower incidence of chronic lung disease).[11] The improved long-term clinical outcomes on HFOV are presumably because of less ventilator-induced lung injury. As experience with HFOV in older patients grows, ventilator technology matures, and understanding of the pathophysiology of ARDS deepens, it is likely that HFOV will find widespread use for the management of respiratory failure caused by acute lung injury in patients from preterm neonates to adults.

Full potential of HFV is yet to be realized in spite of 20 years of intensive studies. In air leak syndromes, including pulmonary interstitial emphysema and bronchopleural fistula, HFV improves outcome.[11] In congenital diaphragmatic hernia or pulmonary hypoplasia, its benefits are not clear. In seemingly intractable respiratory failure, studies suggest that HFOV is a better rescue therapy and also decreases the requirement of extracorporeal membrane oxygenation. In neonates with RDS, earlier trials with HFV have been contradictory but later trials are encouraging, especially along with the use of surfactant.[11]

Standard guidelines for use of HFV in neonates and older children are yet not available. Most clinical guidelines have been arbitrary and heavily depend upon experience, biases and, at times, idiosyncrasies of authors. Many different systems are in use all over the world and each HFV system is different in its functioning. There is no clear standard of practice.

High frequency ventilation has its own problems. As HFV is known to produce higher end-tidal volumes at lower proximal airway pressures, it can lead to an increasing auto PEEP. In many trials, pulmonary leaks increased in HFV as compared to CMV. Also, it is difficult to adjust the tidal volume so that there are neither underdistension and atelectasis of alveoli nor overdistension of alveoli.[11] Close observation and repeated X-rays of the chest may be necessary to determine if the lungs are inflated to the right extent. Even so, it is difficult to monitor lung volumes at the bedside.

Due to economic constraints and selected indications, we have had little experience with HFV. Outcome of preterm neonates with RDS has considerably improved with the use of surfactant. However, in our experience, conventional ventilation in RDS generally suffices and the need for HFV is not commonly felt.[12-14] In older children presenting with ARDS, who fail to improve on conventional ventilation strategies, the availability of HFV would perhaps make a difference.

In summary, HFV looks to be an exciting and useful form of ventilation. However, indications for its use are limited to select few patients and it is not yet standardized.

CHAPTER 83

Fluid and Electrolyte Disturbance in the Critically Ill Child

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

INTRODUCTION

Infants and children contain higher amounts of body water and electrolytes per kg body weight as compared to adults. Immaturity of renal function, particularly in early infancy, and increased vulnerability to dehydration and electrolyte disturbances, make the management of fluid and electrolyte imbalance an integral part of pediatric intensive care.

ENTERAL VERSUS PARENTERAL THERAPY

Though the enteral route is most physiological and ideal, intravenous (IV) fluid and electrolyte administration is imperative in almost every pediatric intensive care unit (PICU) patient for a variety of reasons. In a normal preterm neonate, the gastrointestinal (GI) tract needs to be rested for the first few days, till it stabilizes and starts functioning optimally. Also in every serious illness, the GI tract and the skin are always sacrificed in preference to more important vital organs, and hence the need for IV fluid therapy at least till the acuity of illness peaks off. Persistent vomiting, respiratory distress and risk of aspiration are additional factors necessitating IV therapy so as to prevent and rapidly treat significant dehydration and dyselectrolytemia. With the advent of several devices like butterfly scalp-vein needles, intracaths, and infusion syringes and pumps, fluids can be infused in any desired composition and concentration at any given speed, at any age over any period of time. Though IV fluid therapy is no longer a difficult technique, it should never be taken lightly as it carries the risk of infection, thrombophlebitis, overloading and cardiac failure.

NORMAL REQUIREMENTS[1-3]

On day one of life, a newborn needs 50 mL/kg of body weight of fluids per day, increasing on every subsequent day by 10 mL/kg, to reach 100 mL/kg of body weight per day by the 4th or 5th day. Till 1 year of age, or up to 10 kg of body weight, fluid requirements are constant at the rate of 100 mL/kg per day. Between 10 and 20 kg of weight, fluid requirements are computed at 100 mL plus 50 mL/kg per day for each kg beyond 10 kg weight, and subsequently over 20 kg body weight as 1,500 mL plus 20 mL/kg per day for each kg of body weight. Sodium and potassium are the two major electrolytes concerned with fluid therapy, though calcium and magnesium also play a role, especially in sick infants and children. A normal newborn is not able to handle electrolytes efficiently during the first 3–4 days, and should not be given supplements of sodium or potassium. There after, 2–4 mEq/kg per day of both the electrolytes are sufficient as maintenance requirements, spread uniformly over 24 hours. Potassium should never be infused in a concentration more than 4–60 mEq/L of fluid, even in the presence of normal renal function. Hyperosmolar solutions containing higher dextrose concentrations (more than 10–12.5%) are particularly harmful in small children. Similarly, in neonates and young infants, the rate of the dextrose infusion should be maintained constant at 5–6 mg/kg per minute so as to avoid hypoglycemia or hyperglycemia.

PATHOLOGICAL STATES

Dehydration

Acute diarrhea is the most common condition leading to dehydration in pediatric patients; other causes of dehydration

include persistent vomiting, polyuria or a diminished intake. Depending on the severity of dehydration, the deficit to be replaced may amount to 50, 100 or even 150 mL/kg per day of total fluids during infancy; further ongoing losses may also have to be replenished. Based on the type of fluids lost as in diarrhea, or vomiting, the electrolyte composition of infusion fluids needs to be modified. Commercial preparations like isolyte P contain a balanced composition of electrolytes. If these are not available, combinations of dextrose saline with required amounts of potassium chloride and sodium bicarbonate may be administered according to the need. In the majority of infants with diarrhea, dehydration is accompanied by hyponatremia, hypokalemia and metabolic acidosis, while in patients with vomiting, a hypochloremic metabolic alkalosis exists. In diabetic coma, dehydration may be accompanied by ketoacidosis, hyponatremia and hyperkalemia. In capillary leak syndromes as in septic shock, due to third space losses, dehydration may coexist with increased total body water.

Hyponatremia is common in many diseases such as pneumonia or meningitis. Even when the primary disease is not serious, hyponatremia may endanger life due to resultant brain edema. Hence, it is important to recognize hyponatremia and its probable cause in every hospitalized patient, as not every hyponatremic patient needs replacement of sodium. Evaluation should take into account volume status of the patient and urinary sodium content.

Hypovolemic hyponatremia and urine sodium more than 20 may suggest cerebral salt wasting syndrome that needs sodium replacement while normovolemic hyponatremia and urinary sodium more than 20 may denote SIADH (syndrome of inadequate antidiuretic hormone) that is managed by restriction of fluids. Hyperglycemia and hyperlipidemia may result in pseudohyponatremia. Hypervolemic hyponatremia with urinary sodium more than 20 indicates renal failure.

OTHER SPECIAL SITUATIONS

Acute renal failure demands stringent balance between intake and output of fluids to maintain optimum fluid and electrolyte balance. In acute liver cell failure, constriction of the IV volume along with coexistent edema may justify the simultaneous use of IV fluids and diuretics. In acute bronchiolitis, restriction of fluids due to fear of worsening the pulmonary edema is no longer justified, as multiple variable factors are known to increase the fluid requirements in such cases. The same principle holds true in patients with acute brain cell edema where better monitoring in individual patients should decide the actual fluid requirements, rather than routinely restricting fluids to two-thirds the normal maintenance levels. A case of burns is a special situation needing large amounts of fluid replacement, including colloids.

Significant electrolyte disturbances often accompany states or dehydration as well as edema. Clinical judgment of dyselectrolytemia is usually difficult and must be supplemented by biochemical and biophysical monitoring. Serum levels of sodium and potassium should be considered in conjunction with the acid-base status, total body electrolyte content, urinary electrolyte concentrations, electrocardiographic and neuropsychological states. As water and electrolytes are in dynamic equilibrium, correction of one element may precipitate changes in the other, and demands careful handling. Swings from undercorrection to overcorrection are difficult to assess and harmful to the patient. Daily biochemical monitoring is the only guide in optimum management, especially in complex situations.

CHAPTER 84

Nutritional Support in the Pediatric Intensive Care Unit

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

Nutritional failure is a serious problem, especially in patients suffering from subacute or chronic illnesses and also in acute conditions in the younger age group.[1-4] Newborns or young infants may suffer from significant nutritional depletion within 4–7 days of lack of feeding, and ideally need nutritional support to avoid deleterious effects.[5] Nutritional failure may lead to delayed recovery from infection, and wound healing is slow due to impaired immune mechanisms. Prolonged nutritional depletion results in malnutrition with decrease in muscle mass and easy fatigability. This may interfere with normal respiratory effort and cause difficulty in weaning the patient off the ventilator. In addition to a lack of nutritional intake, critically ill children also have increased caloric needs due to catabolic stress. Thus, the goal of nutritional support is to achieve a positive nitrogen balance. This is done by giving 100–120 calories/day and 2–3 g/kg per day of proteins.

The enteral route is always preferred because of ease of administration. It helps to maintain the normal physiological processes of digestion and absorption as it stimulates the gut hormones and enzymes. Also it is safe, cheap, effective and does not need any monitoring. Milk enriched with oil (preferably coconut oil), egg-flips or commercial formulae may be administered through the nasogastric tube, or other semisolids may be fed with a spoon. Necessary supplements of vitamins and minerals as well as extra proteins can be easily supplied through available market preparations.[6]

However, when enteral feeding is not possible or contraindicated, one has to resort to parenteral feeding[6] (especially if enteral feeding is not possible for >4–5 days). The main indications for parenteral alimentation include extremely premature babies [very low birth weight (VLBW)], after major surgical procedures, in post-traumatic conditions, burns, severe gastrointestinal disorders, disseminated infections and multiorgan failure. Total parenteral nutrition (TPN) should be administered ideally by infusions through a central vein and should consist of adequate calories optimally derived from carbohydrates, proteins and fats. Minerals and vitamins should always be supplied. About 55–60% of calories must be supplied from carbohydrates, 30–35% from fats and 5–10% from proteins. Peripheral venous access can also be conveniently used, in which case a concentration of not more than 10–12.5% dextrose solution can be given. In such a situation, fats may be infused in slightly higher amounts to make up for the calories. Proteins are supplied in the form of amino acid mixtures, while fats are provided as intralipids containing adequate essential fatty acids. Commercial solutions for parenteral nutrition are freely available, and are administered through a three-way connection so that infusions of amino acids, intralipids and dextrose are administered separately and get combined at the vein entrance. In infants and children, we preferably use a peripheral venous access. Routine protocol consists of dextrose infusions for the first 3–4 days, followed by additional amino acid mixtures over the next 3–4 days; intralipids are added at a later stage if enteral feeding is still not possible.

Catheter-related complications are rare when a peripheral vein is used. However, infection and sepsis are the most commonly encountered problems. Other complications include hepatic dysfunction and cholestasis, metabolic acidosis, disturbed glucose metabolism, hyperammonemia and fat overload. Vitamin and mineral deficiencies are easily prevented by proper supplementation. Repeated biochemical monitoring is mandatory, and includes daily serum electrolyte estimations, blood glucose, acid-base status, urine examination, frequent liver function tests and other relevant hematological parameters.

Clinical experience with TPN has shown that when used in selected situations, it has improved survival rates in pediatric ICU patients. However, TPN is costly, technically difficult and needs careful monitoring. The cost-risk-benefit ratio should always be considered before starting on this form of nutritional support.

CHAPTER 85

Pediatric Life-threatening Infections Requiring Critical Care

YK Amdekar *MD, DCH. Consultant Pediatrician, Breach Candy Hospital and Jaslok Hospital, Mumbai, Maharashtra, India. Retired Honorary Professor of Pediatrics, Grant Medical College and the JJ Group of Hospitals, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

Infections are common in an intensive care unit (ICU) setting. It has been observed that 30–40% of pediatric admissions to the ICU are related to community-acquired infections. A number of other admissions in the pediatric age group are likely to develop infections due to a variety of adverse background factors, e.g. specific organ dysfunction, trauma or surgery. Infections pose a constant threat to life, despite proper treatment with antimicrobial drugs. Prevention, early diagnosis and prompt treatment of existing infections are important challenges faced in the management of pediatric ICU patients.[1-2]

Several factors contribute to the increased vulnerability to life-threatening infections in the ICU. Younger age itself makes a pediatric patient more susceptible to serious infections, as newborns and infants are physiologically more deficient in natural defense mechanisms. Malnutrition,[3] especially when induced by lactation failure, promotes easy access to infection, with quick dissemination of infection, with an increased morbidity and mortality. Developmental defects and anatomical malformations are additional risk factors. Immune deficiency disorders, either congenital or acquired (as in malignancy or in patients on steroid therapy), are also occasionally responsible for infection in the pediatric age group. Children with ventriculoperitoneal shunts or prosthetic valves, and patients with severe burns, are particularly vulnerable to serious infections. Nosocomial infections are difficult to prevent in an ICU setting, especially in patients on ventilators with central lines and other invasive interventions.

The site of infection and host responses to various types of microbial invasions decide the outcome of infections. Intracranial infections, like encephalitis and meningitis, fulminant pneumonias, endomyocarditis and necrotizing enterocolitis may lead to specific organ failure, endangering life. On the other hand, any infection may induce severe immune-mediated responses in the host and may threaten life, as is seen in septic shock, staphylococcal or streptococcal toxic shock syndrome (TSS) and staphylococcal scalded skin syndrome (SSSS).

ETIOLOGY

A majority of serious infections are bacterial, both Gram-positive and Gram-negative. Staphylococcal infections and infections due to *Pseudomonas aeruginosa*, klebsiella and proteus can often turn fulminant and life-threatening. Many other infections in the pediatric age group may require critical care, particularly in vulnerable situations. Tuberculous meningoencephalitis and miliary tuberculosis pose a significant threat to life, especially in infants. It is feared that tuberculosis in human immunodeficiency virus (HIV) infected individuals will constitute a significant proportion of life-threatening infections in the near future.

Viruses also cause life-threatening infections, though not as commonly as bacterial infections. It is difficult to prove viral infections due to constraints of relevant laboratory facilities, though in clinical practice, some of the viral infections can be diagnosed by characteristic clinical findings. These include measles, poliomyelitis and infections due to the herpes virus. Measles encephalitis or pneumonia, poliomyelitis affecting the brainstem or causing weakness of the respiratory muscles, herpes encephalitis and viral myocarditis constitute life-threatening infections in children. Dengue fever and

Japanese B viral encephalitis deserve special mention, as they occur in some parts of our country, and are associated with a significant morbidity and mortality.

Parasitic infections are rarely life-threatening though with a resurgence of malaria, cerebral malaria due to *Plasmodium falciparum* infections is a distinct threat to life. Fungal sepsis is being recognized in patients treated with prolonged antibiotic therapy. In immunocompromized patients, other opportunistic infections such as those due to *Pneumocystis carinii*, toxoplasma and cytomegalovirus may endanger life. Anaerobic bacterial infections may cause serious diseases in certain situations.

CLINICAL APPROACH

It is the high index of suspicion based on clinical experience, evaluation of host factors and knowledge of epidemiology that may lead to an early diagnosis. Newborns and infants may demonstrate a wide spectrum of clinical presentations, some often vague without localization. Refusal of feeds, lethargy, temperature instability, behavior disturbances, disproportionate tachypnea and tachycardia, widened core skin temperature difference, mottling of skin, prolonged capillary refill are some of the symptoms and signs suggesting serious infections. Localizing symptoms and signs of meningitis or pneumonia offer easy clues to the diagnosis and demand close monitoring of specific organ functions.

INVESTIGATIONS

Nonspecific tests like the blood count, acute phase reactants like the erythrocyte sedimentation rate and C-reactive protein, routine urine analysis, spinal tap, chest X-ray may support a diagnosis of infections. Though any acute infection may present with neutrophilic leukocytosis with a shift to the left and eosinopenia, newborns often react with leukopenia. In fact, a normal blood count does not rule out the possibility of infection. Anemia and thrombocytopenia may favor a diagnosis of malaria. Low platelet counts may suggest disseminated intravascular coagulopathy, which may be confirmed by raised levels of fibrin degradation products, and a decrease in coagulation factors. Abnormal cerebrospinal fluid (CSF) may denote intracranial infection, though at times, in children, it is difficult to differentiate partially treated bacterial meningitis from tuberculous meningitis.

Specific diagnosis rests on demonstration of organisms on smear, or culture of blood, CSF, urine, stools or any other body fluids. Pretreatment with antibiotics, and poor techniques including a risk of contamination make the diagnosis of bacterial infection difficult. Often, the clinician has to resort to a presumptive diagnosis of infection based on circumstantial evidence. Special techniques are required to culture viruses and other organisms. Detection of antigen by rapid immunological methods, as well as demonstration of antibodies, is a suitable alternative, though often not easily available. Interpretation of antibody levels against specific infections needs to be considered against the background of local epidemiology. Other tests are required to monitor specific organ functions, and include various noninvasive or invasive interventions.

MANAGEMENT

Specific treatment with chemotherapeutic agents or antibiotics whenever available forms the mainstay of curative management. Obviously, the choice of such a therapy depends upon a precise diagnosis of the infection. As this is often not feasible, empirical treatment is started based on clinical judgment of specific situations. For example, newborns and young infants are covered with a broad-spectrum combination of penicillin and an aminoglycoside (ampicillin + gentamicin). Nosocomial infections may often need newer antibiotics so as to take care of resistant strains of Staphylococci, Pseudomonas and other organisms. Immunocompromized hosts may justify antifungal, antiviral or antiparasitic drugs in addition to antibacterial agents.

Supportive management includes maintenance of fluid, electrolyte and acid-base balance, adequate ventilation and oxygenation, maintenance of optimum cardiac output and circulatory state, and homeostasis of other organ functions. In addition, newborns and sick children need an isothermal environment, especially in centrally air-conditioned units, where special heating devices like radiant warmers are necessary. In special circumstances, even intravenous infusions and humidified oxygen may have to be warmed, as in newborns cold injury is often lethal. Adequate nutrition and a positive nitrogen balance are desirable, and are important, particularly in the long-term management of such patients. Though enteral feeding is the first choice, in conditions where enteral feeds are contraindicated or not tolerated, one may have to resort to total or partial parenteral nutrition.

Having realized that outcome of infection is decided by immunological response of the host, induced by interactions with the organism, immune response modifiers have been tried. These include steroids, nonsteroidal anti-inflammatory drugs (NSAIDs), interferons, growth factors, intravenous immunoglobulins, monoclonal antibodies and naloxone. Transfusion of blood and its components, as well as exchange transfusions have also been tried. All these measures have given equivocal results and many of them are costly, rarely available in developing countries, and may produce considerable side effects. With the exceptions of a few agents, most of them cannot be advocated for routine use.

PREVENTION

Early diagnosis and prompt treatment of trivial infections often prevent life-threatening infections. Vaccine-preventable diseases are easily controlled by proper immunization. Hand washing, proper asepsis and use of disposables go a long way in preventing nosocomial infections. ICUs should formulate specific policies regarding entry of staff and visitors, isolation of patients, disposal of patients' excreta and infected secretions, general cleanliness, fumigation, sterilization of

equipments, bacteriological surveillance and antibiotic usage. All such infection control measures should be monitored by specially designated staff guided by an infection control committee, comprising of clinical and laboratory experts. Prophylactic antibiotics are best avoided in general, as they may often lead to infections by resistant strains of organisms. In certain situations, postoperative antibiotic prophylaxis may be used for one or two doses.

SPECIAL INFECTIONS

Viral Infections

Most viral infections are self-limiting, though at times they may result in serious complications. It is not always possible to anticipate complications but early diagnosis of complications is mandatory to save life. Viral infections may present with biphasic fever and normally the second phase is shorter with lower degree of fever. However, if the second phase presents with drowsiness and oliguria, it suggests a capillary leak and demands urgent intravascular resuscitation. Similarly, development of new symptoms such as severe abdominal pain or vomiting may herald onset of complications.

Dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) are characterized by evidence of plasma leakage in terms of hemoconcentration (>20% rise above base level or area-specific cut-off around 36%) with the ultrasonography (USG) showing pleural effusion, ascites and gallbladder edema, hepatomegaly, splenomegaly and perinephric fluid. USG findings are sensitive in diagnosis of DHF and DSS. Hepatitis and macrophage activation syndrome (MAS) are the known complications of viral infection.

Influenza viral infection resulted in the recent pandemic due to H1N1 virus. In India, the recent epidemic affected more young people than old with significant mortality in hospitalized patients. Severe disease was seen in children aged 5–12 years. High-risk situations include malnourished children and those with congenital malformations such as heart defects. Acute respiratory distress syndrome (ARDS) is a common complication of influenza; tachypnea in a child suffering from influenza-like syndrome justifies treatment with oseltamivir pending proof of diagnosis by throat or nasal swab.[4] Besides anti-viral drug therapy, such a child would obviously need proper management of respiratory failure.

Central Nervous System Infections

Meningococcemia with or without meningitis is a life-threatening disease. Acute onset of fever followed by purpuric spots offers a clue to the probable etiology. Meningococcemia without meningitis carries a poor prognosis, death resulting from adrenal failure and shock. Development of meningitis denotes ability to localize the disease, and has a better prognosis. Early diagnosis and prompt treatment with penicillin is mandatory for survival.

Other bacteria causing meningitis have many features in common. Risk factors include younger age, marked change in sensorium, focal neurological abnormalities, persistent increase in intracranial tension and gross CSF abnormalities. Besides proper antibiotic therapy (Table 1), control of

Table 1: Empiric antibiotic therapy in pediatric life-threatening infections

Age	*Suspected organism*	*Antibiotic*	*IV dose* (mg/kg/day)
Birth to 3 months (Bacterial Infections)	Gram-positive—Staphylococci— • Streptococci • Listeria	Ampicillin + Gentamicin	200 7.5
		or	
	Gram-negative—*E. coli* • Klebsiella • Pseudomonas	Ampicillin + Ceftazidime	200 200
3 months to 5 years (bacterial infections)	Gram-positive—Staphylococci— • Streptococci Gram-negative—*H. influenzae* • Klebsiella • Pseudomonas	Ampicillin and/or Chloramphenicol Ceftazidime	200 100 200
>5 years (bacterial infections)	Gram-positive—Staphylococci— • *Strep. pneumoniae* Gram-negative—*H. influenza*— • Meningococci	Ampicillin and/or Chloramphenicol + Ceftriaxone	200 100 200
All ages (other organisms)	Herpes virus *P. falciparum* Fungal infections	Acyclovir Quinine Fluconazole	25 25 5

Comments: Therapy is later modified as per bacteriological reports. Other antibiotics which can be used are amikacin 15 mg/kg/day, and vancomycin 30 mg/kg/day.
Abbreviation: IV, intravenous.

increased intracranial tension and seizures is important. Early administration of steroids[5] before administration of the first dose of antibiotic has been shown to be beneficial in minimizing the squeal, especially in *Haemophilus influenzae* and pneumococcal meningitis. Cerebral edema in tuberculous meningitis requires prompt control with mannitol (2 g/kg per day in 4–6 divided doses), and steroids (hydrocortisone 10 mg/kg per day). Hydrocephalus should be treated by a timely ventriculoperitoneal shunt. Ideally, patients suffering from meningitis should undergo continuous monitoring of intracranial pressure; this however is not possible in most of the institutions in our country.

Cerebral malaria is an immune-mediated disseminated vasculitis occurring as a result of *P. falciparum* infection. Diagnosis is difficult unless blood smears demonstrate parasites. In many situations, clinical suspicion may justify therapy with quinine (25 mg/kg per day). Mortality is high unless promptly treated early in the course of the disease.

Herpes encephalitis may be considered in the presence of xanthochromic CSF and localized temporal lesions, as evidenced by an electroencephalography (EEG) or a computed tomography (CT) scan. Early institution of therapy with acyclovir (25 mg/kg per day) is life-saving.

Toxic Shock Syndrome[6]

Though most of the superficial infections of skin and soft tissue are benign, a few toxin-producing strains of Staphylococci and Streptococci may lead to a fulminant infection with the development of shock. Such infections often follow trauma or surgical procedures. If not recognized early, they may be fatal.

Staphylococcal Scalded Skin Syndrome[7]

This syndrome is seen primarily in younger children; at times, epidemics in newborn nurseries have been reported. It is a toxin-mediated disease, characterized by skin lesions which vary from bullous impetigo to widespread exfoliative dermatitis. Early recognition and treatment are mandatory for survival.

Septic Shock[8]

Cardiac output is manipulated in children mainly by altering the heart rate, and not by significant changes in the stroke volume. There is therefore limited ability to maintain cardiac output in adverse situations, often resulting in early decompensation in shock. Thus progression from sepsis to severe sepsis, and thence to septic shock and multiple organ dysfunctions occurs rather rapidly in children. Recognition of early sepsis and of the reversible stage of shock assumes added importance in proper management. Apart from this, the pathogenesis and management of septic shock in children are similar to that in adults.

INFECTIONS IN THE IMMUNOCOMPROMIZED AND CRITICALLY ILL CHILDREN

These differ not only in etiology but also in clinical presentation. Many of these children have serious infections without any fever. Clinical symptoms, signs and progression vary a great deal and aggressive treatment is mandatory in these individuals.

Any infection in newborns and infants must be viewed as a potentially life-threatening one; the distinction between mild or trivial and life-threatening infections however is not easy, and calls for sound clinical judgment.

Table 1 details the empiric treatment of acute fulminant pediatric infections, and lists the important drugs, their dosages and the common organisms encountered in life-threatening pediatric infections.

NORMAL RENAL PHYSIOLOGY IN INFANTS AND CHILDREN

Renal function starts to develop in the fetal period and continues to evolve throughout the first years of life until it reaches its complete adult level. The human kidney begins to develop in the 5th gestational week and starts to produce urine between the 10th and 12th week of gestation. Nephrogenesis is complete around the 35th–36th week so that a term neonate is born with all its nephrons, something which is not the case for a premature one, born before nephrogenesis is complete.

The kidney regulates homeostasis by two fundamental functions: (1) the glomerular and (2) the tubular. In neonates, both the functions are deficient and although the neonatal kidneys are well equipped to sustain physiological processes, they are severely limited in their response to stress.

Neonates have glomerular filtration rate (GFR) as low as 20 mL/min/1.73 m^2 at birth, which rises gradually to reach the adult rates at 18 months. Additionally, due to immature tubular function, neonates have reduced concentrating capacity, negative sodium equilibrium and reduced bicarbonate levels and they are, thus, prone to dehydration and hyponatremia.

NORMAL RENAL FUNCTION TESTS IN INFANTS AND CHILDREN

Serum creatinine measured at birth reflects the maternal renal function rather than the infant's renal function. In term babies, the serum creatinine normally rises in the first 24–36 hours after birth, subsequently decreasing and stabilizing at approximately 0.4 mg/dL by 5 days of age.

Table 1: Normal serum creatinine concentrations at different ages

Age	*Serum creatinine (mg/dL)*
Term neonates (<34 weeks GA)—	
<2 weeks old	0.7–1.4
>2 weeks old	0.7–0.9
Term neonates (>34 weeks GA)—	
<2 weeks old	0.4–0.6
>2 weeks old	0.3–0.5
2 weeks to 5 year	0.2–0.5
5–10 years	0.3–1.0
>10 years	0.6–1.4

In preterm infants, the peak value is at 2–3 days after birth and stabilization occurs after 6 days of age (Table 1).

ACUTE KIDNEY INJURY

Definition

The term acute renal failure has been replaced by the term "acute kidney injury" (AKI) due to many fallacies in the term "acute renal failure". The inability of serum creatinine to accurately reflect kidney function has been especially problematic for clinical research in pediatric AKI. This has resulted in the use of more than 35 definitions of AKI in clinical studies, ranging from small changes in serum creatinine to dialysis requirement. Recognizing a need for a consensus definition of AKI to facilitate clinical research on prevention and treatment of AKI, a consensus definition called the RIFLE classification of AKI based on changes in serum creatinine and urine output was developed by nephrologists and intensive care physicians.

Table 2: Adult RIFLE classification[1]

	Estimated CCl	*Urine output*
Risk	eCCl decreases by 25%	<0.5 mL/kg per hour for 8 hours
Injury	eCCl decreases by 50%	<0.5 mL/kg per hour for 16 hours
Failure	eCCl decreases by 75% or eCCl <35 mL/min/1.73 m^2	<0.3 mL/kg per hour for 24 hours or anuric for 12 hours
Loss	Persistent failure >4 weeks	
End stage	End-stage renal disease (persistent failure >3 months)	

Abbreviations: eCCl, estimated creatinine clearance; pRIFLE, pediatric risk, injury, failure, loss and end-stage renal disease.

Box 1: Common causes of acute kidney injury in infants

- Renal dysgenesis
- Obstructive uropathy
- Renovascular accidents
- Congenital heart disease
- Dehydration
- Sepsis, hypoxia
- Renal vein thrombosis

Box 2: Common causes of acute renal failure in children

- Prerenal causes—
  - Hypovolemia
  - Hypotension
  - Hypoxia
- Renal causes—
  - Glomerulonephritis
  - Hemolytic uremic syndrome
  - Renal vein thrombosis
  - Acute tubular necrosis
  - Acute interstitial nephritis
  - Hereditary nephritis
- Postrenal causes—
  - Obstructive nephropathy
  - Vesicoureteric reflux
  - Calculi

The RIFLE criteria consist of three graded levels of injury (risk, injury and failure) based upon either the magnitude of elevation in serum creatinine or urine output, and two outcome measures (Loss and End-stage renal disease).

pRIFLE is a pediatric modification of the adult RIFLE classification which is given in the Table 2.

Epidemiology of Acute Kidney Injury[2,3]

The epidemiological characteristics of AKI have changed over the past three decades. There has been an increase in the overall incidence of AKI with the changing etiology of AKI in recent years. Incidences of obstetrical, surgical and diarrheal AKI have decreased significantly, whereas those of AKI associated with malaria, sepsis, nephrotoxic drugs and liver disease have increased.

Causes of Acute Kidney Injury

The common causes of AKI in infants and children are given in Boxes 1 and 2 respectively.

Pathogenesis of Acute Kidney Injury

Various causes of AKI ultimately culminate in the cascade leading to AKI. These causes have been shown in Flowchart 1.[4]

Clinical Features

The clinical features are usually related to the precipitating disease. The signs and symptoms related to renal failure are oliguria, edema, hypertension, pallor, nausea, vomiting and lethargy. At a later stage, the patient may present with mental obtundation progressing to coma due to hypertensive encephalopathy or uremia; gastrointestinal bleeding is often observed.

Diagnosis of Acute Kidney Injury

All premature and full-term infants void within the first 24 hours after birth. If an infant does not void in 24 hours, a search should be initiated for underlying abnormalities. In the majority of patients with AKI, the common causes are mainly extrarenal; renal causes are responsible for AKI in only a few patients.

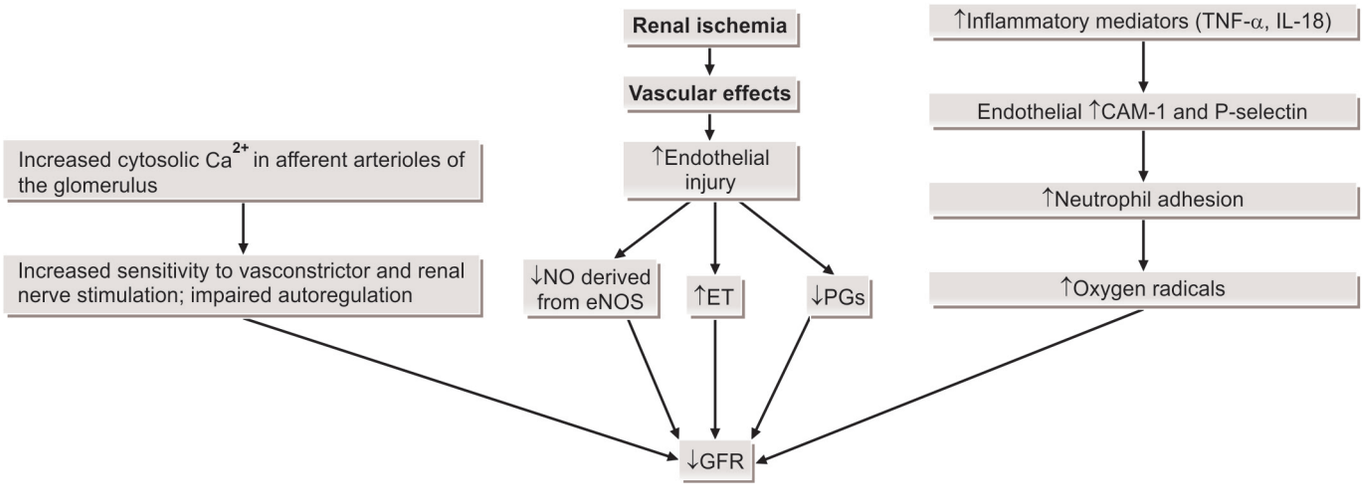
History

A careful history will aid in the diagnosis in a majority of patients. Vomiting, diarrhea and fever suggest dehydration. At times, these symptoms may be present in a patient with hemolytic uremic syndrome (HUS) or renal vein thrombosis. A history of a throat or skin infection will suggest the diagnosis of post-streptococcal glomerulonephritis. History of exposure to drugs (antibiotics, analgesics or other forms of therapy) may suggest interstitial nephritis due to drugs. Presence of a mass in the renal area may suggest diagnosis of renal vein thrombosis or tumor. Presence of rash, purpuric spots, with history of arthralgia or fever may suggest the diagnosis of Henoch-Schonlein purpura or systemic lupus erythematosus (SLE).

Laboratory Investigations

- *Urine examination* is of utmost value in cases of renal injury. Presence of proteinuria and hematuria with red blood cell casts point to a glomerulonephritis, while urine with a large number of pus cells indicates urinary tract infection. The urine may be normal in acute tubular necrosis and in obstructive uropathy.

Flowchart 1: Various causes of AKI



Abbreviations: NO, nitrous oxide; ET, endothelin; PG, prostaglandin; GFR, glomerular filtration rate.

Table 3: Urinary indices which distinguish between prerenal and renal causes of acute renal failure

	Prerenal	*Renal*
Urinary Na (mEq/L)	<10	>50
Fractional excretion of Na (%)	<1	>2
Urine osmolality (mOsm/kg H_2O)	>500	<300
Urine/Plasma osmolality	>1.5	<1.2
BUN/Creatinine	>20	20 or less

- *Urinary indices* are of utmost importance in deciding whether renal injury is prerenal or renal in origin but they are not always accurate (Table 3).
- *Biochemical tests* Patients with AKI may have anemia (mild to moderate) with a raised BUN and serum creatinine. Anemia may be due to hemolysis, bone marrow depression due to lack of erythropoietin or blood loss. Presence of leucopenia may be suggestive of SLE or severe sepsis. Thrombocytopenia may indicate sepsis, HUS or SLE. Hyponatremia (most likely dilutional) and hyperkalemia with acidosis are common in patients with advanced renal failure. Positive ANA and anti-DNA tests with diminished complement levels will be present in cases of SLE. The antistreptolysin O (ASO) titer is raised in cases of post-streptococcal glomerulonephritis.
- *Radiology* Cardiomegaly may be noted on chest X-ray due to overhydration and hypertension. Ultrasonography of the kidneys and bladder is of great help in establishing the etiology in AKI. It is mandatory to do this investigation to rule out any correctable pathology. CT scan or MRI of urinary tract and nuclear imaging may be needed in selected cases. In selected patients, a micturating cystourethrogram may be done to rule out vesicoureteric reflux. Renal biopsy may be necessary in a few cases of non-resolving acute glomerulonephritis [to rule out rapidly proliferative glomerulonephritis (RPGN)]. Renal biopsy should also be considered in a patient with prolonged (>3 weeks) duration of AKI.
- *Role of BIOMARKERS*[5] Accessible markers of AKI can be components of serum or urine or can be imaging studies or any other quantifiable parameter. The urine has yielded the most promising markers for the early detection of AKI and further characterization is anticipated, which will qualify these markers as useful tools for the earlier diagnosis, identification of mechanism of injury, and assessment of site and severity of injury. Hopefully, one or more of these biomarkers, either alone or in combination, will prove to be useful in facilitating early diagnosis, guiding targeted intervention and monitoring disease progression and resolution.

These potential biomarkers are not available commercially in India. The potential biomarkers are—
- N-acetyl-β-glucosaminidase.
- β2-microglobulin.
- α1-microglobulin.
- Retinol-binding protein.
- Cystatin-C.
- Kidney injury molecule-1.
- Neutrophil Gelatinase-associated Lipocalin (NGAL).
- Interleukin-18.

MANAGEMENT OF ACUTE KIDNEY INJURY

The treatment of AKI is as follows—
- Assess the circulatory volume by careful physical examination—dry skin and mucus membranes with associated tachycardia suggest dehydration, while peripheral edema with gallop rhythm, hepatomegaly, bilateral crepitations and hypertension point to fluid overload. In doubtful cases, it may be advisable to insert a central venous catheter for accurate assessment of central venous pressure.

Table 4: Emergency treatment of hyperkalemia

Drugs	*Dose*	*Onset of action*	*Duration of action*
Calcium gluconate	0.5 mL/kg over 5–10 minutes, slowly	Within minutes	30–60 minutes
Sodium bicarbonate	1–2 mEq/kg over 15–30 minutes	Within minutes	1–2 hours
Dextrose with insulin	0.5–1 g/kg dextrose with 0.1–0.2 units insulin/kg slowly	Within minutes	2–4 hours
Kayexalate	1 g/kg in 70% sorbitol orally, or in 30% sorbitol as a retention enema	30 minutes	4–6 hours

- In cases of suspected hypovolemia, give a fluid challenge—10–20 mL/kg of normal saline. Avoid hydroxyethyl starch (voloven) for volume expansion, which has shown to increase the incidence of AKI and the need for dialysis. Normal saline or ringer lactate is an ideal solution for this purpose.
- Avoid use of diuretics and vasopressor agents till hypovolemia is corrected.
- If there is adequate response with fluid challenge continue fluid replacement under close medical supervision.
- If response to fluid challenge is inadequate, as judged by the urine output, do not give more fluids as the patient may have developed acute tubular necrosis. Excess fluid may produce overhydration, hypertension and congestive cardiac failure.
- A trial of diuretics is given after correction of hypovolemia—furosemide 1 mg/kg is given intravenously and the response is noted. If the response is poor, give a higher dose (up to 10 mg/kg), and this may be repeated every 6–8 hours.
- A high dose of furosemide helps in converting oliguric renal failure to nonoliguric renal failure. This helps in clinical management as hyperkalemia and hypervolemia are less likely to occur in patients with nonoliguric renal failure, but it does not alter the underlying condition or prognosis.
- Low dose of dopamine (1–2.5 µg/kg) may help in improving the renal circulation and urine output but use of low dose dopamine is now avoided.
- Hyperkalemia should be promptly corrected as suggested in Table 4.
- *Management of established renal failure* Management of acute tubular necrosis (a common and important pathology) is briefly described below. It aptly illustrates the basic principles of treatment in established acute renal failure. Good conservative therapy will go a long way in preventing complications and avoiding or postponing the need for dialysis. Most of these patients have oliguric renal failure and usually do not respond to volume load and the use of furosemide as described above. These patients should then be treated as follows—
  - Thorough daily physical examination.
  - Maintenance of accurate intake and output charts (record output from all sources) with record of daily weight.
  - Daily laboratory investigations—HB, PCV, BUN, serum creatinine, serum electrolytes, arterial pH and arterial blood gases; chest X-ray for cardiac size and evidence of pulmonary congestion.
  - Intake to be restricted as per output + 400 mL/m^2 per day.
  - Paying particular attention to serum potassium and avoiding fruits, fruit juices, coconut water, dry fruits, chocolates, soups and soft drinks to prevent hyperkalemia.
  - Replace or restrict sodium as needed.
  - Use diuretics in cases of volume overload.
  - Avoid an in-dwelling catheter unless the patient is unconscious, as a catheter is a potential source of infection.
  - Maintain nutrition giving sufficient calories with a high carbohydrate and low protein (0.5–0.7 g/kg) diet; however, proteins should not be unduly restricted to avoid dialysis as this may cause malnutrition, if prolonged.
  - Antibiotics are administered if needed. Avoid nephrotoxic drugs as far as possible. If they have to be used, give in appropriate dosages, preferably monitoring blood levels.
  - Use sodium bicarbonate to counter acidosis.
  - Control hypertension. For severe hypertension, administer diazoxide, hydralazine or a calcium-channel blocker sublingually. In patients with mild to moderate hypertension, use beta-blockers or alpha-methyldopa together with a diuretic.
  - In cases of AKI due to systemic or intrinsic kidney diseases like post-streptococcal glomerulonephritis, Henoch-Schönlein purpura, systemic lupus erythematosus or crescentic glomerulonephritis, in addition to general therapy for AKI, additional therapy like immunosuppressive drugs, corticosteroids, or plasmapheresis with plasma infusion may be required.

Renal Replacement Therapy (RRT)

Even with good conservative therapy some patients will require dialysis. Dialysis may be either peritoneal dialysis (PD), hemodialysis (HD) or continuous arteriovenous hemofiltration (CAVH).

Peritoneal dialysis is safest but cannot be done in patients with recent abdominal surgery, hypercatabolic patients with severe metabolic acidosis or severe volume overload, or in patients with severe respiratory distress. HD requires vascular access and the availability of a dialysis machine with

trained staff. It also requires use of heparin. Even minimal use of heparin cans produces bleeding and hypotension in some patients. Patients with cardiac instability do not tolerate this form of dialysis. Critically ill patients in a catabolic state or even severely overhydrated patients may be treated with CAVH or continuous arteriovenous hemodiafiltration (CAVHD). This form of dialysis is life-saving in critically ill patients and can be done in an ICU setting when it is difficult to transfer the patient to the dialysis unit. However, it requires an expert technical know-how and a good ICU setup. Fluid removal to the extent of 100–300 mL or more per hour may be possible and may require large fluid replacement with close monitoring of patients. It also requires use of heparin in large dosages and may therefore produce bleeding. Patients with prolonged oliguria and those who require hyperalimentation are ideal candidates for CAVH or CAVHD.

- Absolute indications for dialysis are as follows—
  - Gross overhydration.
  - Intractable hyperkalemia.
  - Severe acidosis.
  - Signs and symptoms of uremia.
  - Severe prolonged oliguria during which period hyperalimentation is necessary to maintain an adequate caloric intake.

Renal Replacement Therapy in Neonates

Renal replacement therapy in neonates has a high morbidity and mortality during acute and chronic treatment phase. In general, RRT is only indicated if aggressive symptomatic treatment fails to manage life-threatening conditions such as hyperkalemia, fluid overload, severe acidosis or hypertension. PD or CAVH or continuous venovenous hemofiltration (CVVH) have been done in small series of patients. PD is the method of choice because of its simplicity, easy availability, effectiveness and relative safety in any age group including low birth weight neonates and infants. CAVHD and CVVHD are the treatment of choice in patients with very significant fluid overload and in refractory acidosis as well as severe catabolic renal failure. This mode of therapy requires an expensive machine with a special hemofiltration cartridge as well as tubing for neonates. The risk of hypotension and bleeding is very high. This should be done in very well experienced units only. However, many ethical and medical problems have to be considered in decision-making.

Renal Replacement Therapy in Children

Renal replacement therapy becomes mandatory when conservative treatment fails, and the child develops signs and symptoms of uremia, fluid overload, hyperkalemia, electrolyte imbalance or severe refractory acidosis. Three modalities of therapy are available: (1) PD; (2) HD or (3) continuous arteriovenous or venovenous hemofiltration (CAVH or CVVH) (Box 3).

Box 3: Types of renal replacement therapy

Peritoneal dialysis
It is relatively easy to perform and can be done with the availability of pediatric size PD catheter and PD fluid. It is safe and easily tolerated by most patients including very small patients, and hypovolemia or hypotension is less likely to occur with this procedure compared to HD or CAVHD/CVVHD. However, fluid removal is limited in patients with hypotension, abdominal distension with respiratory embarrassment and a high risk of infection is likely.

Hemodialysis
HD is very effective in treating hyperkalemia, acidosis and fluid overload. HD requires availability of HD machines along with special hemodialysis cartridges and very well trained staff as children tend to develop hypotension.

CAVH/CAVHD
Easy to perform and does not require any special continuous renal replacement therapy (CRRT) machine. The main disadvantages are the need for good arterial access (femoral) and continuous anticoagulation with heparin. It is difficult in patients with hypotension.

CVVH/CVVHD
This is very good for catabolic patients and patients who require removal of large amounts of fluid. However, this modality requires access to a CRRT machine, special hemofiltration cartridge, patient immobilization and anticoagulation.

Recovering Phase of Renal Failure

A patient may remain in the oliguric phase for 3 days to 3 weeks, and at times, even longer. After this, the patient passes into the diuretic phase. In this phase, the patient starts passing large quantities of urine; close monitoring of fluids and electrolytes is mandatory as these patients may get dehydrated and/or have severe electrolyte imbalance. This phase lasts for a few days. The commonest error committed by the physician during the management of this phase is chasing the urine output for a prolonged period. The urine output should be chased (intake increased as per urine output) for the first 2–3 days; subsequently the intake should be gradually decreased over the next 2–3 days. The electrolytes should be carefully monitored, as hyponatremia and hypokalemia are frequently observed.

Long-term Effects of Acute Kidney Injury

Previously it was thought that AKI once recovered has no long-term effects. However, recent studies have shown that AKI is not benign in the long term and may have adverse renal and cardiac consequences. Development of hypertension, chronic

kidney disease, end stage renal disease, atherosclerosis and coronary artery disease have been seen to develop at a later age in the survivors of AKI. Thus, children who have recovered from AKI should be followed up regularly.

End of Life Care in the Intensive Care Unit

- End of Life Care in the Intensive Care Unit

CHAPTER 87

End of Life Care in the Intensive Care Unit

"It is not death I fear to face, it is dying."

—Robert Louis Stevenson

INTRODUCTION

Death stalks the intensive care unit (ICU) frequently; it is the final arbiter of life. Pascal, the famous French scientist philosopher, has aptly said, "on mourra seul—one dies alone". I have often wondered what it must feel when one is actually dying. One shall never know until one's time comes. It is the duty of a physician to ease a patient's transition from life to death, from one state of being to another. Even so, some die peacefully and some die after a struggle.

There are a number of problems and challenges an intensive care physician faces with regard to critically ill patients who have reached the end stage of their lives. To start with there is the difficulty in predicting outcomes in individual patients in the early course of their critical illness. Then, there is the difficulty in assessing the patient's wishes and preferences with regard to his or her management, particularly at a point in time when death seems near. The challenges of decision-making, the problems in communication with family and friends in whom emotions run riot, and, last but not the least, the concerns on how best to manage and ease the last days and hours of a patient are both formidable and distressing.

The first question one always needs to ask is—what time frame does one apportion as the end of life? Does one compute the end of life in hours or days or weeks? It is not always easy to answer this question. One can do so, for example in a patient with fulminant sepsis who is pulseless, without a recordable blood pressure, who has failed to respond to all that medical science has to offer. In a patient such as this, the writing is on the wall. On the other hand, take a patient who for some reason is admitted to the ICU, who has widespread metastatic cancer, who refuses chemotherapy or for whom no chemotherapy is possible. This patient too is approaching the end, but it may take weeks or even a few months for him or her to cross the line.

It is perhaps better to consider care of a terminally ill patient rather than end of life care, because it is easier to define a terminal illness rather than the end of life. A terminal illness is one which is deemed incurable and in which death is inevitable and usually imminent. In the ICU, a terminal illness may last for a few hours or at most a few days. It is important in a given patient to review the word terminal from hour to hour or day to day. Occasionally what appears terminal at one point offers hope after a lapse of time. Patients judged terminal by the treating physician have been known to get well and go home. The responsibility of judging a patient as terminal is therefore immense. At times the decision is easy and at times difficult. Clinical judgment, experience, wisdom are all involved in this decision. It may be impossibly difficult to decide when and where to draw the line. If there is indeed the slightest doubt, it is better for all concerned to continue critical care, and review events from time to time. Yet on a number of occasions, the discerning physician can see the nearness and inevitability of death. The resource crunch in health care all over the world (particularly in poor countries) should prompt the physician in such a situation to refrain from using medical technology that merely prolongs death, or that makes death excessively lonely, gruesome, dehumanizing, perhaps even obscene, and ruinous to the patient and the family.

It is important in an acute illness which in spite of all efforts appears to progress relentlessly to an inexorable fatal outcome to ascertain the wishes of the patient and the family. It is equally important never to forget that the patient

comes first and foremost and then the family. The patient in our part of the world invariably follows the physician's advice and the relatives too are similarly influenced. This is indeed an added and extremely heavy responsibility on the physician because poor judgment can unnecessarily prolong the act of dying and can also in the bargain financially cripple the patient's family. Better judgment could have perhaps prevented this calamity. Judgment is terribly difficult, particularly when it concerns young patients in the prime of their lives. Alas! It is not always that a Daniel comes to judgment.

A decision not to initiate invasive support, for example, the use of a ventilator, or the use of dialysis in a terminally ill patient is far more easy than the decision to withdraw support that has already been initiated at a point in time when the life-threatening acute illness seemed potentially reversible. A detailed discussion with the family and close friends plays an important role in decision-making. The family needs to be persuaded to accept that there comes a point in time when intensive care is futile and when support in all forms is either not initiated or withdrawn.

The practice of withdrawing support in all forms when death is close and inevitable varies in different parts of the world. It is an accepted practice in the Western world. It is also increasingly practiced in India, notwithstanding the legal issues involved. Management of terminal illness is further helped by the following principles—

- The physician should under no circumstances administer a drug or perform an act which purposefully kills the patient. There is therefore a distinction drawn between the act of killing and allowing to die.
- Withholding treatment in a terminal illness (end stage of life) is legitimate and an act of compassion. Withdrawal of life support and treatment in the West is considered the equivalent of withholding treatment. The acceptance and practice of withdrawal of support is however contentious and varies in different civilizations.
- The doctrine of "double effect" permits assertive symptomatic treatment with medication for patient relief and comfort, even if this treatment inadvertently causes death—example, the use of morphine with the express purpose to relieve pain or breathlessness can inadvertently lead to death from respiratory arrest.
- Palliative care is not just related to relief of pain, breathlessness and other forms of physical discomfort, but is also concerned with resolving anxiety, restlessness, delirium, irritability and in offering emotional and spiritual support to the patient. It therefore involves care in every aspect of the word.
- The proper training of doctors, nurses and students in the management of terminal illness with special reference to palliative care is of great help.
- The offering of true compassion to patients—a quality that can neither be bought nor taught, but which should come naturally to all well-trained staff in good centers.

COMMUNICATION WITH PATIENTS, FAMILY OR SURROGATES[1-3]

Communication with the family, friends and the patient if he or she is conscious and without cognitive impairment is of vital importance. It is important to discuss at length, without using technical jargon, the nature of a patient's illness, what has been done for the patient, the complications during his or her illness, the measures taken to counter them, the reasons for a deteriorating state and why further measures are not likely to help the patient, but merely prolong the act of dying. It is of immense help if communication with the family is established early, from the time of admission, and continued on a daily basis. The communication should be detailed and take into account the emotional trauma the near and dear ones of a dying patient go through. Here again a note of true compassion and caring goes a long way in making the family understand the overall picture as the physician sees it. In spite of every practiced art of communication, in our country it is at times difficult to convince relatives and friends that the end is near and that further treatment will be of no avail. It is doubly difficult to convince them to allow discontinuation of life support systems. It is wise in our prevailing legal and social circumstances not to withdraw support if the family of a terminally ill patient insists that the support system be continued. Emotions often run riot among relatives of Indian patients under these circumstances, and not respecting these wishes may cause legal problems both for the intensivist and the hospital concerned.

It is equally important to communicate with the patient provided he or she has retained the cognition to allow communication. It is a cardinal principle to keep the patient informed of what is happening to him and as to what measures you as a physician are taking to help him get well. A crucial question that arises is—Does the intensivist tell the patient the truth about his illness—that he or she is dying or will soon die? In the West, particularly in the United Kingdom and the United States of America, the whole truth is told particularly when a specific question with regard to the possibility of impending death is put to the physician. But social and ethical norms are different in the east as also in many countries of Eastern Europe and South America. In my experience, it is very rare for a patient in our country to ask the physician a direct question—Will I die? Am I dying? Will I never get well? In fact, almost always, even a doctor in our part of the world, who is dying and remains conscious and cognitive, will not talk of death. What is more if one does directly or indirectly touch on the subject, the patient invariably changes the conversation. In our social set up, it would be wrong to tell the bitter truth to a dying patient. It is not the calling of a physician to add to a patient's anguish, to extinguish the flickering flame of hope burning in every patient's heart, however close he may be to death. It is however extremely important to tell the truth and nothing but the whole truth to the patient's family and friends.

END OF LIFE DECISION-MAKING[4,5]

Decision-making in relation to end of life patient care should involve the physician, the patient, the family of the patient or the surrogates. The patient and the family have the right to information. Involving family friends and surrogates is vital in the decision-making process, considering that a large number of ICU patients lack the capacity to decide. A large number of factors may influence a physician's attitude and recommendations with regard to end of life questions and decisions. These include his religion, his upbringing, social and ethical norms prevailing in the country he practices in, his philosophy and outlook on life. Whatever these may be, he needs to consider and integrate the patient's and the family's views and values into his recommendation for the holistic care of the dying patient. Also his recommendation must be clinically realistic, beneficent and morally irreproachable. This is easier said than done, more so if the approach of the family and friends is palpably wrong or unrealistic. Here again, it is good communication that holds the key to an integrated decision-making process, communication which starts early, on admission of the patient, and not just when the patient is close to the end of life.

A simplified mnemonic for effective patient family communication is VALUE. *V*alue and appreciate what is said by family members, *A*cknowledge the family member's emotions, *L*isten, *U*nderstand who the patient is as a person, *E*licit questions from family members.[6]

It should be realized that there is no protocol that can be followed in the end of life decision-making process. Nor are there likely to be any sensible evidence-based guidelines on this issue, and obviously no randomized controlled studies to help the physician in this important aspect of life! This is because each human being is a unique individual and the problems and challenges to guide the patient, family or surrogates through the decision-making in the ICU will have special unique aspects.

In spite of kindness, compassion, wisdom and good clinical judgment, the physician may find himself in an irreconcilable conflict—either ethical, moral or clinical with the patient's family or surrogates. Here again frank open and often lengthy communication may be the key to the problem. If problems still persist, the physician should advise mediation through the Ethics Committee of the hospital.

TREATMENT GOALS AT THE END OF LIFE

The answer to the management of an incurable terminal illness in the ICU lies in the practice of palliative care, which includes the practice of palliative medicine. The latter has now become a speciality which deals with various physical and emotional vicissitudes encountered in the terminally ill. Pain control has evolved far beyond the mere administration of opiates, opiate derivatives and sedatives. Yet in poor countries, these drugs still remain the sheet-anchor of pain control. Many doctors, nurses and health care workers fail to use an appropriate dose of opiates or their derivatives for fear of depressing respiration and circulation, thereby endangering life or hastening death. In this connection, a quote from a judgment delivered in the United Kingdom by Judge Delvin is indeed of unsurpassed guidance and relevance—"The proper medical treatment that is administered and that has an incidental effect in determining the exact moment of death is not the cause of death in any sensible use of the term".[5]

The World Health Organization (WHO) defines palliative care as follows—The act of total care of patients whose disease is not responsive to curative treatment. Control of pain or other symptoms and of psychological, social and spiritual problems is paramount. The goal of palliative care is the achievement of the best possible quality of life for the patient and the family.

Palliative medicine is comparatively cheap. It respects life and considers death as a natural inevitable sequel. When correctly practised, it neither protracts the art of dying nor generally hastens it. It helps to support the patient in the transition from life to death and lends support and comfort to those close to the patient during this period of time. Palliative medicine when practised with an equal measure of skill and compassion should hopefully render the current commotion and debate on euthanasia in the West obsolete.

WITHDRAWAL OF LIFE SUPPORT[7,8]

In India, this indeed is both a difficult and thorny problem. It is easy to go off inotropes, vasopressors, intravenous (IV) fluids, dialysis, to remove invasive lines, catheters, etc. Other interventions such as pacemakers, antibiotics and monitors can be stopped once a decision to end life-support has been made. Does one inform the patient before withdrawing life support? In the West, particularly in the United States of America and the United Kingdom, they do so. Ethical, philosophical and social values differ in different civilizations. The practice in India is not to inform a conscious patient on the decision to withdraw support. I well remember a patient who had a suspicion that we were going to withdraw support. He turned to me with a piteous look and said, "Doctor, have you decided to abandon me?" The question of informed withdrawal obliviously does not arise in an obtunded or comatose patient.

There are two further debatable points in relation to withdrawal of support. Should one stop fluids and nutrition? And the next question—should one withdraw ventilator support in a patient who has already been on it? There are many intensivists who would say "Yes" to both these questions when referring to a terminal illness in the ICU. But much can be said on both sides. Does palliative care not look to the comfort of the patient? Parenteral nutrition is of course stopped both because of its futility and expense. Yet does stopping fluids and basic nutritional support, either orally or through a nasogastric tube already in place, disturb significantly the comfort level of a dying patient, particularly if he is awake and conscious? We are told that there is no proof that it does so. But an absence of proof is not a proof of absence. Also, does giving fluid or some oral nutritional

support significantly prolong the act of dying? I for one do not think so.

Removing ventilator support in a comatose patient just about to die is a practice observed in all units in the West and in many units in our country. To do so in a dying patient who is conscious could certainly produce significant discomfort to the patient as also to those around the patient. It should be noted that the law in India prohibits the withdrawal of ventilator support, though many units do practice withdrawal when the end is near.

There are no cut and dry definite answers to many questions relating to life and death. There is no absolute right. There are shades of right and wrong. The shades one opts for depend on one's philosophy of life and death, on social, moral and religious beliefs and on the law of the land one lives in.

In conclusion, the management of a terminal illness lies in caring for the dying patient. Is it perhaps too much to ask that the physician should care for death and dying as much as he cares for life and living?

The lines of John Donne come to mind—

> "Every man's death diminishes me,
> For I am concerned with the whole of mankind.
> Therefore, send not to ask for whom the bell tolls.
> It tolls for thee."

Appendix

1. Normal Blood Gas and Respiratory Parameters, and Gas Transport Equations

Abbreviation	*Parameters (full form)*	*Equations*	*Normal values*
pH			7.35–7.45
PAO_2	Partial pressure of oxygen in alveolus		104 mm Hg
$PACO_2$	Partial pressure of carbon dioxide in alveolus		40 mm Hg
PaO_2	Partial pressure of oxygen in arterial blood		75–100 mm Hg
$PaCO_2$	Partial pressure of carbon dioxide in arterial blood		35–45 mm Hg
$P\bar{v}O_2$	Partial pressure of oxygen in mixed venous blood		35–45 mm Hg
SaO_2	Arterial oxygen saturation		96–100%
$S\bar{v}O_2$	Mixed venous oxygen saturation		70–80%
RQ	Respiratory quotient	$\dot{V}CO_2/\dot{V}O_2$	0.8
CaO_2	Arterial oxygen content	$(1.39 \times SaO_2\%/100 \times [Hb]) + (0.0031 \times PaO_2)$	18–21 mL/dL
$C\bar{v}O_2$	Mixed venous oxygen content	$(1.39 \times S\bar{v}O_2\%/100 \times [Hb]) + (0.0031 \times P\bar{v}O_2)$	14–15 mL/dL
$C(a\text{-}\bar{v})O_2$	Arteriovenous oxygen difference	$CaO_2 - C\bar{v}O_2$	4–6 mL/dL
CcO_2	Pulmonary capillary oxygen content	$(1.39 \times [Hb]) + (0.0031 \times PAO_2)$	20–23 mL/dL
$\dot{V}O_2$	Oxygen consumption	$C(a\text{-}\bar{v})O_2 \times CO \times 10$	195–285 mL/min
$\dot{D}O_2$	Oxygen delivery	$CaO_2 \times CO \times 10$	950–1150 mL/min
O_2ER	Oxygen extraction ratio	$C(a\text{-}\bar{v})O_2/CaO_2$	0.24–0.28
$(A\text{-}a)DO_2$	Alveolar-arterial oxygen gradient	$PAO_2 - PaO_2$	
	On $FiO_2 = 0.21$		5-25 mm Hg
	On $FiO_2 = 1.0$		25–65 mm Hg
$\dot{Q}_S/\dot{Q}_T$	Shunt fraction	$(CcO_2 - CaO_2)/(CcO_2 - C\bar{v}O_2)$	3–8%
V_D/V_T	Dead space fraction	$[PaCO_2 - P_ECO_2]/PaCO_2$	0.25–0.4

Abbreviations: CO, cardiac output; P_ECO_2, partial pressure of carbon dioxide in expired gas.

2. Arterial Blood Gases (at sea level) while Breathing Room Air at Different Ages

Age (years)	*PaO_2 (mm Hg)*	*$PaCO_2$ (mm Hg)*	*$(A\text{-}a)PO_2$ (mm Hg)*
20	84–95	33–45	4–17
30	85–94	34–45	7–21
40	80–90	34–45	10–24
50	75–90	34–45	14–27
60	75–88	34–47	17–31
70	70–86	34–47	21–34
80	67–80	34–47	25–38

3. Alveolar Oxygen Tension (PAO_2) in Non-acclimatized Subjects Breathing Air at Sea Level and at Varying Altitudes

(Modified from Cotes JE. Lung Function—Assessment and Application in Medicine. Melbourne, London: Blackwell Scientific Publications; 1979. pp. 463.)

Altitude		*Barometric pressure (mm Hg)*	*PAO_2 (mm Hg)*
Meters	Feet		
0 (sea level)	0	760	102
1500	5000	632	82
3000	10,000	523	61
4600	15,000	429	44
6100	20,000	349	35
7600	25,000	282	33

4. Normal Hemodynamic Parameters and Calculations

See Chapter on Cardiac Monitoring in Adults.

5. Daily Requirements of Important Electrolytes in Critically Ill Patients

Electrolytes	*Enteral nutrition*	*Parenteral nutrition*
Sodium	1.3–3.3 g 60–150 mEq	60–150 mEq
Potassium	2–5.5 g 40–80 mEq	40–80 mEq
Chloride	40–100 mEq	40–100 mEq
Magnesium	350 mg 10–20 mEq	10–20 mEq
Phosphorus	800 mg 10–60 mmoL	10–60 mmoL
Calcium	800 mg 5–20 mEq	5–20 mEq

6. Daily Vitamin Requirements in Critically Ill Patients

Vitamins	*Enteral nutrition*	*Parenteral nutrition*
Vitamin A	3300 IU	3300 IU
Vitamin D	400 IU	200 IU
Vitamin E	10–20 IU	10 IU
Vitamin K	-	10 mg/week IM
Vitamin C	50–60 IU	100 IU
Thiamine	1.5 mg	3 mg
Riboflavin	1.8 mg	3.6 mg
Niacin	20 mg	40 mg
Pyridoxine	2 mg	4 mg
Pantothenic acid	7 mg	15 mg
Folic acid	200 µg	400 µg
Vitamin B_{12}	2 µg	5 µg
Biotin	100 µg	60 µg

7. Daily Requirements of Important Trace Elements in Critically Ill Patients

Trace element	*Enteral nutrition*	*Parenteral nutrition*
Zinc	3 mg	2.5–4 mg
Copper	1.5 mg	1–1.5 mg
Iron	-	1–2 mg
Manganese	150–800 µg	200–800 µg
Molybdenum	75–250 µg	100–200 µg
Selenium	40–120 µg	40–120 µg
Chromium	10–15 µg	10–20 µg
Cobalt	1.1 mg	-
Iodine	-	120 µg

8. Composition of Plasma Compared to Some Commonly Used Crystalloid Solutions

Solution	*Na^+ (mEq/L)*	*Cl^- (mEq/L)*	*K^+ (mEq/L)*	*Ca^{++}/Mg^{++} (mEq/L)*	*Buffer*	*pH*	*Osmolality (mOsm/kg)*
Plasma	141	103	4–5	5/2	HCO_3^- (26)	7.4	289
0.9% Saline	154	154	-	-	-	4.5–7	308
Ringer lactate	130	109	4	3/0	Lactate (28)	6–7.5	273
Dextrose-Saline	154	154	-	-	-	3.5–6.5	586

9. Important ICU Drugs with their IV Dosages and Infusion Rates

9A. Dopamine

Preparation: 600 mg in 500 mL 5% dextrose
Concentration: 1200 µg/mL or 20 µg/microdrop

Desired effect	Dose (µg/kg/min)	Weight (kg)						
		40	50	60	70	80	90	100
		Infusion rate (microdrops/min)						
Renal vasodilatation	1	2	2.5	3	3.5	4	4.5	5
(1–5 µg/kg/min)	5	10	12.5	15	17.5	20	22.5	25
Increase in cardiac output	6	12	15.0	18	21.0	24	27.0	30
(6–10 µg/kg/min)	10	20	25.0	30	35.0	40	45.0	50
Vasoconstriction	11	22	27.5	33	38.5	44	49.5	55
(11–20 µg/kg/min)	20	40	50.0	60	70.0	80	90.0	100

9B. Dobutamine

Preparation: 500 mg in 500 mL 5% dextrose
Concentration: 1000 µg/mL or 16.7 µg/microdrop
Usual Dose: 5–15 µg/kg/min

Dose (µg/kg/min)	Weight (kg)						
	40	50	60	70	80	90	100
	Infusion rate (microdrops/min)						
5	12	15	18	21	24	27	30
10	24	30	36	42	48	54	60
15	36	45	54	63	72	81	90
20	48	60	72	84	96	108	120
40	96	120	144	168	192	216	240

9C. Norepinephrine

Preparation: 4 mg in 500 mL saline
Concentration: 8 μg/mL
Administration: Beta dose 1–10 μg/min
Alpha dose >10 μg/min

Dose (μg/min)	*Infusion rate (mL/hr)*
1	7.5
2	15.0
4	30.0
6	45.0
8	60.0
10	75.0
12	90.0
14	105.0
16	120.0
18	135.0
20	150.0

9D. Nitroglycerin

Preparation: 100 mg in 500 mL 5% dextrose
Concentration: 200 μg/mL or 3.33 μg/microdrop
Dose: Venodilator Dose 1–50 μg/min
Usual Dose 1–400 μg/min

Dose (μg/min)	*Infusion rate (microdrops/min)*
5	1.5
10	3.0
25	7.5
50	15.0
100	30.0
150	45.0
200	60.0
250	75.0
300	90.0
350	105.0
400	120.0

9E. Lidocaine and Procainamide

Preparation: 1g in 250 mL 5% dextrose
Concentration: 4 mg/mL
Usual Dose: 1–4 mg/min

Dose (mg/min)	*Infusion rate (mL/hr)*
1	15
2	30
3	45
4	60

9F. Nitroprusside

Preparation: 50 mg in 500 mL 5% dextrose
Concentration: 100 μg/mL or 1.67 μg/microdrop
Usual dose: In heart failure 0.5–2 μg/kg/min*
In hypertension 2–5 μg/kg/min

Dose (μg/kg/min)	*Weight (kg)*						
	40	50	60	70	80	90	100
	Infusion rate (microdrops/min)						
0.5	12	15	18	21	24	27	30
1.0	24	30	36	42	48	54	60
1.5	36	45	54	63	72	81	90
2.0	48	60	72	84	96	108	120
2.5	60	75	90	105	120	135	150
3.0	72	90	108	126	144	162	180
3.5	84	105	126	147	168	189	210
4.0	96	120	144	168	192	216	240
4.5	108	135	162	189	216	243	270
5.0	120	150	180	210	240	270	300

*In patients with heart failure, 50 mg of nitroprusside are added to 250 mL of 5% dextrose, and the infusion rate is halved.

10. Serum Levels of Commonly Used ICU Drugs

Drug	*Serum levels*	
	Therapeutic range	Toxic range
Paracetamol	10–30 μg/mL	>200 4 hrs post-ingestion
Amikacin	Peak: 25–35 μg/mL Trough: 1–4 μg/mL	>35 >10
Gentamicin	Peak: 5–10 μg/mL Trough: 1–2 μg/mL	>10 >2
Vancomycin	Peak: 40–50 μg/mL Trough: 5–15 μg/mL	>80 >20
Tobramycin	Peak: 8–10 μg/mL Trough: 1–2 μg/mL	>10 >2
Barbiturates – Short-acting – Intermediate acting – Phenobarbitone	 1–2 μg/mL 1–5 μg/mL 15–40 μg/mL	 >5 >10 >40-nystagmus; >65-coma
Lithium	0.6–1.2 mEq/L	>2
Amitryptyline	120–250 ng/mL	>500
Desimipramine	75–160 ng/mL	>1000
Imipramine	125–250 ng/mL	>500
Chlorpromazine	50–300 ng/mL	>750
Diazepam	100–1000 ng/mL	>5000
Pentazocine	0.1–1 mg/L	>2
Pethidine	600–650 μg/L	>10 mg/L
Phenytoin	10–20 μg/mL	>20-nystagmus; >40-mental status
Disopyramide	3–7 μg/mL	>7
Lidocaine	1.5–6 μg/mL	>6
Quinidine	2–5 μg/mL	>6
Procainamide	4–10 μg/mL	>10
Theophylline	10–20 μg/mL	>20
Digoxin	0.8–2 ng/mL	>2
Acetylsalicylic acid	100–350 mg/L	>350

11. Important Drug Interactions in the ICU

(From The ICU Book, 1991. [Ed. Marino PL] Lea and Febiger, Philadelphia, London)

	Serum level	
IV Drug	Increased by	Decreased by
Catecholamines	Agents which alkalinize the urine—diamox	Agents which acidify the urine—Vitamin C
Lidocaine	Cimetidine, beta-blockers	-
Procainamide	H_2-antagonists—cimetidine, ranitidine	-
Beta-blockers – Metoprolol – Propranolol	 Cimetidine Cimetidine, furosemide	 Rifampicin
Aminophylline	Cimetidine, propranolol, erythromycin	Phenobarbital, rifampicin
Digoxin	Quinidine, amiodarone, verapamil, diazepam, erythromycin, spironolactone	Rifampicin
Diazepam	Propranolol	Phenytoin
Phenytoin	Cimetidine	Phenobarbital, rifampicin, diazepam
Pancuronium	Verapamil, clindamycin	Theophylline
Cimetidine		Rifampicin, phenobarbital

12. Compatibility Chart for Commonly Used Critical Care Drugs

From Guglielmo J. Pharmacotherapy. In: Bongard FS, Sue DY (Eds). Current Critical Care Diagnosis and Treatment. New York: McGraw Hill Companies; 1994. pp. 191-8.

Key: C-documented compatibility; M-mixed results; I-documented incompatibility; N-no documented information.

	Aminophylline	Amiodarone	Amrinone	Bretylium	Dobutamine	Dopamine	Heparin	Isoproterenol	Lidocaine	Norepinephrine	Nitroglycerin	Nitroprusside	Phenylephrine	Procainamide	Verapamil

Verapamil	I	C	N	C	C	C	C	C	C	C	C	N	N	C	

[1]May be concentration dependent.

Note:

(a) Administration should be done through y-sets. Most compatibilities are visual, i.e. no visible precipitation.

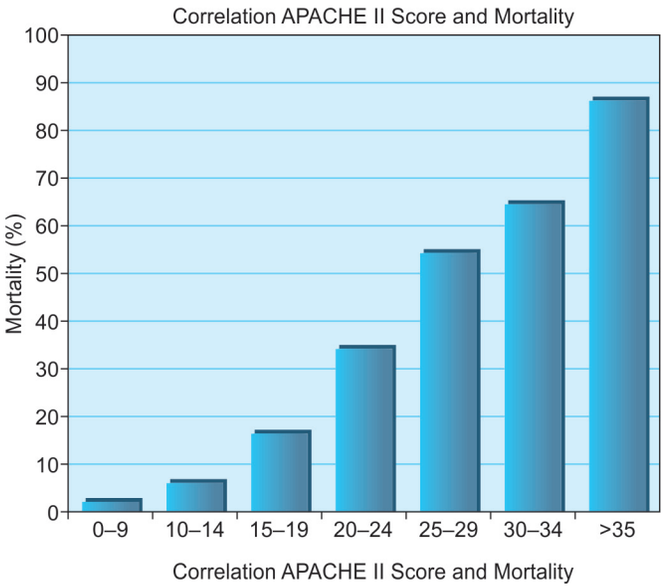
(b) All compatibility data are for 24 hours in D_5W or normal saline. Some combinations may be compatible for shorter durations or under specific conditions.

13. Glasgow Coma Score, Trauma Score, Revised Trauma Score, CRAMS Scale and APACHE II Score

See Chapter on Critical Care Scoring.

14. Correlation between APACHE II Score and Mortality

(From: Breach Candy Hospital ICU data 2001-2003).



15. Criteria for Diagnosis of Brain Death*

[From: ICU Book, 1991, (Ed. Marin PL). Lea and Febiger, Philadelphia, London]

Brain death has occurred if the following criteria are met on two consecutive occasions, at least two hours apart—

1. Does not localize in response to noxious stimuli (i)
2. Body temperature >34°C
3. Serum levels of the following are negligible or subtherapeutic—
   (a) Ethanol; (b) CNS depressant drugs
4. The following movements are absent—
   (a) Decorticate posturing; (b) Decerebrate posturing; (c) Shivering; (d) Spontaneous movements
5. The following reflexes are bilaterally absent (ii)
   (a) Pupillary light reflex; (b) Corneal reflex; (c) Oculovestibular reflex; (d) Oculocephalic reflex (doll's eyes)
6. EEG is isoelectric at maximal gain (iii)
7. Apnea test is confirmatory (iv)
   (a) PaO_2 at end of test_____; (b) $PaCO_2$ at end of test_____

(i) Painful stimuli should be localized to cranial nerve areas because of the risk for spinal cord reflexes with peripheral stimuli. The favored test is supraorbital pressure.

(ii) Pupillary light reflexes can also be absent after eye injury, neuromuscular blocking agents, atropine, mydriatics, scopolamine and opiates.

(iii) Isoelectric EEG does not exclude brainstem activity, and is not to be used in isolation to diagnose brain death.

(iv) The apnea test is confirmatory if there is no evidence of spontaneous ventilatory efforts for at least 3 minutes, and the $PaCO_2$ is >60 mm Hg at the end of the test. If history of chronic CO_2 retention is present, the PaO_2 should be <55 mm Hg at the end of the test.
